Now we want to tell him all about it. Of course, first we can define my thumb-screw, and say, "This, tick, tick, too, too, tick, tick, tick, here . . ." so that gradually he can understand a couple of words, and so on. After a while we may become very familiar with this fellow and he says, "What do you guys think?" He can't visualize correctly, and say, "Well, we are six feet tall." He says, "Wait a minute, what is she fast?" Is it possible to tell him what six feet is? Certainly! We say, "You know about the number of hydrogen atoms we are: 7,000,000,000 hydrogen atoms high?" That is possible because hydrogen atoms are not scattered hither and thither, and therefore, we can define an absolute length. And so we define the size of the body, and tell him what the general shape is—the two prongs were the arms sticking out on the ends, and so on, and he follows us along, but we finally describe no motion on the outside, presumably without ever under any particle-to-particle collision. He is even making a model of a screwdriver—says, "Say, you are definitely very familiar with it now, now what is on the inside?" So we start to describe the various parts on the inside, and we come to the heart and we carefully describe the shape of it, and say, "Now put the heart on the left side!" He says, "Which is the left side?" Now our problem is to describe to him which side the heart goes on without his ever seeing anything. Just we see, and we hear him ever sending any sample to him of what we mean by "right" the standard right-handed action. Can we do it?

52-7 Finally & not answered:

It turns out that the laws of gravitation, the laws of electricity and magnetism, nuclear forces, all or by the principles of reflection, are all these laws, or anything derived from them, cannot be used. But we know about the many particles that are found . . . among them is a phenomenon called beta decay, or weak decay. One of the examples of weak decay, in connection with a part of the material in about 1937, posed a strange puzzle. There was a certain charged particle which disintegrated into three neutrinos as shown schematically in Fig. 52-5. This particle was called, for a while, a π -meson. Now in Fig. 52-5 we also see another particle which disintegrates into two neutrinos, the third component, from the π -meson.

spectrum of energy. The particle was called a π -meson. So on the one hand we have a particle called π , which disintegrates into three π 's, and on the other it disintegrates into two π 's. Now it was soon discovered that the π 's and the π 's are almost equal in mass, in fact, rather than experimental error, they are equal. Next, the length of time it took for them to disintegrate into three π 's and two π 's was found to be almost exactly the same; they live the same length of time. Next, whenever they were made, they were since at the same proportion, say, 14 percent to 86 percent of.

Any one of his higher mind realizes immediately that they must be the same particle, that we merely produce an object which has two different ways of disintegrating—two very different possibilities. This object, too, can disintegrate in two different ways has, therefore, the same lifetime and the same disintegration ratio. Because this is simply the ratio of the odds with which it disintegrates into these two kinds.

However, it was possible to prove (and we cannot here explain it in detail) from the principle of reflection symmetry in quantum mechanics that it was impossible to have two such forms from the same particle—the same particle could not disintegrate in both of these ways. The observations are corresponding to the principle of reflection symmetry is something which has no classical analog, and so this kind of quantum-mechanical conservation law is called the conservation of parity. So, it was a result of the conservation of parity or, more precisely, from the symmetry of the quantum-mechanical equations of the weak decay under reflection, that the same particle could not go one way, so it must be some kind of antiparticle. It does, however, and we do. But, the particle was studied, the more remarkable it is to find that, and the suspicion gradually grew that possibly the deep law of reflection symmetry of nature may be false.

As a result of this apparent trouble, the physicists Fermi and Tamm suggested that other experiments be done in metal crystals to try to see whether the law was correct in other cases. The first such experiment was carried out by Miss Wu from Columbia, and was done in Cobalt. Using a very strong magnet at a very low temperature, it turns out that a certain isotope of cobalt which has electrons by colliding, an electron, is magnetic, and if the temperature is low enough and the thermal oscillations do not jolt the atomic magnets about too much, they line up in the magnetic field. As the cobalt atoms will all line up in this strong field, they then disintegrate with polarization, and it was discovered that when the atoms were lined up in a field where it would polarize upward most of the electrons were emitted in a downward direction.

It was, in my "lisp" to the world, such a result that did not yield anything of significance, but it was apparently a problem and interesting. Many of us could, then, see that as a most dramatic discovery: Were we not cobalt atoms in some arbitrary other magnetic field, something like electrons going down than up. Therefore, we went to put in a current-carrying experiment in a "magnet" which the electric charge would be used up at the opposite direction, they would split their electrons up, not down! No action is ungrammatical. For example, our power failed. The south pole of a magnet is of such a kind that the electrons in a direction of migration will begin to turn in, but, unfortunately, in a clockwise way, the north pole from the south pole.

After this, a lot of other experiments were done: the disintegration of the π in a spin experiment and also new times nowadays the Λ , etc., excited and π , disintegration of Z 's, and many other disintegrations. In fact, in almost all cases where it could be expected, all have been found not to obey reflection symmetry. Fundamentally, the law of reflection symmetry at this level in physics, is broken.

In short, we can tell the world, when to put the heart, we say, "Listen, build yourself a magnet, and put the wire in, and p. Turn it on, and then take some cobalt and lower the temperature. Arrange the experiment so the current goes from the feet to the head. Then the direction in which the current goes through the coils is the direction that goes up on what we call the right and comes up on the left." So it is possible to do, a right and left, now, in doing an experiment of this kind.

Fig. 52-5. A schematic diagram of the disintegration of a n into a p + $e^- + \bar{\nu}$.

There are lots of other features that may have been predicted. For example, it turned out that the spin, the angular momentum of the electron alone before disappearance, is always odd, and after disappearance, is 4 units. The electron carries an angular momentum... and that is known to me now. It is easy to see from this that the electron must carry its spin angular momentum aligned along its direction of motion, the neutrino likewise. So, it looks as though the electron is spinning to the left, and the neutrino also clockwise. In fact, it was calculated right here at Caltech by Bethe and Weizsäcker, that the electron spins really to the left. (There were some other predictions that gave the opposite answer, but they were wrong.)

The next problem, of course, was to find the law of the behavior of parity conservation. What is the rule that tells us how saving the baryon number is going to be? The rule is that it occurs only in every very slow reaction, called weak decays, and when I say "slow," the rule is that the particle which is my syn. has the electron, neutrino, and so on, etc. travel with a spin (length) to the left. That is a important rule. It connects a particle's spin or velocity and an axial vector angular momentum, and says that the angular momentum is uniquely to be opposite to the velocity vector along it.

Now that is the rule, but today we do not really understand the why and the physics of it. Why is this the right rule, who is the "impartial" reason for it, and how is it connected to something else? At the moment we have been unable to be the "why" that the thing is unsymmetrical. But we have not been able to recover enough to understand what it means with regard to the other rules. However, the subject is still活着, maybe, and still unbroken, so it seems appropriate that we discuss some of the questions a moment with it.

52-4 Antiparticles

The last thing is the third one of the symmetries which is to be immediately go back over the list of known or assumed symmetries and see whether any of the others are lost. Now we did not mention the question of our list, which most interestingly is quibbled, and that is the relation between matter and antimatter. Dirac postulated first in addition to electrons there must be another particle, called the positron discovered by Compton by Anderson, that is necessarily related to the electron. All the properties of these two particles obey certain rules of correspondence; the energies are equal, the masses are equal, the charges are equal; but, more important than anything, the two of them, when they come together, can annihilate each other and liberate their entire mass in the form of energy, say $E=mc^2$. The positron is called a conjugate to the electron, and these are the characteristics of a particle and its antiparticle. It was clear from Dirac's argument that all the rest of the particles of the world should also have corresponding antiparticles. For instance, for the proton there should be an antiproton, which is now synthesized by α . They would have a negative total charge, and the same mass as a proton, and so on. The most important feature, however, is that a proton and an antiproton containing bags, but not opposite each other. The reason we emphasize this is that people do not understand it when we say, "There is a proton and a neutron antiproton, because they say, "A neutron is neutral, so how can it have the opposite charge?" The rule of the "rule" is not just that it has the opposite of bags, it has a certain set of properties. One thinks he is talking about opposites. The antiproton is distinguished from the neutron this way: if we bring two neutrons together, they just stay as two neutrons, but if we bring a neutron and an antineutron together, they annihilate each other with a great explosion of energy being liberated, with various pions, etc., bags, and whatever.

Now if we have antineutrons, antiprotons, and antideuterons, we can make a hydrogen, in principle. They have mutual repulsion, but it is possible to accelerate. For instance, a hydrogen atom has a proton at the center with an electron going around it. Now imagine that somewhere we can make an antiproton with a positron going around, would it go around? Well, first of all, the antiproton is electrically negative and the antineutron is electrically positive, so they attract each other in a corresponding manner. One would do all the same everything as the

same. It is one of the principles of the symmetry of physics, the equal right to show, that if a clock, say, were made of matter on one hand, and then we make the same clock out of antimatter, it would run in this way. (Of course, if we put the clocks together, they would annihilate each other, but that is another story.)

An immediate question then arises. We can build, say, in matter two clocks, one which is "left-handed" and one which is "right-handed." For example, we could build a clock which is set up in a simple way, has two cathodes and magnets and electron detectors, which detect the presence of 0-energy electrons and count them, feel time has occurred, the second hand moves next. To the right of each, respectively, there must now will not run on the same time. So evidently we can make two clocks such that the left-handed clock does not agree with the right-handed one. Let us make, out of matter, a clock which has with the standard or "right-hand" clock. You can make, also, out of matter, a clock which you call a "left-hand" clock. We have just discovered that, in general, these two will not run the same way, perhaps last famous physical discovery, it was thought, that they would. Now it was also suggested that, rather than antimatter were equivalent, that is, if we made a standard clock, right-handed, based on β -ray. Then it would run the same as the right-handed matter clock, and if we made the same clock in the left, it would run the same. In other words, at the beginning it was believed that all four of these clocks were the same; but, of course, we know that the right-hand and left-hand matter are not interchangeable. Presumably, therefore, the right-handed antimatter and the left-handed antimatter are not the same.

So the question is, which goes with which, if either? In other words, does the right-handed matter have the same way as the right-handed antimatter? Or does the right-handed matter believe the same as the left-handed antimatter? Perhaps, to get into it using particle decay instead of time analogy, indicate that this is the difference from matter to the "right" versus the same way as gamma to the "left."

Therefore, at long last, it is really true that right and left symmetry is still violated! If we make a left-handed clock, but since it out of the other kind of matter, antimatter, instead of matter, it would run in the same way. So what has happened is that instead of having two independent types of matter-like symmetries, now, if these race go large, here comes a new rule, which says that matter to the right is symmetrical with antimatter to the left.

So our theory is made of antimatter and we give him his own symmetries, this "right" handed model like us, it will, of course, run in the other way around. What would happen if we, after much conversation back and forth, we each leave taught the other to make every thing and we meet halfway in empty space? You have the right side, either on our computers, and so forth, and the two of us come rushing out in opposite hands. Well, if he puts out his left hand, watch it.

21.9 Broken symmetries

The real question is, what sort of rules out of laws which are *not* symmetrical? The most interesting about all of this, I think, is a wide range of important strong consequences—nuclear forces, electrical phenomena, and much more—but give them over a tremendous range of physics, all the laws for these seem to be symmetrized. On the other hand, the last term goes to say, "No, the laws are not symmetrical!" How is it the laws can be Lorentz-symmetrized, yet perfectly non-symmetrized? What shall we make of this? First, do we have any other examples? I mean, in, well, a foot, does a few other examples. For instance, the nuclear part of the force between proton and proton, between neutron and neutron, and between neutron and proton is all exactly the same. There is a symmetry for that. So, for a long time, that we can interchange neutron and proton. But it evidently is not a general symmetry. For the electrical repulsion between protons at a distance does not exist for neutrons. So, is not generally true that we can always replace a proton with a neutron, but only to a good approximation. Why not? Because the nuclei of protons are much stronger than the

electrical forces. So there are "valence" systems also. But we do have examples in other things.

We have, in our minds, a tendency to accept symmetry as some kind of perfection. In fact it is ~~like~~ ~~the~~ old idea of the Greeks that man were perfect, and it was rather terrible to believe that the planetary orbits were not circles, but only nearly circles. The difference between being a circle and being nearly a circle is not a small difference, it is a fundamental difference for us the mind is concerned. There is a sense of perfection and symmetry in a circle that is not there the moment the circle is slightly off—~~not~~ is ~~not~~ end of it—it is no longer symmetrical. Then the question is why it is only nearly a circle—it's a more critical question. The actual nature of the planets, in general, would be elliptical, but during the ages, because of tidal forces, and so on, they have been made more asymmetrical. Now the question is whether we have a similar problem here. The problem from the point of view of the Greeks is if they were perfect circles there would be nothing to explain, that is clearly simple. But since they are only nearly circles, there is a job to explain, and the job turned out to be a big cosmological problem, and now our problem is to explain why they are nearly symmetrical by looking at tidal forces and so on.

So our problem is to explain where symmetry comes from. Why is nature so nearly symmetrical? We have ~~no~~ ~~any~~ idea why. The only thing we might suggest is something like this. There is a pale in Japan, a pale in Neolithic, which is ~~suspected~~ ~~and~~ by the Japanese. In most religions, goes up all Jason; it was built in a time when there was great influence from Chinese art. This is very elaborate, with lots of pillars and beautiful carvings and lots of figures and what not. Heads and personages all over the pillars, and so on. But when one looks closely he sees that in the elaborate and complex design along one of the pillars, one of the ~~say~~ ~~design~~ elements is sexual reproduction; otherwise the thing is completely without material. One asks why this is, the story is that it was sexual appeal: down we that the gods will set the jealousy of the perfection of man. So they probably put someone in there, or for the gods would not be jealous and get angry with human beings.

We might like to turn the idea around and look at the true explanation of the near-symmetry of nature is that God made the laws only nearly symmetrical so that we should not be jealous of His perfection!

Letter of George C. Clark, Chairman, A.C.M.T.C.

5000 University, Pasadena, Calif.

Introduction & Preface

These are the lectures I planned that I gave last year and the year before in the fall and spring semesters at Caltech. The lectures are, of course, not complete—they have been edited, some parts necessary and some not, so the lectures form only part of the complete course. The whole group of 196 students is listed—a big because most were weak in fact these lectures did not fully update some large portion of the students in certain sections, either too good or else too strong. In addition, there was a laboratory every seven weeks.

The space problem we had to grapple with was how to give a minimum number of lectures yet enthusiasm and interest among students coming out of 116 high schools and 116 backgrounds. This has included students less interesting and exciting physics—such as theory of relativity, quantum mechanics, and other modern areas. By the end of two years or one previous course, study would be very advanced, but not necessarily in the same, say, order, since it is not necessary. They were interested in relativity, quantum mechanics, and so forth, and also in general theory of everything. The question was whether or not we could make it possible to do so the more advanced and excited students by maintaining enthusiasm.

The culture from my point of view is to take every course, but not very seriously. I thought to address myself to the most intelligent in the class and to make sure, if possible, that what I used to help them was available to everybody, especially my bright students in the course—by providing in appendices an approach of the sort and success in various directions outside the main line of attack. For this reason, though, I tried very hard to "simplify" the situation so as always as possible, to point out in every case where the student has an interest and also the body of material, and then, when they wanted more—things were to be modified. I also felt like for such students it is important to indicate what it is they can do—say in a difficult problem—so that it could be distinguished from what has been done before, so that it is being presented as something new. When new ideas came in, I would try either to deduce them if they were deductive, or to explore them in a new field which had likely been in the past. If so, then what had already learned and what was not supposed to be previously—but was just called “”.

In several of the lectures I assumed that the student knew something about the course of high school—with that as background, implies, say, geometry, logic, and so on. I also, of course, left some basic material to make the lectures

for a definite order, ... I assume that I would not be allowed to introduce something until I've really understood it in detail. This was a great deal of trouble at things, to do, to teach, without complete consequences. These more complete consequences would come later on, the dependent lecture more advanced. Examples are the two responses of molecular and of the laser levels, which are at the moment ... in a very qualitative way and the laser development completely.

In the same time that I was talking to the most active student, I also wanted to understand the others, for whom the extra knowledge that applications are already cropping up and who cannot be expected to have most of the material in the book at all. The basic student I wanted there to be at least a general idea of problems of material which he could get. Even if he didn't understand everything, I hoped he wouldn't get nervous. I didn't expect him to understand everything, all the central and most direct features. In other words, of course, a certain intelligence on his part is necessary, and the central feature, a fundamental concept, and where the more elaborate calculations begin, which he may understand only at best.

In giving these lectures there was one serious difficulty. In the way the course was going, I was getting very feedback from the audience to the beginning, indicating how well the lectures were going over. This is almost a very serious difficulty, and I don't know how avoid the interaction with the audience. The whole thing was essentially an experiment. And it is not always a question about the same way that I hope I don't have to do it again. I think though, that things worked somewhat to the degree I experienced satisfactorily in the first year.

In the second year I was much less satisfied. In the first year of the course, dealing with electricity and magnetism, I couldn't think of any really unique or different way of doing it, of any way that would be substantially more exciting than the usual way of proceeding. So I didn't think I'd deliver very much in the lectures on electricity and magnetism. In the second year I had originally intended, as in the first, to discuss quantum theory, by giving some more lectures on the properties of matter, so as mainly to take up things like fundamental waves, solutions of the Schrödinger equation, interacting systems, orthogonal functions, calculating the first stage of what are usually called "the mathematical methods of physics." In retrospect, I think now, if I were doing it again, I would probably do this straightforward. I mean, I was not planning, in the second year, giving these lectures again, never suggesting reading assignments, or exercises or the like, or any direction in the quantum mechanics which you see, said in Volume II.

It is perfectly clear now, students were still majoring physics, even to limit their third year to quantum mechanics. Of course, based on the argument we made that many of the students in our course study physics as a background for their primary interests in other fields. And the usual way of dealing with quantum mechanics makes them pay a heavy price, probably more than necessary, to students because they have to take a long time to learn the details of real applications. Such skills in more complex applications such as solid state engineering and electronics - the full machinery of the Schrödinger equation appears to be rarely used. So I tried to describe the basics of quantum mechanics in a way which wouldn't require the user to know the mathematics of perturbation theory, scattering, etc., for a progress. I might say, in an interesting thing to try to do - to present quantum mechanics in the reverse direction, for several lessons which may be apparent in the literature elsewhere. However, I think that the experiments in the quantum mechanics part were not completely successful, in any part, because I really did not have enough time at the end of it should, for instance, have had them for some lectures in order to deal more explicitly with matter in energy bands and the overall dependence of amplitudes. And, I had never presented the subject this way before, so the bulk of feedback was predominantly negative. I now believe the quantum mechanics should be given at a lower level. Maybe, I now believe by non-symmetry. Then I think it's right.

The reason there are no lectures on how to solve problems is because there were no assignments. At 2, only I did problems, so I can't say what I did in the first year or how to solve problems. They are not important here. As a general way, I think, of solving

gives no search for only cataloged items by subject or reading system, but why was nothing easily available? The 10th and 11th editions of *Calculus* due to Mathematics Faculty, and from my own.

The question of course is how well the experiment has succeeded. My own point of view, which however does not seem to be shared by most of the people who worked out the system is, I assume, I didn't do it and we will be in trouble. When I look at the way the majority of the students handle the systems *Calculus* *Computers*, I think that the system is a failure. Of course, if I assume that, as I did, there were no errors, our students were more surprised single-handedly able to understand in all of the lectures, and who were quite active, I working with the project, and working upon their own projects in all subjects and interested was. I like people have now. I believe a first rate computing program they are excellent. I think I even can be asked. A man "in possession" of certain possibilities of mathematics except in his happy "specimens" where it cannot cope due to "difficulties".

Still, I didn't want to leave my student in silence, almost as perhaps I did. I think one way was probably better than none more useful, by putting more time into developing a series of problems which would give the only use of the books in the lecture. Problems give a great opportunity to fill out the material in the lecture and make it more meaningful, more complete and more selfful in the mind the ideas that have been exposed.

I think, however, that there isn't any solution to this problem. A plausible answer is to teach the best teaching you, reading only when, but less a real individual relationship between a teacher and a good teacher-student, where the student reads & the teacher talks about the things, and talk about the things. It's impossible to have such a simple situation, so much be simple reading problem that was assigned. But in our modern times we have so many students to teach that we have to hire the same substitute for the teacher. Perhaps we "hires" as a teacher or as substitute. Perhaps it is a small place where there are "hired" a teacher and student. They may get some improvement since there there is better. Perhaps they will have run through them through, or going on to another one of the best teacher.

John C. P. Tassoudji

JPNW 2967

Foreword

Over seven years Richard P. Feynman focused his interests on the subjects comprising the physical world, and it is his skillful writing and the depth of his ideas, now, in his given two years of his activity and his energy to his Lectures on Physics for beginning students. For them he has distilled the essence of his knowledge, and his efforts—so far as they can help to give a picture of the physicist's attitude. In his lectures he has brought the brilliance and clarity of his thought, the originality and vitality of his approach, and the courageous enthusiasm of his delivery. It was a joy to behold.

The first year's lectures formed the basis for the first volume of this set of books. We have inserted in this one second volume of texts, some kind of a part of the second year's lectures—which were given as the sophomore course during the 1949-1950 academic year. The rest of the second year's lectures will make up Volume II.

Of the second year of lectures, the first two-thirds were devoted to a fairly complete treatment of the physics of electricity and magnetism. The presentation was intended to serve a dual purpose. We hoped, first, to give the students a straightforward view of the great chapters of physics—from the early grouping of brackets through the great synthesis of Maxwell, on to the complete electron theory of the solid, properties and finally with the still unbroken connection of the electromechanical cell energy. Are we hopeful, second, by introducing at the outset the basic notion of vector fields, to give a subtle education in the mathematical language of field theories?—a knowledge, I repeat, of the mathematical methods needed subjects from 2000 parts of physics were sometimes analyzed together with their classical counterparts. We maintained, in this case, however, the generality of the mathematics, while concentrating upon the few, the more difficult. And we emphasized, again, by the kinds of exercises and exercises, to give you both the concepts.

Following the electromagnetism there are two chapters on an auxiliary topic: "Time." In the first chapter of each pair, the elementary and practical views are presented. The second chapter on each topic attempts to give an analysis of the whole complex subject of quantum mechanics. The subject can lead to, these two chapters, and well be pursued without serious loss, even though they are not at all necessary preparation for Volume II.

The last quarter, approximately, of the second year was dedicated to an introduction to quantum mechanics. This material was left out in the third volume.

In the second year, Feynman's lectures, we wished to do more than provide a transcription of what was said. We hoped to make the written version as close as possible to the ideas on which the original lectures were based. For this reason figures due credit be given by making only minor adjustments of the wording in the original. Likewise, the others of the lectures, I may say, the reporting and rearrangement of the material was equal. So, lectures we felt we should now better prepared to improve the clarity or balance of the presentation. Throughout the process we consulted from the original books and corrected our material whenever.

The translation of the 1949-1950 spoken words into a coherent text is a difficult task; it is, however, the primary aim to be accomplished by the

other academic buildings which come with the introduction of a new course—preparing for written exams, and giving students, designing exercises and examinations, and grading them, and so on. Many hours—and heads—will now have to be spent on this task, one which, I believe, from 1946, no longer is of vital interest or a readily-reachable *product* of the original *Program*. In other words we have failed to shorten this task. Our successors and ours' will therefore inherit the legacy, we regret.

As explained in detail in the *Procedure to Admit*, these lectures were but one aspect of a programme which was supervised by the Physics Course Committee (R. P. Leighton, Chairman, L. V. Bates, and M. Sones); at the Communication of Technology, and suggested, informed by the Technical Education. In addition the teaching people helped with any aspect of another of the responsibilities of Oxford Institute for the Armed Services: T. K. Crowley, M. V. Clegg, J. R. Clegg, J. B. Flavin, T. W. H. Harvey, M. H. Jones, W. J. Keras, A. W. Langford, R. P. Leighton, J. Matthews, M. S. Mayes, F. J. Quinn, W. Whalley, C. H. White, and E. Z. Williams. Others who assisted indirectly through their work on the courses: J. Bush, G. D. Caudine, M. J. Chesser, R. Dolan, H. H. Hall, and A. M. T. Dr. Professor Gerry Mullings, though he did not always do his task with intelligence, did nevertheless become the butt of much

The story of physics you find here would, however, not have been complete for the armed services had it not included the following: Richard P. Feynman,

CHAPTER 4. ELECTRODYNAMICS

- 4.1 Gauss 4.1
- 4.2 Continuity law (dissipation) 4.2
- 4.3 Electric potential 4.3
- 4.4 $E = -\nabla V$ 4.5
- 4.5 The flux of E 4.5
- 4.6 Gauss law; divergence of E 4.9
- 4.7 Field of a spherical charge 4.10
- 4.8 Field lines, eq. potential surfaces 4.11

CHAPTER 5. EQUILIBRIUM OF CHARGE

- 5.1 Equilibrium of charge example 5.1
- 5.2 Equilibrium in an electrostatic field 5.1
- 5.3 Equilibrium with conditions 5.2
- 5.4 Stability of charge 5.2
- 5.5 The field of a line charge 5.3
- 5.6 A sheet of charge; resistance 5.4
- 5.7 A shell of charge; a spherical shell 5.4
- 5.8 Is the field of a point charge constant? 5.7
- 5.9 Instability of a conductor 5.7
- 5.10 The field in a cavity of a conductor 5.8

CHAPTER 6. THE ELECTRIC FIELD BY PARTICLES

- 6.1 Equations of the electrostatic potential 6.1
- 6.2 The electric dipole 6.2
- 6.3 Boundary value equations 6.4
- 6.4 The dipole potential in a problem 6.4
- 6.5 The dipole approximation for an arbitrary distribution 6.6
- 6.6 The fields of charged condensers 6.7
- 6.7 The method of images 6.7
- 6.8 A point charge near a conducting plane 6.9
- 6.9 A point charge near a conducting sphere 6.10
- 6.10 Conductors: parallel plates 6.11
- 6.11 High-voltage breakdown 6.13
- 6.12 The dielectric breakdown 6.14

CHAPTER 7. THE DIELECTRIC FIELD & MAXWELL'S EQUATIONS (CONTINUED)

- 7.1 Methods for finding the dielectricity 7.1
- 7.2 Two-dimensional fields; functions of the complex variable 7.2
- 7.3 Phonon oscillations 7.5
- 7.4 Colloidal particles in an electrolyte 7.6
- 7.5 The electrostatic field of a grid 7.10

CHAPTER 8. ELECTROSTATIC ENERGY

- 8.1 The electrostatic energy of charges. A uniform sphere 8.1
- 8.2 The energy of a condenser. Based on energy conservation 8.2
- 8.3 The electrostatic energy of a dipole 8.4
- 8.4 Dielectric energy in space 8.5
- 8.5 Energy in the electrostatic field 8.9
- 8.6 The energy of a point charge 8.12

CHAPTER 9. ELECTROLYSIS IN THE ATMOSPHERE

- 9.1 The electric potential gradient of the atmosphere 9.1
- 9.2 Electric currents in the atmosphere 9.2
- 9.3 Origin of the atmospheric currents 9.4
- 9.4 Tornadoes 9.5
- 9.5 The mechanism of charge separation 9.7
- 9.6 Lightning 9.10

CHAPTER 10. DIPOLESES

- 10.1 The dielectric constant 10.1
- 10.2 The polarization vector P 10.2
- 10.3 Polarization charges 10.3
- 10.4 The electrostatic equations with dielectrics 10.6
- 10.5 Fields and forces with dielectrics 10.7

CHAPTER 11. ISOTROPIC DIPOLES

- 11-1 Molecular dipoles 11-1
- 11-2 Dielectric polarization 11-1
- 11-3 Polarizability; orientation polarization 11-2
- 11-4 Electric field in vicinity of a dipole 11-3
- 11-5 The electric potential resulting from a dipole: Maxwell's equation 11-5
- 11-6 Self-electrostatic energy 11-7
- 11-7 Electrostatics: Biot-Savart law 11-8

CHAPTER 12. ELECTROSTATICS AND FIELD

- 12-1 The same charges have the same solutions 12-1
- 12-2 The flux of field at point source due to infinite plane boundary 12-2
- 12-3 The electrostatic moment 12-3
- 12-4 The diffusion of neutrons: a uniform spherical source in a homogeneous medium 12-6
- 12-5 Levitating fluid over the Moon just a sphere 12-7
- 12-6 Chromatography: sorting of particles 12-10
- 12-7 The "underappreciation" of science 12-12

CHAPTER 13. MAGNETOSTATICS

- 13-1 The magnetic field 13-1
- 13-2 Electric current; the conservation of charge 13-1
- 13-3 The magnetic force on a current 13-2
- 13-4 The magnetic field of steady currents 13-4
- 13-5 The magnetic field of a straight wire and of a solenoid: atomic current 13-5
- 13-6 The relativity of magnetism and electric fields 13-6
- 13-7 The transformation of currents and charges 13-11
- 13-8 Susceptibility; the light bulb rule 13-11

CHAPTER 14. THE MAXWELL FIELD IN VARIOUS SITUATIONS

- 14-1 The scalar potential 14-1
- 14-2 The vector potential of known currents 14-2
- 14-3 A solenoid 14-4
- 14-4 A long solenoid 14-5
- 14-5 The field of a open loop: the magnetic dipole 14-7
- 14-6 The vector potential of a circuit 14-8
- 14-7 The law of Biot and Savart 14-9

CHAPTER 15. THE VARIATIONAL PRINCIPLE

- 15-1 The force on a current loop: center of a dipole 15-1
- 15-2 Mechanical and electrical energy 15-3
- 15-3 The energy of steady currents 15-6
- 15-4 Sources 15-9
- 15-5 The wave-polarized and quantum mechanics 15-8
- 15-6 What is the best state? Rutherford dynamics 15-17

CHAPTER 16. ISOTROPIC DIPOLES

- 16-1 Molecular polarizability 16-1
- 16-2 Transformation and reduction 16-4
- 16-3 Purcell's induced current 16-5
- 16-4 Technical technology 16-8

CHAPTER 17. THE LAW OF INVERSION

- 17-1 The physics of inversion 17-1
- 17-2 Description terms: "inversion" 17-2
- 17-3 Parity violation in the nuclear electric field; the Ising model 17-3
- 17-4 A paradox 17-5
- 17-5 Alternating-current generators 17-5
- 17-6 Natural selection 17-9
- 17-7 Solid-state 17-11
- 17-8 Infrasound and magnetic energy 17-12

CHAPTER 18. THE MAXWELL EQUATIONS

- 18-1 Maxwell's equations 18-1
- 18-2 How to view networks 18-2
- 18-3 A long circular pipe 18-3
- 18-4 A travelling field 18-5
- 18-5 The speed of light 18-8
- 18-6 Solving Maxwell's equations; the possibility and the necessity of light 18-9

CHAPTER 19. THE PHYSICS OF LIGHT FORCES

Answers

Electromagnetism

1-1 Electrical Forces

Consider a force like gravitation which varies predominately inversely as the square of the distance, but which is about a billion-billion-billion-billion times stronger. And with greater difference. There are two kinds of "matter," which we can call positive and negative. Like kinds repel and unlike kinds attract with a static charge there is only attraction. What would happen?

A bunch of positives would repel with an enormous force and spread out in all directions. A bunch of negatives would do the same. But an evenly mixed bunch of positives and negatives would do something completely different. The opposite pieces would be pulled together by the enormous electrostatics. The net result would be that the terrible forces would balance the repulsion almost perfectly, by forming tight, fine mixtures of the positive and the negative, and the mean two separate bunches of such mixtures there would be practically no attraction or repulsion at all.

There is such a force: the electrical force. And it's nature is a mixture of positive protons and negative electrons which are attracting and repelling with this great force. So perfect is this balance, however, that when you stand next to someone else you don't feel any force at all. If there were even a little bit of imbalance you would know it. If you were standing at arm's length from someone and each of you had one proton more electrons than protons, the repelling force would be impossible. How great? Enough to lift the Empire State Building? Not To It. Never! Except? Not. The repulsion would be enough to lift a "weight" equal to that of the entire earth!

With such enormous forces so perfectly balanced in this intimate mixture, it's not hard to understand that another, trying to keep its positive and negative charges in this balance, has here a great stiffness and strength. The Empire State Building, for example, sways only eight feet in the wind because the electrical force holds every electron and proton onto its legs with a vice-like grip. On the other hand, if we look at a cluster of a scale small enough that we see only a few atoms, any small piece will not usually have an equal number of positive and negative charges, and so there will be strong repulsive electrostatic forces. Even when there are equal numbers of both charges in two neighboring small pieces, there may still be large net electrical forces because the forces between individual charges vary inversely in the square of the distance. A net force can arise if a negative charge of one piece is closer to the positive than to the negative charge of the other piece. The attractive forces can then be larger than the repulsive ones and there can be a net attraction between two small pieces with no excess charges. The forces that hold the atoms together, and the chemical bonds that hold molecules together, are really electrical forces, acting in regions where the balance of charge is not perfect, or where the distances are very small.

You know, of course, that around E & B there will be positive protons in the nucleus and with electrons outside. You may ask: "If this electrical force is so terrific, why don't the positive and electrons just get on top of each other? If they want to be like an isolated molecule, why isn't it still there isolated?" The answer lies in the uncertainty principle. If we try to confine one electron in a region that is very close to the positive, then according to the uncertainty principle they must have some mean kinetic momentum which is larger than the \hbar we use to confine them. It is this relation, required by the laws of quantum mechanics, that keeps the electrical attraction from bringing the charges way closer together.

1-6 Electromagnetism in science and technology

Review Chapter 12, Vol. I, Characteristics of Force

There is another question: "What holds the nucleus together?" To understand, there are several problems, all of which are positive. Why don't they push themselves apart? It turns out that in nuclei there are in addition to attractive "nuclear" forces, called nuclear forces, others are present from the electric forces, and which are able to hold the protons together in spite of the electrostatic repulsion. The nuclear forces, however, have a short range—their force falls off much more rapidly than light. And this has an important consequence. If a nucleus has too many protons in it, it gets too big, and it will not stay together. The example is hydrogen, with 92 protons. The nuclear forces act mainly between each proton (or neutron) and its nearest neighbor, while the electrical forces act over large distances, giving a repulsion between each proton, and all of the others to the nucleus. The mass increases in a nucleus, the stronger is the electrical repulsion, and so in the case of a helium, the balance is so strong that the nucleus is always ready to fly apart from the repulsive electrical forces. If such a nucleus is just "disrupted" lightly one can be done by shooting it, a slow neutron; it breaks into two pieces, and with positive charges, and these pieces fly apart by electrical repulsion. The energy which is liberated is the energy of the nuclear bomb. This energy is usually called "nuclear" energy, but it is really "electrostatic" energy released when electrical forces have overcome the attractive nuclear forces.

We may ask, finally, what holds negatively charged dust together since it has no nuclear forces. If an electron is all made of one kind of substance, each part should repel the other parts. "No, wait, doesn't it do that?" But does the electron have "parts"? Perhaps we should say that the electron is just a point and that electrical forces only act between different point charges, so the electron itself does not yet again itself. Perhaps, all we can say is that the attraction of opposite signs in the electron together has produced many difficulties in the attempt to obtain a complete theory of electromagnetism. The question has never been answered. We will, unfortunately, not be discussing this subject too much in later chapters.

As we have seen, we should expect that it is a combination of electrical forces and gravitation-mechanical effects that will determine the detailed structure of matter's in bulk, and, therefore, their properties. Since atoms are held, some sort of. Some are electrical "conductors"—because their electrons are free to move about, others are "insulators"—because their electrons are held tightly in individual atoms. We will consider later how some of these properties come about, but first to a very incomplete subject, or we will begin by looking at the electrical forces only in simple situations. We begin by treating only the case of electrically insulating materials, which is really a part of the same subject.

We know well that the electrical forces, like gravitational forces, decrease inversely as the square of the distance between charges. This relationship is called Coulomb's law. But it is not precisely true when charges are moving—the electrical forces depend also on the motion of the charges in a complicated way. One part of the force between moving charges we call the magnetic force. It is really one aspect of an electric effect. That is why we call the subject "electromagnetism".

There is an important general principle that makes it possible to treat electromagnetism in a relatively simple way. We find, from experiment, that the force that acts on a particular charge—on other tiny minor other charges there are no force, they are moving—depends only on the position of the particular charge, on the velocity of the charge, and on the amount of charge. We can write the force F on a charging moving with a velocity v

$$F = q(E + v \times B). \quad (1.1)$$

We call E the electric field and B the magnetic field at the location of the charge. The important thing is that the electrical forces from all the other charges in the universe can be summarized by giving just these two forces. Their values will depend on where the charge is, and may change with time. Furthermore, if we replace a test charge with another charge, the force on the new charge will be just proportional to the amount of charge; so among all the rest of the charges in the

Table 1.1 Some basic Greek letters and commonly used capitals

κ	kappa
λ	lambda
μ	mu
ν	nu
ρ	rho
σ	sigma
τ	tau
ϕ	phi
ψ	psi
ω	omega
Ω	Omega

would do in change their positions or motions. (In real situations, of course, each charge produces forces on all other charges in the neighborhood and may cause these other charges to move, and so in some cases the field can change if we replace our particular charge by another.)

We know from Vol. I how to find the motion of a particle if we know the force on it. Equation (1.1) can be combined with the equation of motion to give

$$\frac{d}{dt} \left[\frac{1}{r} - \frac{q_0 q}{\pi^2 c^2 r^2} \right] = F = q(E + v \times B). \quad (1.2)$$

If E and B are given, we can find the motion. Now we need to know how the E 's and B 's are produced.

One of the most important simplifying principles about the way the fields are produced is this: Suppose a number of charges moving in some manner would produce a field E_1 , and another set of charges would produce E_2 . If both sets of charges are in place at the same time (keeping the same locations and motions they had when considered separately), then the field produced is just the sum

$$E = E_1 + E_2. \quad (1.3)$$

This law is called the principle of superposition of fields. It holds also for magnetic fields.

This principle means that if we know the law for the electric and magnetic fields generated by a single charge moving in an arbitrary way, then all the laws of electrodynamics are complete. If we want to know the force on charge A we need only calculate the E 's and B 's produced by each of the charges B , C , D , etc., and then add the E 's and B 's from all the charges to find the fields, and from them the forces acting on charge A . It is bad only to remember that the field produced by a single charge was simple; this would be the easiest way to describe the laws of electrodynamics. We have already given a description of this law (of chapter 25, Vol. I) and it is, unfortunately, rather complicated.

It turns out that the form in which the laws of electrodynamics are simplest are not when you rightly expect. It is not simple to give a formula for the force that one charge produces on another. It is true that when charges are stationary the Coulomb force law is simple, but when charges are moving, from the relativity, the complications by delays in time and by the effects of acceleration, amount of time. As a result, we do not wish to present electrodynamics only through the force laws between charges; we find it more convenient, in another point of view—a point of view in which the laws of electrodynamics appear to be the most easily manageable.

1-2 Electric and magnetic fields

First we must extend somewhat our ideas of the electric and magnetic vectors, E and B . We have defined them in terms of the forces that are felt by a charge. We will now associate electric and magnetic fields with points even when there is no charge present. We are saying, in effect, that since there is a force "acting on" the charge, there is still "something" there when the charge is removed. If a charge located at the point (x, y, z) at the time t feels the force F given by Eq. (1.1) we associate this vector F with the point (x, y, z) . We may think of $F(x, y, z, t)$ and $B(x, y, z, t)$ as giving the vector that would be experienced at time t by a charge located at (x, y, z) , with the condition that placing the charge there did not disturb the positions or field values of all the other charges responsible for the fields.

Following this idea, we associate with every point (x, y, z) in space two vectors E and B , which may be changing with time. The electric and magnetic fields are, then, viewed as vector functions of x , y , z , and t . Since a vector is specified by its components, each of the fields $E(x, y, z, t)$ and $B(x, y, z, t)$ represent three mathematical functions of x , y , z , and t .

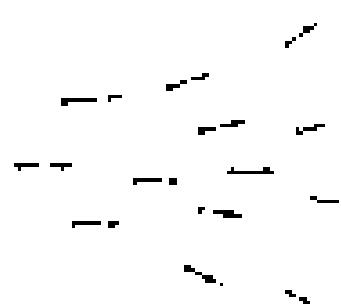

Fig. 1-1. A vector field may be represented by drawing a set of arrows, whose magnitudes and directions indicate the value of the vector field at the particular point where the arrows are drawn.

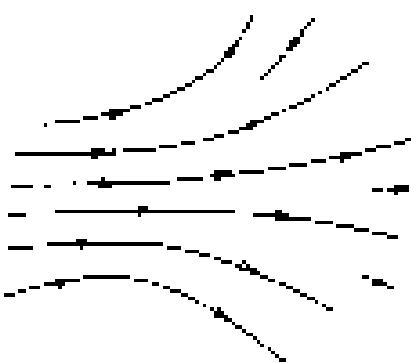

Fig. 1-2. A vector field can be represented by drawing lines which are tangent to the direction of the field vector at each point, and by drawing the density of these proportional to the magnitude of the field vector.

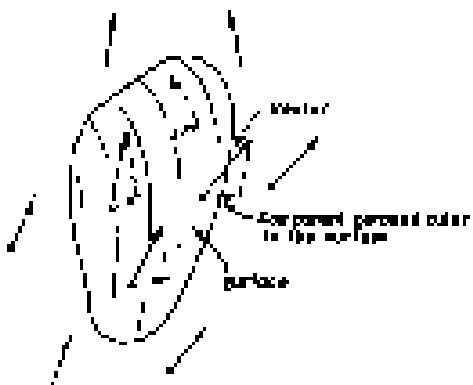

Fig. 1-3. The flux of a vector field through a surface is defined as the average value of the normal component of the vector times the area of the surface.

It is precisely because \mathbf{F} (or \mathbf{B}) can be specified at every point in space that it is called a "field." A "field" is any physical quantity which takes on different values at different points in space. Temperature, for example, is a field—in this case a scalar field, which we write as $T(x, y, z)$. The temperature could also vary in time, and we would say the temperature field is time-dependent, and write $T(x, y, z, t)$. Another example is the "velocity field" of a flowing liquid. We write $\mathbf{v}(x, y, z)$ for the velocity of the liquid at each point in space at the time t ; this is a vector field.

Returning to the electromagnetism field—although they are produced by charges according to complicated formulas, they have the following important characteristic. The relationship between the values of the fields at various points in the volume x is usually quite complex. With only a few such relationships in the form of differential equations we can describe the fields completely. It is a feature of such equations that the laws of electrodynamics are much simpler when they have been written in terms of the behavior of fields.

The most correct is also the most abstract: we simply consider the fields as mathematical functions of position and time. We can also attempt to get a certain picture of the field by drawing vectors at many points in space, each of which gives the field's strength and direction at that point. Such a representation is shown in Fig. 1-1. We can go further, however, and draw lines which are everywhere tangent to the vectors—which, to speak literally, follow the arrows and keep track of the direction of the field. When we do this we lose track of the length of the vectors, but we can keep track of the strength of the field, by drawing the lines far apart where the field is weak and close together where it is strong. We adopt the convention that the number of lines per unit area at right angles to the lines is proportional to the field strength. This is, of course, only an approximation, and it will require, in general, that we have spacetime start up in order to keep the number, up to the strength of the field. The field of Fig. 1-1 is represented by field lines in Fig. 1-2.

1-1. Characteristics of vector fields

There are two mathematically important properties of a vector field which we will use in our description of the laws of causality from the field point of view. Suppose we imagine a closed number of some kind and ask whether we are losing "something" from the inside; that is, does the field have a "valley" or "valley?" For instance, for a velocity field we might ask whether the velocity is always outward on the surface, or more generally whether most fluid flows out (or) into "valleys" coming in. We call the direction of fluid going out through the surface the "flux of velocity" through the surface. The flow strength an element of a surface is just equal to the component of the velocity perpendicular to the surface times the area of the surface. If an arbitrary closed surface, the net outward flux of the velocity is the average normal component of the velocity times the area of the surface.

$$\text{Flux} = \text{Average norm. comp.} \times (\text{Surface area}). \quad (1.1)$$

In the case of an electric field, we can mathematically define something analogous to an "outflow," and we again ask "is there loss?" In fact, however, it is not the flow of any substance, because the electric field is not the velocity of anything. It turns out, however, that the mathematical quantity which is the average normal component of the field will be a useful quantity. We speak, then, of the electric flux—also defined by Eq. (1.1). Finally, it is also useful to speak of the flux not only through a completely closed surface, but through any bounded surface. As before, the flux through such a surface is defined as the average normal component of a vector times the area of the surface. These ideas are illustrated in Fig. 1-3.

There is a second property of a vector field that has to do with a law, called "law" a surface. Suppose again that we think of a velocity field that describes the flow of a liquid. We might ask this interesting question: Is the liquid circulating? I.e.

By "lost we mean: Is there a net "rotational" motion around some loop? Suppose that we inconspicuously freeze the liquid everywhere except inside of a tube which is of uniform bore, and which goes in a loop that closes back on itself as in Fig. 1-4. Outside of the tube the liquid stops moving, but inside the tube it may keep on moving because of the momentum to the trapped liquid: one is, of course, more momentum heading one way around the tube than the other. We define a quantity called the circulation as the angular speed of the liquid in the tube times circumference. We can again extend our loops and define the "circulation" for any vector field (even when there isn't anything moving). For any vector field the circulation around any "closed" closed curve is defined as the average tangential component of the vector (in a consistent sense) multiplied by the circumference of the loop (Fig. 1-5).

$$\text{Circulation} = \text{average tangential component} (\text{reference arc only}). \quad (1.5)$$

You will see that this definition does indeed give a number which is proportional to the circulation velocity in the quickly frozen tube described above.

With just these two ideas—flux and circulation—we can describe all the laws of electricity and magnetism at once. You may not understand the significance of the last right away, but they will give you some idea of the way the physics of electromagnetism will be ultimately described.

1-4 The laws of electromagnetism

The first law of electromagnetism describes the flux of the electric field:

$$\text{The flux of } E \text{ through any closed surface} = \frac{q_0}{\epsilon_0} \text{ net charge inside.} \quad (1.6)$$

where ϵ_0 is a constant constant. (This constant ϵ_0 is usually read as "epsilon-zero" or "spacel-nought".) If there are no charges inside the surface, even though there are charges nearby outside the surface, the average normal component of E is zero, as there is no net flux through the surface. To show the power of this one statement, we consider that Eq. (1.6) is the same as Coulomb's law, provided only that we also add the rule that the field from a single charge is spherically symmetric. For a point charge, we draw a sphere around the charge. Then the average normal component is just the value of the magnitude of E at any point. Since the field must be altered radially and have the same strength for all points on the sphere. Our rule now says that the field at the surface of the sphere, times the area of the sphere—that is, the outgoing flux—is proportional to the charge inside. If we were to make the radius of the sphere bigger, the area would increase as the square of the radius. The average normal component of the electric field times that area must be equal to the same charge inside, and so the field must decrease as the square of the distance—we get an "inverse square" field.

If we have an arbitrary curve in space and measure the circulation of the electric field around the curve, we will find that it is zero, in general, even though there is no free charge inside. Rather, for electricity there is a second law that shows for any surface S (not closed) which cuts the curve C ,

$$\text{Circulation of } E \text{ around } C = \frac{\partial}{\partial t} (\text{flux of } E \text{ through } S). \quad (1.7)$$

We can complete the laws of the electromagnetic field by writing two corresponding equations for the magnetic field B .

$$\text{Flux of } B \text{ through any closed surface} = 0. \quad (1.8)$$

For a surface S bounded by the curve C ,

$$\begin{aligned} \text{Circulation of } B \text{ around } C &= \frac{\partial}{\partial t} (\text{flux of } B \text{ through } S) \\ &\quad + \frac{\text{flux of electric current through } S}{\epsilon_0}. \end{aligned} \quad (1.9)$$

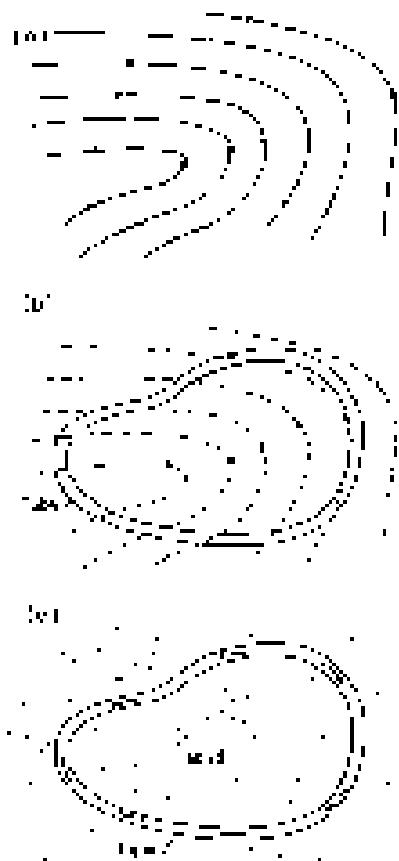

Fig. 1-4. (a) The velocity field in a liquid. Imagine a tube of uniform cross section that follows an arbitrary closed curve as in (b). If the liquid were suddenly frozen everywhere except inside the tube, the liquid in the tube would circulate as shown in (c).

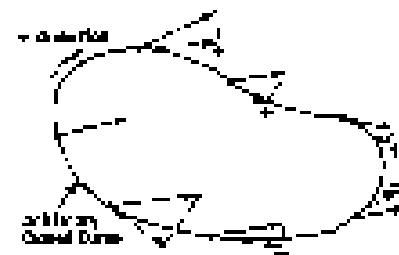

Fig. 1-5. The circulation of a vector field is the average tangential component of the vector (in a consistent sense) times the circumference of the loop.

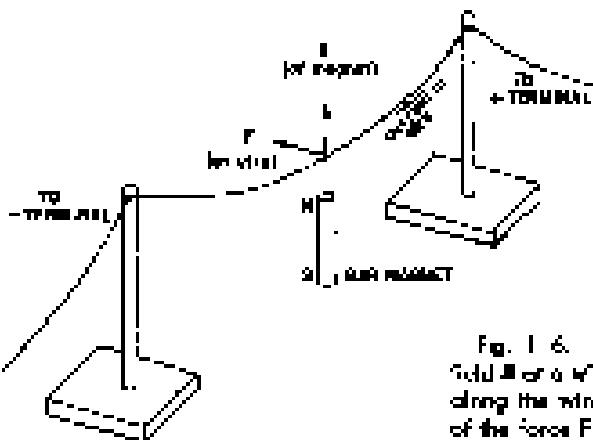

Fig. 1-6. A bar magnet gives a field B to a wire. When there is a current along the wire, the wire moves because of the force $F = qv \times B$.

The constant c^4 that appears in Eq. (1.1) is the square of the velocity of light. It appears because magnetism is in reality a relativistic effect of electricity. The constant c , i.e., the factor in v makes the units of electric current come out in a reasonable way.

Equations (1.6) through (1.8), together with Eq. (1.1), are all the laws of electrodynamics*. As you remember, the laws of Newton were very simple to write down, but they had a lot of complicated consequences and it took us a long time to learn about them all. These laws are not nearly as simple to write down, which means that the consequences are going to be more elaborate and it will take us quite a lot of time to figure them out.

We can illustrate some of the laws of electrodynamics by a series of small experiments which show qualitatively the interrelationships of electric and magnetic fields. We have expressed the first term of Eq. (1.1) when combing your hair, so we won't show that one. The second part of Eq. (1.1) can be demonstrated by passing a current through a wire which hangs above a bar magnet as shown in Fig. 1-6. The wire will move when a current is turned on because of the force $F = qv \times B$. When the current stops, the charges inside the wire are moving, so they have a velocity v and the magnetic field from the magnet exerts a force on them, which results in pulling the wire sideways.

When the wire is pushed to the left, we would expect that the magnet must feel a push to the right. (Otherwise we could put the whole thing on a wagon and have a propulsive system that didn't conserve momentum.) Although the force is too small to make movement of the bar magnet visible, a more sensitively supported magnet, like a compass needle, will show the movement.

How does the wire pull on the magnet? The current in the wire produces a magnetic field of its own that exerts forces on the magnet. According to the last

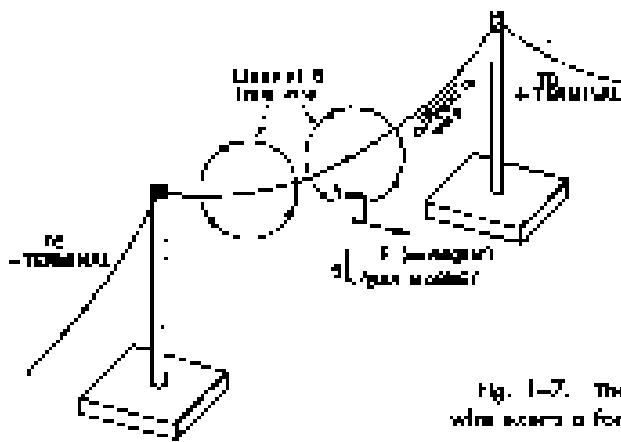

Fig. 1-7. The magnetic field of the wire exerts a force on the magnet.

* We need only add a remark about some conventions for the sign of the circulation.
L-6

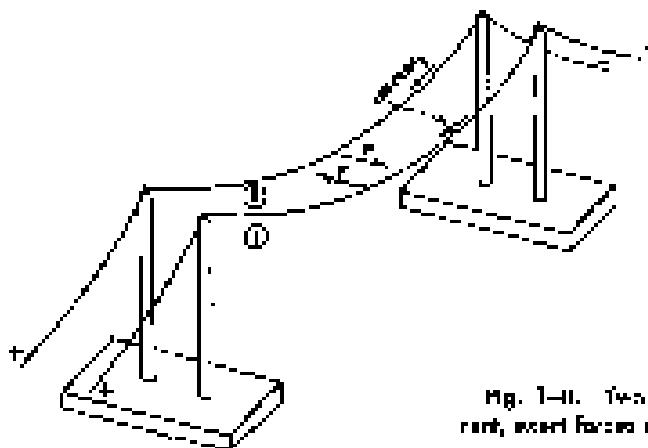

Fig. 1-8. Two wires, carrying current, exert forces on each other.

where in Eq. (1.10), a current much larger than one of I . In this case, the lines of B are loops around the wire, as shown in Fig. 1-7. This B -field is responsible for the force on the magnet.

Equation (1.9) tells us that for a fixed current through the wire, the magnitude of B is the same for any curve that surrounds the wire. For curves—say circles—that are farther away from the wire, the circumference is larger, so the tangential component of B may decrease. You can see this in Fig. 1-7; in fact, expect B to decrease inversely with the distance from a long straight wire.

Now, we have said that a constant current in the wire produces a magnetic field, and that when there is a magnetic field present, there is a force on a wire carrying a current. But we should also expect that if we make a magnet with a current in one wire, it should exert a force on another wire which also carries a current. This can be shown by using two hanging wires, as shown in Fig. 1-8. When the magnets are in the same direction, the two wires repel, because the currents are opposite, they repel.

Is direct electrical current as well as magnetism, make magnetic fields? But wait, what is a magnet, anyway? If magnetic fields are produced by moving charges, is it not possible that the magnetic field from a piece of iron is really the result of currents? It appears to be so. We can replace the bar magnet of our experiment with a coil of wire, as shown in Fig. 1-9. When a current is passed through the coil—as well as through the straight wire above it—we observe a motion of the wire exactly as before, when we had a magnet instead of a coil. In other words, the current in the coil creates a magnet. It happens, then, that a piece of iron acts as though it contains a permanent circulating current. We can, in fact, understand magnets in terms of permanent currents in the atoms of the iron. The force on the magnet in Fig. 1-7 is due to the second term in Eq. (1.1).

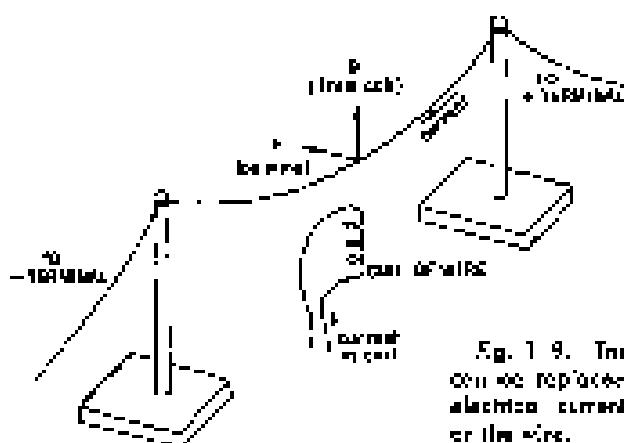

Fig. 1-9. The bar magnet of Fig. 1-6 can be replaced by a coil carrying an electric current. A similar force acts on the wire.

Where do the currents come from? One possibility would be from the motion of the electrons in atomic orbits. Actually, that is not the case for iron, although it is for some materials. In addition to rotating around its atoms, an electron also spins about on its own axis—anything like the spin of the earth—and it is the current along this spin that gives the magnetic field to iron. (We say “rotating like the spin of the earth” because the quantum mechanics tell us that the classical ideas do not really describe things very well.) In most substances, some electrons will rotate with some spin the other, so the magnetism cancels out, but in iron—for a mysterious reason which we will discuss later—many of the electrons are spinning with their axes lined up, and that is the source of the magnetism.

Since the fields of magnets are from currents, we do not have to add any extra term to Eqs. (1.8) or (1.9) to take care of magnetism. We just take all currents, including the circulating currents of the spinning electrons, and then the law is right. You should also notice that Eq. (1.8) says that there are no magnetic “charges” analogous to the electrical charges appearing on the right side of Eq. (1.6). None has been shown.

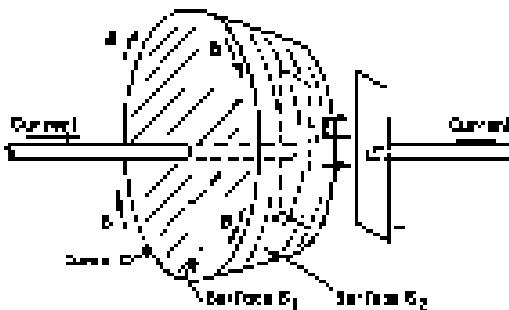

Fig. 1-16. The circulation of \mathbf{B} around the curve C is given either by the current passing through the surface S_1 , or by the rate of change of the flux of \mathbf{E} through the surface S_2 .

The first term on the right-hand side of Eq. (1.5) was discovered theoretically by Maxwell and is of great importance. It says that changing electric fields produce magnetic effects. In fact, without this term the equation would not make sense, because without it there would be no currents in circuits that are not complete loops. But such currents do exist, as we can see in the following example. Imagine a capacitor made of two flat plates. It is being charged by a current that flows between one plate and away from the other, as shown in Fig. 1-18. We draw a curve C around one of the wires and fit it in with a surface which covers the wire as shown by the surface S_1 in the figure. According to Eq. (1.9), the circulation of \mathbf{B} around C is given by the current in the wire times c^2 . But what if we fit in the curve with a different surface S_2 , which is shaped like a bowl and passes between the plates of the capacitor, staying always away from the wire? There is certainly no current through this surface. So, surely, just changing the location of an imaginary surface is not going to change a real magnetic field! The circulation of \mathbf{B} must be what it was before. The last term on the right-hand side of Eq. (1.5) does, indeed, combine with the second term to give the same result for the two surfaces S_1 and S_2 . For S_2 the circulation of \mathbf{B} is given in terms of the rate of change of the flux of \mathbf{E} between the plates of the capacitor. And it works out that the changing E is related to the current in just the way required for Eq. (1.9) to be correct. Maxwell saw that it was needed, and so was the desire to write the complete equation.

With the setup shown in Fig. 1-6 we can remember another of the laws of electromagnetism. We disconnected the ends of the bridging wire from the battery and connect them to a galvanometer which tells us when there is a current through the wire. When we push the wire sideways through the magnetic field of the magnet, we observe a current. Such an effect is again just another consequence of Eq. (1.1). The electrons in the wire feel the force $F = q\mathbf{v} \times \mathbf{B}$. The electrons have a sideways velocity because they move with the wire. This v with a vertical B from the magnet results in a force on the electrons directed along the wire, which makes the electrons moving toward the galvanometer.

Suppose, however, that we leave the car alone and move the magnet. We guess from relativity that it should make no difference, and indeed, we observe a similar current in the galvanometer. This means the moving coil produces forces on charged ones? According to Eq. (1.2) there must be an electric field. A moving magnet must make an electric field. How does it happen is told quantitatively by Eq. (1.7). This equation describes many phenomena of great practical interest such as those that occur in electric generation and transmission.

The most remarkable consequence of our equations is that the combination of Eq. (1.7) and Eq. (1.9) embodies the propagation of the waveform of electromagnetic effects over large distances. The reason is roughly something like this: suppose that somewhere we have a magnetic field which is oscillating because, say, a current is turned on suddenly in a wire. Then by Eq. (1.7) there must be a circulation of an electric field. As the electric field builds up to produce its circulation, then according to Eq. (1.9) a magnetic circulation will be generated. But the building up of this magnetic field will produce a new circulation of the electric field, and so on. In this way fields track their way through space without the trace of charges or currents except at their source. That is the way we see each other! It is all in the equations of the electromagnetic field.

1-5 What are the fields?

We now make a few remarks on the way of looking at this subject. You may be saying, "All this business of lines and distributions is pretty abstract. There are electric fields at every point in space. What does one these 'lines' or 'fields' actually represent?" Why can't you explain it, for instance, by whatever it is that goes between the charges? Well, it depends on your prejudices. Many physicists used to say that direct action with nothing in between was incomprehensible. (How could they find another incomprehensible why it had already been given?) They would say: "Look, the only choices we have is the above account of two pieces of matter interacting. It's impossible that there can be a force with nothing in between!" You what really happens when we apply the "cancellation" of one piece of matter right against another? We discover that it is not one piece right against the other; they are slightly askew, and there are electrical forces acting on a tiny scale. Thus we find that we are going to begin to call other interaction in terms of the picture for electrical forces. It is certainly not sensible to try to insist that an electric force has to look like the old. Similarly, a regular push is pull when we call out that the molecular pushes and pulls are going to be interpreted as electrical forces! The only sensible question is what is the most convenient way to look at electrical fields. Some people prefer to represent them as the interaction of a charge of charge, and to renounce compensated law. Others like the field lines. They draw field lines all the time, and look at things as if they were isolated. The field lines, however, are only a crude way of doing it in a field, and it is very difficult to give the correct quantification laws exactly in terms of field lines. Also, the laws of the field lines do not contain the deepest principle of electrodynamics, which is the superposition principle. Even though we know how the field lines look for one set of charges and what the field lines look like for another set of charges, we don't get any idea about what the field lines produce will look like when both sets are present together. From the mathematical stand point, on the other hand, superposition is easy—you simply add the two vectors. The field lines have some advantages in giving a visual picture, but they also have some disadvantages. The direct interaction view I think is having advantages when thinking of electrical charges at rest, but has great disadvantages when dealing with charges in motion.

The best way is to use the electric field law. That is also not superfluous, but necessary. The attempts to try to represent the electric field as the motion of some kind of particles, or in terms of forces, or of stresses in some kind of material have made to more effort of physicists than it would have taken simply to get the right answers about electrodynamics. It is interesting that the various experiments for the behavior of light in crystals were worked out by McCullough in 1970. (See

people said to him: "Yes but there is no real material whose mechanical properties could possibly satisfy those equations, and since light is an oscillating field, most vibrations are oscillations. We cannot believe this abstract electrical business." If people had been more open-minded, they might have believed in the right equations for the behavior of light & let science have to say the

In the case of the magnetic field we can make the following point: Suppose you finally succeeded in making up a picture of the magnetic field in terms of some kind of lines or of gear wheels running through space. Then you try to explain what happens to two charges moving in space, both of the same speed and parallel to each other. But as they are moving, they will behave like two cars and will have a magnetic field associated with them like the air pressure in the wind, as Fig. 1-1). An observer who was riding along with the two charges, however, would see both charges as stationary and would say that there is no magnetic field. The "gear wheels" or "lines" disappear when you ride along with the object. All we have done is to invent a new problem. How can the gear wheels disappear? The people who have light lines are in a similar difficulty. Not only is it not possible to say where the field lines move or do not move with charges—they may disappear completely in certain coordinate frames.

All that we are saying here is that magnetism is really a relativistic effect. In the case of the two charges we just considered, travelling parallel to each other, we would expect to have to make relativistic corrections to their motion, with terms of order v^2/c^2 . These corrections would correspond to the magnetic force. But what about the force between the two wires in the experiment (Fig. 1-2)? There the magnetic force is the whole force. It didn't look like a "relativistic correction." Also, if we estimate the velocities of the electrons in the wire (you can do this yourself), we find that their average speed along the wire is about 0.01 centimeter per second. So v/c^2 is about 10^{-12} . Surely a negligible "correction." But not! Although the magnetic force is, in this case, 10^{-11} of the "normal" electrical force between the moving electrons, remember now that "normal" electrical forces have disappeared because of the almost perfect balancing out because the wires have the same number of positive and negative. The balance is much more precise than one part in 10^{12} , and the small relativistic force which we call the magnetic force is the only one left. It becomes the dominant force.

It is the near-perfect cancellation of electric effects which allowed relativity theory (*i.e.* in magnetism) to be trusted and the correct equations—the order v^2/c^2 to be discovered, even though scientists didn't know that's what was happening. And that is why, when relativity was discovered, the electromagnetic law didn't need to be changed. Only—unlike mechanics—it was correct to a precision of v^2/c^2 .

1.6 Electromagnetism in science and technology

Let us end this chapter by pointing out that among the many phenomena studied by the Greeks there were two very strange ones: that if you rubbed a piece of amber you could lift up little pieces of paper, and that there was a strange rock from the island of Magnesia which attracted iron. It is interesting to think that these were the only phenomena known to the Greeks in which the effects of electricity or magnetism were apparent. The reason that these were the only phenomena that appeared is due primarily to the fortunate position of the balancing of charges that we mentioned earlier. Study by successive steps after the Greeks intersected one new phenomenon after another that were really quite typical of these amber and/or lodestone effects. Now we realize that the phenomena of chemical interaction and, ultimately, of life itself are to be understood in terms of electromagnetism.

At the same time that an understanding of the subject of electromagnetism was being developed, historical necessities that dictated the explanation of the people that came before were appearing. It became possible to signal by taking up one long distance, and to talk to another person miles away without any connection between, and to run huge power systems—a gear motor wheel, connected by

firearm over hundreds of miles to another engine that runs in resonance in the center wheel—every thousands of branching elements—an incandescent engine in ten thousand places running the machinery of industry and homes—burning because we have knowledge of the laws of Electromagnetism.

Today we are applying even more subtle effects. The electrical forces, enormous as they are, can also be very tiny, and we can control them, and use them in very many ways. So delicate are our instruments that we can tell what a wire is doing by the way it affects the electrons in a thin metal rod hundreds of miles away. All we need to do is to put the rod as an antenna for a television receiver!

From a long view of the history of mankind—seen from, say, ten thousand years from now—there can be little doubt that the most significant event of the 20th century will be judged as Maxwell's discovery of the laws of charge dynamics. The American Civil War will pale into provincial significance in comparison with this important scientific event of the same decade.

Differentiated Function of Vector Fields

2-1 Understanding physics

The physicist needs a facility in looking at problems from outside points of view. The exact analysis of real physical problems is nearly quite complicated, and any particular physical situation may be too complicated to analyze directly by solving the differential equation. But one can still get a very good idea of the behavior of a system if one has some feel for the character of the solution in different circumstances. Tools such as the field lines, capacitors, resistance, and inductance are, for such purposes, very useful. So we will spend much of our time analyzing them. In this way we will get a feeling for what should happen in different electromagnetic situations. On the other hand, some of the heuristic models, such as field lines, is really adequate and accurate for all situations. There is only one possible way of presenting the laws, and that is by means of differential equations. They have the advantage of being fundamental and, as far as we know, precise. If you have learned the differential equations, you can always go back to them. There is nothing to unknown.

It will help you twice now to understand what should happen in different circumstances. You will have to solve the equations. Each time you solve the equations, you will learn something about the character of the solutions. To keep these solutions in mind, it will be useful also to carry their meaning in terms of field lines and of other concepts. This is the way you will really "understand" the equations. That is the difference between mathematics and physics. Mathematicians, or people who have only mathematical minds, are often led away from "studying" physics because they lose sight of the physics. They say, "Look, these hideous equations—the Maxwell equations—are all there is in electromagnetism; i. e. is admitted by the physics and there is nothing else is not contained in the equations. The equations are complicated, but after all they are only mathematical equations and if I understand them mathematically, that's all, I will understand the physics inside out." Only it doesn't work that way. Mathematicians who only play with that pile of new and there have been many of them usually make little contribution to physics, even in fact little in themselves. They fail because the real physical situations in the real world are so complicated that it is necessary to have a much broader understanding of the equations.

What it means really to understand an equation—that is, in more than a strictly mathematical sense—was described by Dirac. He said: "I understand what an equation means if I have a way of figuring out the characteristics of its solution without actually solving it." So if we have a way of knowing what should happen in given circumstances without actually solving the equations, then we "understand" the equations as applied to these circumstances. A physical understanding is a completely nonmathematical, intuitive, and incisive thing, but absolutely necessary for a physicist.

Ordinarily, a course like this is given by developing gradually the physical ideas—by starting with simple situations and going on to more and more complicated situations. This requires that you continuously forget things you previously learned. Things that are true in certain situations, but which are not true in general. For example, the "law" that the electrical force depends on the square of the distance is not always true. We prefer the opposite approach. We prefer to prove first the complete laws, and then to show how and apply them to simple situations, developing the physical ideas as we go along. And that is what we are going to do.

Review: Chapter 1, Vol. I, Errors

Our approach is completely opposite to the historical approach, in which one coverage the subject in terms of the experiments by which the information was obtained. But the subject of physics has been developed over the past 200 years by some very important people, and as we have only a limited time to deduce our knowledge, we cannot possibly cover everything they did. Unfortunately one of the things that we shall have a tendency to lose in these lectures is the historical, experimental development. It is hoped that in the subsequent course of this book, can be corrected. You can also fill in what we must leave out by reading the Physics department's Bulletin, which has excellent historical articles on electricity and on other parts of physics. You will also find historical information in many textbooks on electricity and magnetism.

3-3 Scalar and vector fields—Part A

We begin now with the abstract mathematical view of the theory of electricity and magnetism. The ultimate aim is to deduce the meaning of the laws given in Chapter 1. In order to do this we must first explain a few new notation that we want to use. So let us begin electromagnetism for the moment and discuss the mathematics of vector fields. This is very useful both because, not only for electromagnetism, but for all kinds of physical circumstances. Just as ordinary differential and integral calculus is so important to all branches of physics, so also is the differential calculus of vectors. We turn to that subject.

Below follow some few facts from the algebra of vectors. It is assumed that you already know them.

$$A \times B = \text{scalar} \cdot (A_1 B_2 - A_2 B_1) = A_1 B_2 - A_2 B_1 \quad (2.1)$$

$$A \times B = \text{vector} \quad (2.2)$$

$$(A \times B)_1 = A_1 B_2 - A_2 B_1$$

$$(A \times B)_2 = A_1 B_3 - A_3 B_1$$

$$(A \times B)_3 = A_2 B_3 - A_3 B_2$$

$$A \times J = 0 \quad (2.3)$$

$$J \cdot (A \times B) = 0 \quad (2.4)$$

$$A \cdot (\nabla \times C) = (A \times B) \cdot C \quad (2.5)$$

$$A \times (B \times C) = B(A \cdot C) - C(A \cdot B) \quad (2.6)$$

Small systems are harder.

Also we will want to use the two following equations from the calculus:

$$\Delta f(x, y, z) = \frac{\partial^2 f}{\partial x^2} \Delta x + \frac{\partial^2 f}{\partial y^2} \Delta y + \frac{\partial^2 f}{\partial z^2}, \quad (2.7)$$

$$\frac{\partial^2 f}{\partial x \partial y} = \frac{\partial^2 f}{\partial y \partial x}. \quad (2.8)$$

The first equation (2.7) is, of course, true only in the limit that Δx , Δy , and Δz are small enough.

The simplest possible physical field is a scalar field. By a field, you remember, we mean a quantity which depends upon position in space. By a scalar field we merely mean a field which is characterized at each point by a single number—a scalar. Of course the number may change its value, but we need not worry about that for the moment. We will talk about what the field looks like at a given instant. As an example consider a solid cube of material which has been heated at some places and cooled at others, so that the temperature of the cube varies from point to point in a complicated way. Then the temperature will be a function of x , y , and z , the position in space measured in a regular grid convenient system. Temperature is a scalar field.

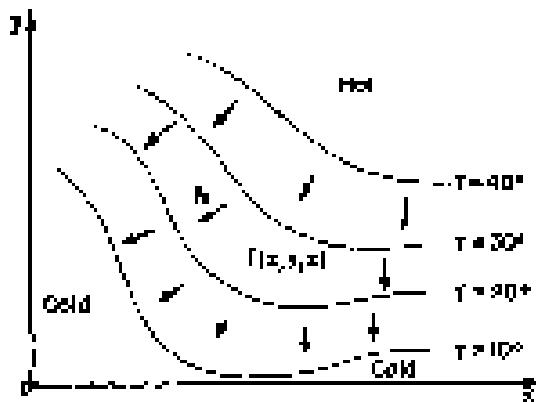

Fig. 2-1. Temperature T is an example of a scalar field. With each point (x, y, z) in space there is associated a number $T(x, y, z)$. All points on the surface marked $T = 20^\circ$ lie on a curve or "isotherm" at the same temperature. The arrows are samples of the heat flow vector \mathbf{h} .

One way of thinking about scalar fields is to imagine "contours" which are imaginary surfaces drawn through all points for which the field has the same value, just as contour lines on a map connect points with the same height. For a temperature field the contours are T and "isothermal surfaces" are "isotherms". Figure 2-1 illustrates a temperature field and shows the dependence of T on x and y when $z = 0$. Several isotherms are drawn.

There are also vector fields. The idea is very simple. A vector is given for each point in space. The vector varies from point to point. As an example, consider a rotating body. The velocity of the material of the body at any point is a vector which is a function of position (Fig. 2-2). As a second example, consider the flow of heat in a block of material. If the temperature in the block is constant in one place and free at another, there will be a flow of heat from the latter place to the former. The heat will be flowing in different directions in different parts of the block. This heat flow is a directional quantity which we call \mathbf{h} . Its magnitude is a measure of how much heat is flowing. Examples of the heat flow vector are also shown in Fig. 2-1.

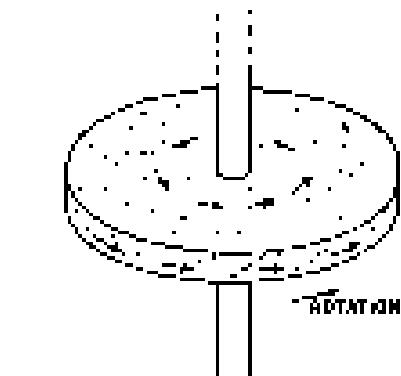

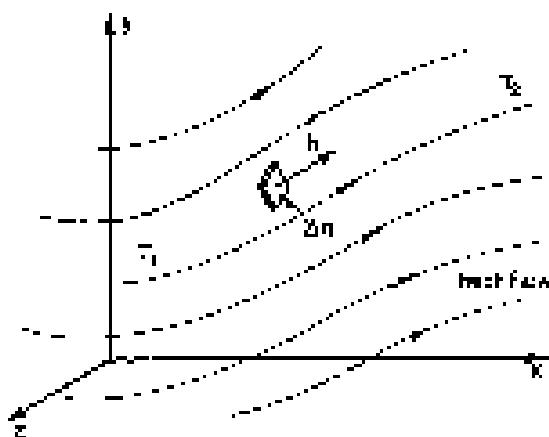

Fig. 2-2. The velocity of the atoms in a rotating object is an example of a vector field.

Let's take a more precise definition of \mathbf{h} : the magnitude of the vector \mathbf{h} at a point is the amount of thermal energy that passes, per unit time and per unit area, through an infinitesimal surface element, at right angles to the direction of flow. The vector points in the direction of flow (see Fig. 2-3). In symbols: If dA is the elemental area that passes per unit time through the surface element, then

$$h = \frac{dQ}{dA} \text{ W/m}^2 \quad (2-9)$$

where q_1 is a unit vector in the direction of flow.

The vector \mathbf{h} can be defined in another way — in terms of its components. We ask how much heat flows through a small surface at an angle with respect to the flow. In Fig. 2-4 we show a small surface dA outlined with dashed lines, which is perpendicular to the flow. The unit vector n is normal to the surface dA . The

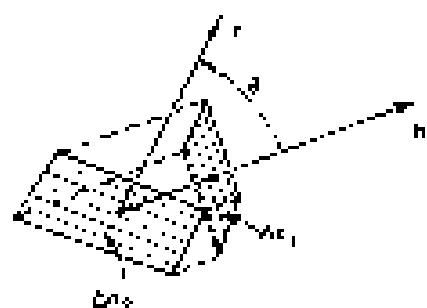

Fig. 2-4. The heat flow through dA is the rate of flow through dA .

angle between \hat{m}_1 and \hat{n} is the same as the angle between the heat flux (normal to \hat{m}_1) and \hat{n} . Now \hat{m}_1 is the heat flow per unit area through \hat{m}_1 . The flow through \hat{m}_1 is the sum of through \hat{m}_1 ; only the areas are different. In fact, $\hat{m}_1 = \hat{m}_2$ since the heat loss through \hat{m}_1 is

$$\frac{\partial T}{\partial n} = \frac{\partial T}{\partial \hat{m}_1} \cos \theta = \hat{m}_1 \cdot \hat{n} \quad (2.10)$$

We increase this equation: the heat flow (per unit time and per unit area) through any surface element whose unit normal is \hat{n} is given by $\hat{m} \cdot \hat{n}$. Equally, we could say: the component of the heat flow perpendicular to the surface element \hat{m}_1 is $\hat{m}_1 \cdot \hat{n}$. We can, if we wish, consider that these statements about \hat{m} are valid by applying the same ideas to other vector fields.

2.5 Derivatives of fields - the gradient

When fields vary in time, we can give the variation by giving their derivatives with respect to t . We want to describe the variations with respect to a similar way, because we are interested in the relationship between ΔT , the temperature at one place and the temperature at a nearby place. Then shall we take the derivative of the temperature with respect to position? Do we differentiate the temperature with respect to x_1 , or with respect to x_2 , or x_3 ?

Theful physics' law does not expand upon the orientation of the coordinate system. It says simply, therefore, *at position x there is a vector field whose components are scalar functions of the coordinates*. What is the derivative of a scalar field, say $\partial f / \partial x_1$? Is it scalar, or a vector, or what? It is neither a scalar nor a vector, so you can easily appreciate, because if we took a different x -axis, $\partial f / \partial x$ would certainly be different. But notice: We have three possible derivatives, $\partial f / \partial x_1$, $\partial f / \partial x_2$, and $\partial f / \partial x_3$. These three are three kinds of derivatives and we know that it takes three numbers to form a vector, perhaps these three derivatives are the components of a vector.

$$\left(\frac{\partial f}{\partial x_1}, \frac{\partial f}{\partial x_2}, \frac{\partial f}{\partial x_3} \right) \equiv \text{a vector} \quad (2.11)$$

Of course, it is not generally true that three numbers form a vector. It is true only if, when we rotate the coordinate system, the components of the vector transform like the components of the coordinate system. So it is necessary to analyse how these derivatives change by a rotation of the coordinate system. We shall show that (2.11) is indeed a vector. The derivatives do transform in the correct way when the coordinate system is rotated.

We can approach in two ways. One way is to ask a question whose answer is independent of the coordinate system, and try to express the answer as f . "It varies." From, for instance, $f = A \cdot R$, and A and R are vectors we know - however we proved it in Chapter 11 of Vol. I - that f is a scalar. We know that f is a scalar without investigating whether it changes with changes in coordinate system. It can't, because it's a dot product of two vectors. Similarly, if we know that A is a vector, and we have three numbers A_1 , A_2 , and A_3 , and we find out that

$$A \cdot B = A_1 B_1 + A_2 B_2 + A_3 B_3 = S \quad (2.12)$$

where S is the same for any coordinate system, then it must be that the three numbers B_1 , B_2 , B_3 are the components B_x , B_y , B_z of some vector B .

Now it's time to talk of the temperature field. Suppose we take two points P_1 and P_2 , separated by the small interval ΔR . The temperature at P_1 is T_1 and at P_2 is T_2 . Then $\Delta T = T_2 - T_1$. The temperature at these real, physical points certainly do not depend on what axes we choose for measuring the coordinates. In particular, ΔT is a number independent of the coordinate system. It is a scalar.

If we choose some convenient set of axes, we could write $T_1 = T(x, y, z)$ and $T_2 = T(x + \Delta x, y + \Delta y, z + \Delta z)$, where Δx , Δy , and Δz are the components of the vector ΔR (Fig. 2-5). Remembering Eq. (2.7), we can write

$$\Delta T = \frac{\partial T}{\partial x} \Delta x + \frac{\partial T}{\partial y} \Delta y + \frac{\partial T}{\partial z} \Delta z. \quad (2.13)$$

The left side of Eq. (2.13) is a scalar. The right side is the sum of three products times Δx , Δy , and Δz , which are the components of a vector. It follows that the three numbers

$$\frac{\partial T}{\partial x}, \frac{\partial T}{\partial y}, \frac{\partial T}{\partial z}$$

are also the x , y , and z -components of a vector. We write this new vector with the symbol ∇T . The symbol ∇ (called "del") is not upside down ∂ , but is supposed to remind us of differentiation. Perhaps read " ∇T " in various ways: "del-T" or "gradient of T ," or "grad T ."

$$\text{grad } T = \nabla T = \left(\frac{\partial T}{\partial x}, \frac{\partial T}{\partial y}, \frac{\partial T}{\partial z} \right)^T. \quad (2.14)$$

Using the notation, we can rewrite Eq. (2.13) in the more compact form

$$\Delta T = \nabla T \cdot \Delta R. \quad (2.15)$$

In Fig. 2-5 this equation says that the difference in temperature between two nearby points is the dot product of the gradient of T and the vector displacement between the points. The form of Eq. (2.15) also illustrates clearly our point above that ∇T is indeed a vector.

Perhaps you are still not convinced? Let's prove it in a different way (and—though if you look carefully, you may be able to reconstruct it's today the form of ∇ a longer winded form). We shall show that the components of ∇T transform like just the three x , y , z -components of ΔR do. If they do, ∇T is a vector according to our original definition of a vector in Chapter 1 of Vol. 1. We pass to a new coordinate system x' , y' , z' , and in this new system we calculate $\partial T/\partial x'$, $\partial T/\partial y'$, and $\partial T/\partial z'$. To make things a little easier, we let $x' = x - x_0$ so that we can forget about the x -coordinate. (You can check out the more general case for yourself.)

We take an $x'y'z'$ -system rotated an angle θ with respect to the xz -system, as in Fig. 2-6(a). For a point (x, y, z) the coordinates in the $x'y'z'$ -system are

$$x' = x \cos \theta - y \sin \theta, \quad (2.16)$$

$$y' = -x \sin \theta + y \cos \theta. \quad (2.17)$$

Or, solving for x and y ,

$$x = x' \cos \theta + y' \sin \theta, \quad (2.18)$$

$$y = x' \sin \theta - y' \cos \theta. \quad (2.19)$$

If any pair of numbers transforms via these equations in the same way that x and y do, they are the components of a vector.

Now let's look at the difference in temperature between the two nearby points P_1 and P_2 , shown as in Fig. 2-6(b). If we calculate with the $x'y'z'$ -coordinates, we would find

$$\Delta T = \frac{\partial T}{\partial x'} \Delta x' \quad (2.20)$$

with $\Delta x' = \Delta x$.

* In computation, the expression (a, b, c) represents a vector with components a , b , and c . If you like to use the unit vectors i , j , and k you may write

$$av = a \frac{\partial v}{\partial x} + b \frac{\partial v}{\partial y} + c \frac{\partial v}{\partial z}$$

Fig. 2-5. The vector ΔR , whose components are Δx , Δy , and Δz .

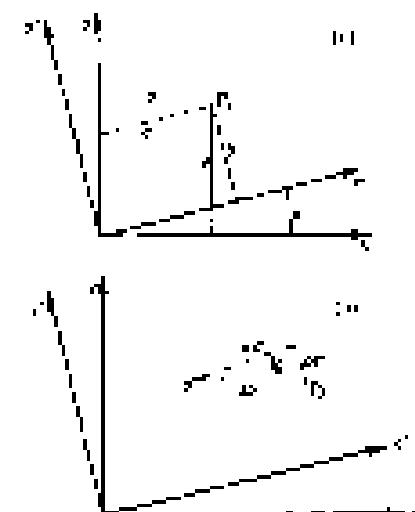

Fig. 2-6. (a) Transformation to a rotated coordinate system. (b) Special case of an interval ΔR parallel to the x -axis.

If we choose some convenient set of axes, we could write $T_1 = T(x, y, z)$ and $T_2 = T(x + \Delta x, y + \Delta y, z + \Delta z)$, where Δx , Δy , and Δz are the components of the vector ΔR (Fig. 2-5). Recalculating Eq. (2.7), we can write

$$\Delta T = \frac{\partial T}{\partial x} \Delta x + \frac{\partial T}{\partial y} \Delta y + \frac{\partial T}{\partial z} \Delta z. \quad (2.13)$$

The left side of Eq. (2.13) is a scalar. The right side is the sum of three products times Δx , Δy , and Δz , which are the components of a vector. It follows that the three numbers

$$\frac{\partial T}{\partial x}, \frac{\partial T}{\partial y}, \frac{\partial T}{\partial z}$$

are also the x , y , and z -components of a vector. We write this new vector with the symbol ∇T . The symbol ∇ (read "del") is at upside down a , and is supposed to remind us of differentiation. People read ∇T in various ways: "del-T" or "gradient of T " or "grad T ".

$$\text{grad } T = \nabla T = \left(\frac{\partial T}{\partial x}, \frac{\partial T}{\partial y}, \frac{\partial T}{\partial z} \right)^T. \quad (2.14)$$

Using the notation, we can rewrite Eq. (2.13) in the more compact form

$$\Delta T = \nabla T \cdot \Delta R. \quad (2.15)$$

In Fig. 2-5 this equation says that the difference in temperature between two points is the dot product of the gradient of T and the vector displacement between the points. The form of Eq. (2.15) also illustrates clearly our point above that ∇T is indeed a vector.

Do larger vectors still transform? Let's prove it in a different way (and, though if you look carefully, you may be able to reconstruct it's today the form of a longer winded form). We shall show that the components of ∇T transform just the same way that components of \vec{R} do. If they do, ∇T is a vector according to our original definition of a vector in Chapter 1 of Vol. 1. We pass to a new coordinate system x' , y' , z' , and in this new system we calculate $\partial T/\partial x'$, $\partial T/\partial y'$, and $\partial T/\partial z'$. To make things a little easier, we let $x' = x - x_0$ so that we can forget about the x -coordinate. (You can check out the more general case for yourself.)

We take an $x'y'z'$ -triangle, shown in Fig. 2-6(a) with respect to the x -system, as in Fig. 2-6(b). For a point (x, y, z) the coordinates in the prime system are

$$x' = x \cos \theta - y \sin \theta, \quad (2.16)$$

$$y' = -x \sin \theta + y \cos \theta. \quad (2.17)$$

Or, solving for x and y ,

$$x = x' \cos \theta + y' \sin \theta, \quad (2.18)$$

$$y = x' \sin \theta - y' \cos \theta. \quad (2.19)$$

If any pair of numbers transforms via these equations in the same way that x and y do, they are the components of a vector.

Now let's look at the difference in temperature between the two nearby points P_1 and P_2 , shown as in Fig. 2-6(b). If we calculate with the $x'y'z'$ coordinates, we would write

$$\Delta T = \frac{\partial T}{\partial x'} \Delta x' \quad (2.20)$$

with $\Delta x' = \Delta x$.

* In computation, the expression (a, b, c) represents a vector with components a , b , and c . If you like to use the unit vectors i , j , and k you may write

$$wv = i \frac{\partial T}{\partial x} + j \frac{\partial T}{\partial y} + k \frac{\partial T}{\partial z}$$

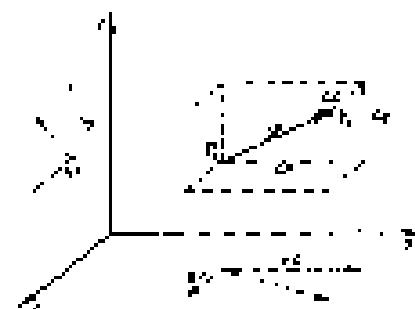

Fig. 2-5. The vector ΔR , whose components are Δx , Δy , and Δz .

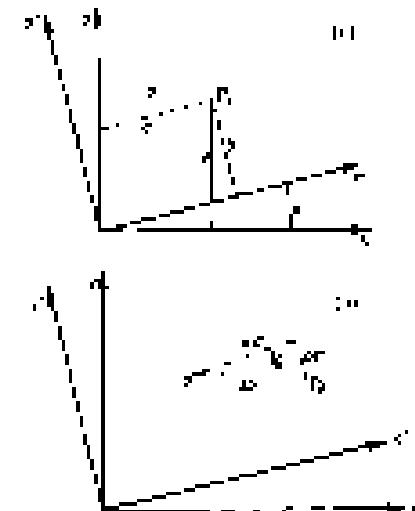

Fig. 2-6. (a) Transformation to a rotated coordinate system. (b) Special case of an interval ΔR parallel to the x -axis.

This would be a continuation of the point system, part 7. We would have gotten

$$\Delta T = \frac{\partial T}{\partial x} \Delta x + \frac{\partial T}{\partial y} \Delta y. \quad (2.21)$$

Looking at Fig. 2.4(b), we see that

$$\Delta x = \Delta r \cos \theta \quad (2.22)$$

and

$$\Delta y = \Delta r \sin \theta. \quad (2.23)$$

Note Δx is negative when θ is positive. Substituting these in Eq. (2.21), we find that

$$\Delta T = \frac{\partial T}{\partial x} \Delta x + \Delta y \frac{\partial T}{\partial y} \quad (2.24)$$

$$= \left(\frac{\partial T}{\partial x} \cos \theta + \frac{\partial T}{\partial y} \sin \theta \right) \Delta r. \quad (2.25)$$

Comparing Eqs. (2.25) with (2.20), we get that

$$\frac{\partial T}{\partial r} = \frac{\partial T}{\partial x} \cos \theta + \frac{\partial T}{\partial y} \sin \theta. \quad (2.26)$$

This equation says that $\partial T/\partial r$ is obtained from $\partial T/\partial x$ and $\partial T/\partial y$, just as x is obtained from x' and y' in Eq. (2.18). But $\partial T/\partial x$ is the *x-component* of a vector. The same kind of arguments would show that $\partial T/\partial y$ and $\partial T/\partial z$ are *y- and z-components*. So ∇T is definitely a vector. It is a vector field, derived from the scalar field T .

2.4 The operator ∇

Now we can do something that is extremely exciting and ingenious—and characteristic of the things that make mathematics beautiful. The argument that $\partial T/\partial r$, $\partial T/\partial x$, ∇T , is a vector did not depend upon this scalar field, T , or r ; it didn't matter. All the arguments would go through if T were replaced by any other field. Since the transformation equations are the same no matter what T differences, we could just as well call the T and replace Eq. (2.26) by the operator equation

$$\frac{\partial}{\partial x} = \frac{\partial}{\partial x'} \cos \theta - \frac{\partial}{\partial y'} \sin \theta. \quad (2.27)$$

We leave the operators $\cos \theta$ and $\sin \theta$ “hungry for something to differentiate.”

Since the derivative operator transforms like the components of a vector should, we can call them components of a vector operator. We can write the

$$\nabla = \left(\frac{\partial}{\partial x'}, \frac{\partial}{\partial y'}, \frac{\partial}{\partial z'} \right), \quad (2.28)$$

which means, of course,

$$\nabla_x = \frac{\partial}{\partial x}, \quad \nabla_y = \frac{\partial}{\partial y}, \quad \nabla_z = \frac{\partial}{\partial z}. \quad (2.29)$$

We have extracted the gradient away from the T —there is the wonder!

You must always remember, of course, that ∇ is an operator—alone. It means nothing. ∇ by itself means nothing; what does it mean if we multiply it by a scalar—say T ?—to get the product $T\nabla$? (One can always multiply a vector by a scalar.) It still doesn't mean anything. (It's *noncommutative*.)

$$T \frac{\partial}{\partial x}, \quad (2.30)$$

where T is not necessarily the *last* term of a product. However, according to the *rule of vectors* we would still call $T\nabla$ a vector.

Now let's multiply ∇ by a scalar on the right side, and we have the product (∇T). In ordinary algebra

$$\nabla A = AT. \quad (2.11)$$

but we have to remember that covariant algebra is a little different from ordinary vector algebra. With operators we must always keep the sequence right, so that the operator comes first. This will become clear if you just remember that the operator ∇ obeys the same commutator as has derivative calculus. What is to be differentiated must be placed on the right of the ∇ . For one is important.

Keeping in mind this point, in order to understand that ∇T is an operator, but the product $T\nabla$ is no longer a hungry operator, the operator is completely stabilized. It becomes a physical vector having a meaning. It represents the spatial rate of change of T . The components of ∇T is the rate T changes in the direction. When we are directional of the vector ∇T , we know that the rate of change of T in the direction is the component of ∇T in that direction (see Eq. 2.12). It follows that the direction of ∇T is that in which it has the largest possible magnitude—in other words, the direction in which T changes the fastest. The gradient of T has the slope of the steepest uphill slope on T .

2.5 Operators with ∇

Consider any other algebra with the scalar operator T^A . Let's try combining it with a vector. We can combine two vectors by making a dot product. We could make the products

$$\text{for example } \nabla \cdot T \quad \text{or} \quad \nabla \cdot (T \text{ times})$$

The first one doesn't mean anything yet, because T is still an operator. What it might ultimately mean would depend on what T is taken to operate on. The second product is somewhat absurd. ($A \cdot B$ is always a scalar.)

Let's say the dot product of ∇ with a vector field \mathbf{A} known, say \mathbf{A} . We write out the components:

$$\nabla \cdot \mathbf{A} = \frac{\partial A_x}{\partial x} + \frac{\partial A_y}{\partial y} + \frac{\partial A_z}{\partial z}. \quad (2.12)$$

or

$$\nabla \cdot \mathbf{A} = \frac{\partial A_x}{\partial x'} + \frac{\partial A_y}{\partial y'} + \frac{\partial A_z}{\partial z'}. \quad (2.13)$$

This sum is invariant under a coordinate transformation. If we were to choose a different system (indicated by primes), we would have

$$\nabla' \cdot \mathbf{A}' = \frac{\partial A'_x}{\partial x'} + \frac{\partial A'_y}{\partial y'} + \frac{\partial A'_z}{\partial z'}, \quad (2.14)$$

which is the same number as would be gotten from Eq. (2.12), even though it looks different. That is,

$$\nabla' \cdot \mathbf{A}' = \nabla \cdot \mathbf{A} \quad (2.15)$$

for every point in space. So $\nabla \cdot \mathbf{A}$ is a scalar field, which must represent some physical quantity. You should realize that the combinations of derivatives in $\nabla \cdot \mathbf{A}$ is rather special. There are all sorts of other combinations like $\nabla \times \mathbf{A}$, which are neither scalars nor components of vectors.

The scalar quantity $\nabla \cdot \mathbf{A}$ (or $\nabla \cdot \mathbf{v}$) is extremely useful in physics. It has been given the name "divergence." For example,

$$\nabla \cdot \mathbf{A} = \text{rate } \mathbf{A} \text{ "dissipates" } \quad (2.16)$$

In the next section we can associate a physical significance to $\nabla \cdot \mathbf{A}$. We shall, however, postpone that until later.

¹We think of A as a scalar quantity that depends on position in space, and not entirely like mathematical functions of three variables. When A is "differentiable" with respect to x, y , and z , it is an infinitely differentiable function, and " ∇ " the mathematical expression for it must then be expanded into a function of the appropriate variables.

First we wish to see what else we can cook up with the vector cross $\nabla \times \mathbf{A}$. What about a cross product? We must expect that

$$\nabla \times \mathbf{A} = \text{vector.} \quad (2.37)$$

If it's a vector whose components we can write by the usual rules for cross products (see Eq. 2.36)

$$(\nabla \times \mathbf{A})_x = A_y \partial_z - A_z \partial_y = \frac{\partial A_x}{\partial z} - \frac{\partial A_z}{\partial y}. \quad (2.38)$$

Similarly,

$$(\nabla \times \mathbf{A})_y = A_z \partial_x - A_x \partial_z = \frac{\partial A_y}{\partial z} - \frac{\partial A_x}{\partial y}, \quad (2.39)$$

and

$$(\nabla \times \mathbf{A})_z = A_x \partial_y - A_y \partial_x = \frac{\partial A_z}{\partial y} - \frac{\partial A_y}{\partial x}. \quad (2.40)$$

The combination $\nabla \times \mathbf{A}$ is called "the curl of \mathbf{A} ". The reason for the name and the physical meaning of the combination will be discussed later.

Summarizing, we have three kinds of combinations with ∇ :

$$\nabla T = \text{scalar } T = \text{scalar,}$$

$$\nabla \cdot \mathbf{B} = \nabla \cdot \mathbf{B} = \text{scalar,}$$

$$\nabla \times \mathbf{A} = \text{curl } \mathbf{A} = \text{vector.}$$

Using these combinations, we can write down the spatial variations of fields in a conductor; why?... a way that is general, i.e. that doesn't depend on any particular set of axes.

As an example of a law of nature for sufficiently-pure \mathbf{E} , we might get a situation where eq. above which contains the same laws of electromagnetism that we have in words in Chapter 1. That is called Maxwell's equations.

Maxwell's equations

$$\begin{aligned} (1) \quad & \nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0} \\ (2) \quad & \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \\ (3) \quad & \nabla \cdot \mathbf{B} = 0 \\ (4) \quad & \nabla \times \mathbf{B} = \frac{\partial \mathbf{E}}{\partial t} + \frac{\mathbf{j}}{\mu_0} \end{aligned} \quad (2.41)$$

where ρ is the "electrostatic charge density," is the amount of charge per unit volume, and \mathbf{j} is the "electric current density," is the rate at which charge flows through a unit area per second. I hope (but I'm not sure) you've seen the complete classical theory of the electromagnetic field. You see what an elegantly simple form we can get with our new toolkit!

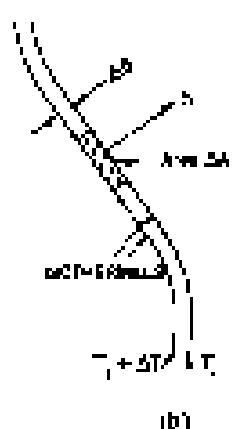

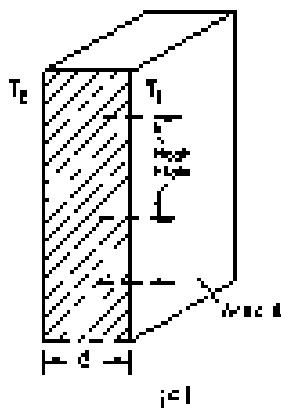

Fig. 2-7. (a) Heat flow through a slab. (b) An infinitesimal disk parallel to an interface surface in a large block.

2.4 The differential equation of heat flow

Let me give another example of a law of physics written in vector notation. This law is not a pristine one, not for many metals and a number of other substances that conduct heat it is quite accurate. You know that if you take a slab of material and heat one face to temperature T_0 and cool the other at a different temperature T_1 , the heat will flow through the material. In Fig. 2-7(a) the heat flow is proportional to the area A of the faces, and to the temperature $\Delta T = T_0 - T_1$ in inverse proportion to d , the distance between the faces. (For a given temperature difference, the thicker the slab the greater the heat flow.) Letting q be the thermal one per unit area per unit time through the slab, we write

$$q = k(T_0 - T_1) \frac{A}{d}. \quad (2.42)$$

The constant k of proportionality (k appa) is called the thermal conductivity.

What will happen to a more complicated case? Say in an odd-shaped block of material in which the temperature varies in peculiar ways? Suppose we look at a tiny piece of the block and imagine a slab like that of Fig. 2-7(a), on a microscopic scale. We orient the faces parallel to the mathematical surface, as in Fig. 2-7(b). Is Eq. (2.42) in correct for the small slab?

If the area of the small slab is ΔA , the heat flow per unit time is

$$\Delta Q = -k \nabla T \frac{\Delta A}{\Delta x}, \quad (2.47)$$

where Δx is the thickness of the slab. Now $k/\Delta x$ was defined earlier as the magnitude of k , whose direction is the heat flow. The heat flow will be from $T_{x+\Delta x}$ toward T_x , and so it will be perpendicular to the boundaries, as shown in Fig. 2-7(b). Above, $\partial T/\partial x$ is just the rate of change of T with position. And since the position change is perpendicular to the boundaries, $\partial T/\partial x$ is the maximum rate of change. I.e., therefore, out the magnitude $\|\nabla T\|$. Now since the direction of ∇T is opposite to that of k , we can write (2.47) as a vector \mathbf{q}_1 , where:

$$\mathbf{q}_1 = -k \nabla T. \quad (2.48)$$

(This minus sign is necessary because \mathbf{q}_1 does "downhill" in temperature.) Equation (2.48) is the differential equation of heat conduction in bulk materials. You can now type a proper computer program. Each variable is a vector of size just a number. It is the generalization to arbitrary cases of the second relation (2.42) for rectangular slabs. Later we should learn to write all sorts of elementary physics relations (Eq. 2.48) in the much more dignified vector notation. This notation is useful not only because it makes the equations more compact. It also makes more clearly the physical content of the equations without reference to any arbitrarily chosen coordinate system.

2-1 Second derivatives of vector fields

So far we have had only first derivatives. What are second derivatives? We could have several answers:

- (a) $\nabla \cdot (\nabla T)$
 - (b) $\nabla \times (\nabla T)$
 - (c) $\nabla(\nabla \cdot \mathbf{A})$
 - (d) $\nabla \cdot (\nabla \times \mathbf{A})$
 - (e) $\nabla \times (\nabla \times \mathbf{A})$
- (2.49)

You can check that there are *at least* the possible combinations.

Let's look first at the second one, (c). It has the same form as

$$\mathbf{A} \times (\mathbf{A} \mathbf{T}) = (\mathbf{A} \times \mathbf{A}) \mathbf{T} = 0,$$

since $\mathbf{A} \times \mathbf{A}$ is always zero. So we should have

$$\text{curl}(\text{grad } T) = \nabla \times (\nabla T) = 0. \quad (2.46)$$

We can see how this equation comes about if we go through once with the components:

$$\begin{aligned} [\nabla \times (\nabla T)]_x &= \tau_x(\nabla T)_x - \tau_y(\nabla T)_y \\ &= \frac{\partial}{\partial z} \left(\frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{\partial T}{\partial x} \right), \end{aligned} \quad (2.50)$$

which is zero (by Eq. 2.4). It goes the same for the other components. So $\nabla \times (\nabla T) = 0$, for any temperature distribution T that is an *scalar* function.

Now let us take another example. Let us see whether we can find another zero. The dot product of a vector with a cross product which contains that vector is zero.

$$A \cdot (A \times B) = 0. \quad (2.48)$$

Because $A \times B$ is perpendicular, or to A , and so has no component in the direction of A . The same conclusion applies to all of (2.45), so we have

$$\nabla \cdot (\nabla \times A) = \nabla \cdot (\text{curl } A) = 0. \quad (2.49)$$

Again, it is easy to show that it is zero by carrying through the operations with components.

Now we are going to state a famous mathematical theorem, but we will not prove. They are very interesting and useful theorems for physicists to know.

In a physical problem we frequently find that the curl of some quantity ϕ of the vector field A is zero. Now we know from (Eq. 2.46) that the curl of a gradient is zero, which is easy to remember because of the way the vectors work. It could certainly be, for example, that A is the gradient of some quantity because then its curl would necessarily be zero. Unfortunately it's not true that if the curl is zero, then A is always the gradient of something. There is some scalar field ψ (perhaps) such that A is equal to $\nabla \psi$. In other words, we have the

Theorem:

$$\text{If} \quad \nabla \times A = 0 \\ \text{then there is a} \quad \psi \\ \text{such that} \quad A = \nabla \psi. \quad (2.50)$$

There is a similar theorem. If the divergence of A is zero, we saw in Eq. 2.47 that the divergence of ∇ and of something is always zero. If you could choose a scalar field B for which $\text{div } B$ is zero, then you can conclude that B is the curl of some vector field C .

Theorem:

$$\text{If} \quad \nabla \cdot D = 0 \\ \text{then there is a} \quad C \\ \text{such that} \quad D = \nabla \times C. \quad (2.51)$$

By looking at the possible combinations of two ∇ operators, we have found that two of them always give zero. Now we look at the cases that are not zero. Take the one condition $\nabla \cdot (\nabla T)$, which was last in our list. It is not, in general, zero. We write out the components:

$$\nabla T = \nabla_x T + \nabla_y T + \nabla_z T.$$

Then

$$\begin{aligned} \nabla \cdot (\nabla T) &= (\nabla \cdot \nabla_x T) + (\nabla \cdot \nabla_y T) + (\nabla \cdot \nabla_z T) \\ &= \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}. \end{aligned} \quad (2.52)$$

which you'll in general want to be some number. It's a scalar field.

You see that we do not need to keep the parentheses, but can write, without any chance of confusion:

$$\nabla \cdot (\nabla T) = \nabla \cdot \nabla T = (\nabla \cdot \nabla)T = \nabla^2 T \quad (2.53)$$

We call ∇^2 a new operator. It is a scalar operator. Because it appears often in physics, it has been given a special name—the Laplacian.

$$\text{Laplacian: } \nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}. \quad (2.54)$$

Since the Laplacian is a scalar operator, we may operate with it on a vector—by which you mean the same vectorial on each component in rectangular coordinates:

$$\nabla^2 \mathbf{A} = (\nabla^2 A_x, \nabla^2 A_y, \nabla^2 A_z).$$

Let's look at one more possibility: $\nabla \times (\nabla \times \mathbf{A})$, where was (6) in the list (2.45). Now the curl of the curl can be written differently if we use the vector identity (2.6):

$$\mathbf{A} \times (\mathbf{B} \times \mathbf{C}) = \mathbf{B}(\mathbf{A} \cdot \mathbf{C}) - \mathbf{C}(\mathbf{A} \cdot \mathbf{B}). \quad (2.55)$$

In order to use this formula, we should replace \mathbf{A} and \mathbf{B} by the operator ∇ and put $\mathbf{C} = \mathbf{A}$. If we do this, we get

$$\nabla \times (\nabla \times \mathbf{A}) = \nabla(\nabla \cdot \mathbf{A}) - \mathbf{A}(\nabla \cdot \nabla). \quad (2.56)$$

Wait a minute! Something is wrong. The first two terms are vectors all right. (The operator one is valid), but the last term doesn't come out to anything—it's still an operator. (The trouble is that we haven't been careful enough about keeping the order of our terms straight). If you look again at Eq. (2.55), however, you see that we could equally well have written it as

$$\mathbf{A} \times (\mathbf{B} \times \mathbf{C}) + \mathbf{B}(\mathbf{A} \cdot \mathbf{C}) - (\mathbf{A} \cdot \mathbf{B})\mathbf{C}. \quad (2.56)$$

The second term looks better. It's easier to make the substitution in (2.56). We get

$$\nabla \times (\nabla \times \mathbf{A}) = \nabla(\nabla \cdot \mathbf{A}) + (\nabla \cdot \nabla)\mathbf{A}. \quad (2.57)$$

This form looks all right. It is, in fact, correct, as you can verify by computing the components. The last term is the Laplacian, so we can equally well write

$$\nabla \times (\nabla \times \mathbf{A}) + \nabla(\nabla \cdot \mathbf{A}) = \nabla^2 \mathbf{A}. \quad (2.58)$$

We have had something to say about all of the combinations in one line of double ∇ 's, except for (a), $\nabla(\nabla \cdot \mathbf{A})$. It is a possible vector field, but this is nothing special to say about it. It's just some vector field which may occasionally come up.

It will be convenient to have a table of such combinations.

- | | |
|-----|--|
| (a) | $\nabla \cdot (\nabla T) = \nabla^2 T$ — a scalar field |
| (b) | $\nabla \times (\nabla T) = 0$ |
| (c) | $\nabla(\nabla \cdot \mathbf{A}) = \mathbf{a}$ vector field |
| (d) | $\nabla \cdot (\nabla \times \mathbf{A}) = 0$ |
| (e) | $\nabla \times (\nabla \times \mathbf{A}) = \nabla(\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A}$ |
| (f) | $(\nabla \cdot \nabla)\mathbf{A} = \nabla^2 \mathbf{A}$ — a vector field |
- (2.59)

You may notice that we haven't tried to invert a new vector operator ($\nabla \times \nabla$). Do you see why?

2-8 Pitfalls

We have been applying our knowledge of ordinary vector algebra to the algebra of the operator ∇ . We dare to be careful, though, because it is possible to go astray. There are two pitfalls which we shall mention, although they will not come up in this course. What would you say about the following expression, for example, the inverse of the two scalar functions ϕ and ψ (3.3):

$$(\nabla \phi) \times (\nabla \psi)^{-1}$$

You might want to say: it must be zero because it's just like

$$(A\phi) \times (A\psi),$$

which is now because the cross product of two square vectors $A \times A$ is always zero. But in our example the two operators ∇ are different. One is the derivative operator, the other is the gradient operator, or a different function, ϕ . So it might be represented there by the same symbol, ∇ , they must be considered as different operators. Clearly, the direction of $\nabla\phi$ depends on the function, ϕ , so it is not likely to be parallel to $\nabla\psi$.

$$(\nabla\psi) \times (\nabla\phi) \neq 0 \quad (\text{generally})$$

Fortunately, we won't have to deal with expressions like this we have said doesn't change the fact that $\nabla \times \nabla\phi = 0$ for any scalar field, because here both ∇ 's operate on the same function.

The last number ten rule (again we need not get into it in this context) is the following: The rules can we have outlined here are simple and also when we use rectangular coordinates. For example, if we have $\nabla^2\psi$ and we want the x -component it is

$$\nabla^2\psi_x = \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2} \right) \psi_x = \nabla^2\psi_x \quad (2.60)$$

The same expression would not work if we were to ask for the radial component of $\nabla^2\psi$. The radial component of $\nabla^2\psi$ is not equal to $\nabla^2\psi_r$. The reason is that when we are dealing with the algebra of vectors, the directions of the vectors are all quite definite. But when we are dealing with vector fields, their directions are different at different places. If we try to describe a vector field by say, polar coordinates, what we call the "radial" direction varies from point to point. So we run into a lot of trouble when we want to differentiate the components. For example, even for a constant vector field, the radial component changes from point to point.

It is usually safest and simplest just to stick to rectangular coordinates and avoid trouble, but there is one exception: **POLAR COORDINATES:** Since the Laplacian ∇^2 is a scalar, we can write it in any coordinate system we want to (for example in polar coordinates). It is since it is a differential operator, we should use it only on vectors whose components are in a fixed direction, that means rectangular coordinates. So we don't express ∇^2 of our vector fields in terms of their x , y , and z -components when we write our vector differential equations, but in components.

Vector Integrals; Curves

3-1 Vector Integrals; the Line Integral of $\nabla\phi$

We found in Chapter 2 that there were various ways of taking derivatives of fields. Some gave vector fields, some gave scalar fields. Although we developed many different formulas, everything in Chapter 2 could be summarized in one rule: the operations $\partial/\partial x$, $\partial/\partial y$, and $\partial/\partial z$ are the three components of a vector operator ∇ . We would like to get some understanding of the "significance" of the derivatives of fields. We will then have a better feeling for what a vector field represents.

We have already discussed the meaning of the gradient, equation 17 on 2 readers. Now we turn to the meanings of the divergence and curl operators. The interpretation of these quantities is best done in terms of certain vector integral and algorithms relating such integrals. These equations, known uniformly, are obtained from vector algebra by some very common rules, so you will just have to learn them as something new. Of these integral formulas, one is physically trivial, but the other two are not. We will derive them and explain their implications. The equations we shall study are really mathematical theorems; they will be useful not only for interpreting the meaning and the control of the divergence and the curl, but also in working out general physical theories. These mathematical theorems are for the theory of fields, what the theorem of the conservation of energy is to the mechanics of particles. Let me, therefore, stress that these are important for a deeper understanding of physics. You will find, though, that they are not very useful for solving problems—except in the simplest cases. It is important, however, that in the beginning of our subject there will be some simple problems which can be solved with the three integral formulas we are going to meet. We will see, however, in the problems you hunger, that you will longer use these simple methods.

We take up first an integral formula involving the gradient. The relation contains a very simple idea: Since the gradient represents the rate of change of a field quantity, if we integrate that rate of change, we should get the total change. Suppose we have the scalar field $\phi(x, y, z)$. At any two points (1) and (2), the function ϕ will have the values $\phi(1)$ and $\phi(2)$, respectively. [This uses a convenient notation, in which (2) represents the point (x_2, y_2, z_2) and $\phi(2)$ means the same thing as $\phi(x_2, y_2, z_2)$.] If γ is a curve joining (1) and (2), as in Fig. 3-1, the following relation is true:

Theorem 1.

$$\phi(2) - \phi(1) = \int_{(1)}^{(2)} (\nabla\phi) \cdot d\mathbf{r} \quad (3-1)$$

The integral is a line integral, from (1) to (2) along the curve γ , of the dot product of $\nabla\phi$ —a vector—with $d\mathbf{r}$ —another vector which is an infinitesimal line element of the curve γ (selected away from (1) and toward (2)).

First, we should review what we mean by a line integral. Consider a scalar function $f(x, y, z)$, and the curve γ joining two points (1) and (2). We mark off the curve at a number of points and join them together by straight-line segments, as shown in Fig. 3-2. Each segment has the length Δs_i , where i is an index that runs 1, 2, 3, ... By the line integral

$$\int_{(1)}^{(2)} f d\mathbf{r}$$

3-8 Summary

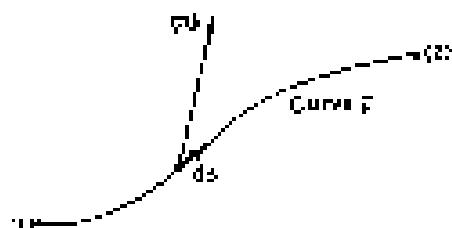

Fig. 3-1. The terms used in Eq. (3-1). The vector $n\delta\mathbf{r}$ is evaluated at the line element $\delta\mathbf{r}$.

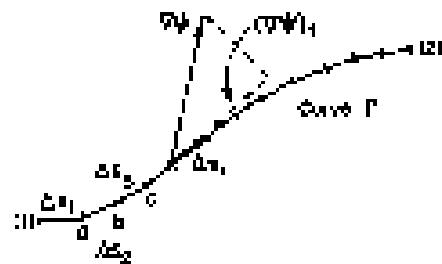

Fig. 3-2. The line integral is the limit of a sum.

we mean the limit of the sum

$$\sum_i f_i \Delta x_i$$

where f_i is the value of the function at the i th segment. The limiting value is what the sum approaches as we take many and many segments (in a sensible way, so that the largest $\Delta x_i \rightarrow 0$).

The integral in our theorem, Eq. (3.7), means the same thing, although it looks a little different. Instead of f_i , we have another scalar—the component of $\nabla \psi$ in the direction of Δx . If we write (3.7) for the trapezoidal approach, it is clear that:

$$(\nabla \psi) \cdot \Delta x = (\nabla \psi) \cdot ds. \quad (3.2)$$

The integral in Eq. (3.1) means the sum of such terms.

Now let's see why Eq. (3.1) is true. In Chapter 1, we showed that the component of $\nabla \psi$ along a small displacement Δx was the rate of change of ψ in the direction of Δx . Consider the line segment Δx_1 from (1) to point a in Fig. 3-2 according to our definition.

$$\Delta x_1 = \psi(a) - \psi(1) = (\nabla \psi)_1 \cdot \Delta x_1. \quad (3.3)$$

At x_1 , we have

$$\psi(0) = \psi(1) + (\nabla \psi)_1 \cdot \Delta x_1, \quad (3.4)$$

where, of course, $(\nabla \psi)_1$ means the gradient evaluated at the segment Δx_1 , and $(\nabla \psi)_2$ the gradient evaluated at Δx_2 . If we add Eqs. (3.3) and (3.4) we get

$$\psi(0) - \psi(1) = (\nabla \psi)_1 \cdot \Delta x_1 + (\nabla \psi)_2 \cdot \Delta x_2. \quad (3.5)$$

You can see that if we keep adding such terms, we get the result:

$$\psi(0) - \psi(1) = \sum_i (\nabla \psi)_i \cdot \Delta x_i. \quad (3.6)$$

The left-hand side doesn't depend on how we chose our intervals; if (1) and (2) are large, always the same—so we might take the limit of the right-hand side. We have therefore proved Eq. (3.1).

You can see from the proof that just as the equality doesn't depend on how the points x_1, x_2, x_3, \dots are chosen, similarly it doesn't depend on what we choose for the curve C to join (1) and (2). Our theorem is correct for any curve from (1) to (2).

One remark on notation: You will see later that it is common if we write for convenience

$$(\nabla \psi) \cdot dx = \nabla \psi \cdot ds. \quad (3.7)$$

With this notation, our theorem is

$$\text{Therefore, } \int_C \psi(0) - \psi(1) = \int_{S_1}^{S_2} \nabla \psi \cdot ds. \quad (3.8)$$

3-3. The Flux of a Vector Field

Before we consider our divergence theorem—a theorem about flux over surfaces—we would like to study a related idea which has an easily understood physical significance in the case of heat flow. We have defined the vector k , which represents the rate of flow through a unit area in a unit time. Suppose that inside a closed shell of volume V we have some closed surface S which encloses the volume V (Fig. 3-3). We would like to find out how much heat is leaving out of this volume. Written, of course, this is by calculating the total heat flow out of the surface S .

We write dA for the area of an element of the surface. The symbol stands for a two-dimensional differential. If, for instance, the open happened to be in the xy -plane we would have

$$dA = dx dy.$$

Fig. 3-3. The closed surface S contains the volume V . The unit vector n is the outward normal to the surface element dA and k is the heat-flow vector at the surface element.

Later we shall have integrals over volume and for these it is convenient to consider a differential volume that is a little cube. So when we write dV we mean

$$dV = dxdydz$$

Some people like to write $d^3\mathbf{r}$ instead of $dxdydz$, themselves, but it is kind of a second-order quantity. They would also write dV instead of dV . We will use the simple notation, and assume that you can remember that dV has two dimensions and dV has three.

The heat flow \mathbf{q} through the surface element $d\mathbf{S}$ is the heat times the component of \mathbf{q} perpendicular to $d\mathbf{S}$. We have already defined \mathbf{n} as a vector pointing outward at right angles to the surface (Fig. 3-2). The component of \mathbf{q} that we want is

$$\mathbf{q}_n = \mathbf{q} \cdot \mathbf{n} \quad (3.9)$$

heat flow out through $d\mathbf{S}$ is then

$$d\Phi = \mathbf{q}_n d\mathbf{S} \quad (3.10)$$

To get the total heat flow through any surface we sum the contributions from all the elements of the surface. In other words, we integrate (3.10) over the whole surface:

$$\text{Total heat flow outward through } S = \int_S \mathbf{q}_n d\mathbf{S} \quad (3.11)$$

We are also going to call this surface integral "the flux of \mathbf{q} through the surface." Originally the word flux meant flow, so that the surface integral just means the flow of \mathbf{q} through the surface. We may think of the "average density" of \mathbf{q} as \mathbf{q} and the surface integral of \mathbf{q} is the total heat current directed out of the surface, i.e., is, the "current density per unit time (rate per second).

We would like to generalize this idea to the case where the surface does not intersect the flow of anything; for instance, it might be the electric field. We can certainly still integrate the normal component of the electric field over an area S without. Although it is not the flow of anything, we still call it the "flux." We say

$$\text{Flux of } \mathbf{E} \text{ through the surface } S = \int_S \mathbf{E} \cdot \mathbf{n} d\mathbf{S} \quad (3.12)$$

We generalize the word "flux" to mean the "surface integral of the normal component of a vector." We will also use the same definition even when the surface contains a nonclosed curve, as in Fig. 3-3.

Returning to our special case of heat flow, let us take a situation in which $\mathbf{q}(x)$ is constant. For example, imagine some material in which there is no heat loss or further heat energy is generated or absorbed. Then if there is a net heat flow out of a given surface, the heat content of the volume inside must decrease. So, in circumstances in which heat would be conserved, we say that

$$\int_S \mathbf{q}_n d\mathbf{S} = -\frac{dQ}{dt}, \quad (3.13)$$

where Q is the heat inside the surface. The heat flux out of S is equal to minus the rate of change of Q with respect to time of the total heat Q inside S . This interpretation is possible because we are speaking of heat flow and also because we supposed that the heat was conserved. We could just, of course, speak of the total heat inside the volume if heat were being generated there.

Now we shall prove an interesting fact about the flux of any vector. You may think of the heat flow result, if you like, but what we say will be true for any vector field \mathbf{q} . Imagine that we have a closed surface S that encloses the volume V . We now separate the volume into two parts by some kind of a "cut," as in Fig. 3-4. Now we have two closed surfaces and volumes. The volume V_1 is enclosed in the surface S_1 , which is made up of part of the original surface S , and of the surface of the cut, S_{21} . The volume V_2 is enclosed by S_2 , which is made up of the rest of the original surface S and closed off by the cut S_{12} . Now consider the

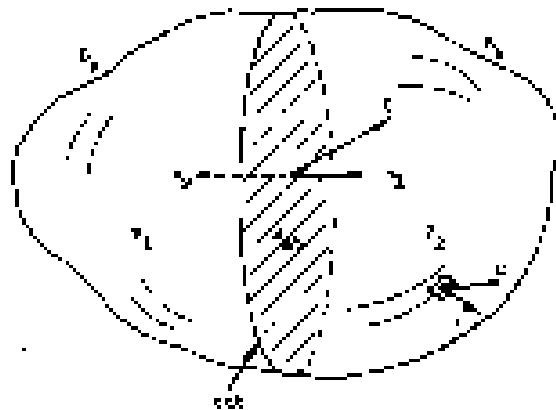

Fig. 3-4. A volume V contained inside the surface S is divided into two pieces by a "cut" at the surface S_{12} . We now have the volume V_1 enclosed in the surface $S_1 = S_1 - S_{12}$ and its volume V_2 enclosed in the surface $S_2 = S_2 - S_{12}$.

Following question: Suppose we calculate the flux $\int_C \mathbf{C} \cdot d\mathbf{s}$ through surface S_1 , and add on it the flux $\int_C \mathbf{C} \cdot d\mathbf{s}$ through surface S_2 . Does the sum equal the flux through the whole surface S ? Can we ignore S_{12} ? The answer is yes. The flux through the part of the surface S_1 common to both S_1 and S_2 just exactly cancels out. For the flux of the vector field \mathbf{C} in V_1 , we can write

$$\text{Flux through } S_1 = \int_{S_1} \mathbf{C} \cdot \mathbf{n}_1 d\mathbf{s} + \int_{S_{12}} \mathbf{C} \cdot \mathbf{n}_1 d\mathbf{s}, \quad (3.14)$$

and for the flux out of V_2 ,

$$\text{Flux through } S_2 = \int_{S_2} \mathbf{C} \cdot \mathbf{n}_2 d\mathbf{s} + \int_{S_{12}} \mathbf{C} \cdot \mathbf{n}_2 d\mathbf{s}. \quad (3.15)$$

Note that in the second integral we have written \mathbf{n}_2 for the outward normal for S_2 , when it belongs to S_1 , and \mathbf{n}_1 when it belongs to S_2 , as shown in Fig. 3-4. Clearly, $\mathbf{n}_1 = -\mathbf{n}_2$ so that

$$\int_{S_{12}} \mathbf{C} \cdot \mathbf{n}_1 d\mathbf{s} = - \int_{S_{12}} \mathbf{C} \cdot \mathbf{n}_2 d\mathbf{s}. \quad (3.16)$$

If we now add Eqs. (3.14) and (3.15), we see that the sum of the fluxes through S_1 and S_2 is in fact the sum of two integrals which, taken together, give the flux through the original surface $S = S_1 + S_2$.

We see that the flux through the complete outer surface of can be considered as the sum of the fluxes from the two parts into which the volume was broken. We can similarly subdivide space—say by cutting V in n two pieces. You see that the same arguments apply. So the only way of dividing the original volume, if indeed it generally true that the flux through the outer surface, which is the *original* integral, is equal to a sum of the fluxes out of all the tiny interior pieces.

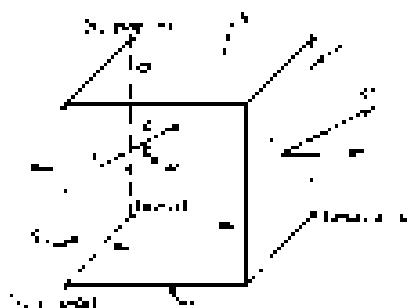

Fig. 3-5. Computation of the flux of \mathbf{C} out of a small cube.

3-5 The flux from a cubic Gauss' theorem

We now face the special case of a small cube and find an interesting formula for the flux out of it. Consider a cube whose edges are all up with the axes as in Fig. 3-5. Let us suppose that the coordinates of the corner points lie in integers x_1, x_2, x_3 . Let a_1 be the length of the cube in the x_1 direction, a_2 be the length in the x_2 direction, and a_3 be the length in the x_3 direction. We wish to find the flux of a vector field \mathbf{C} through the surface of the cube. We do this by making a sum of the fluxes through each of the six faces. First, consider the face marked n_1 in the figure. The flux outward on this face is the negative of the x_1 -component of \mathbf{C} , integrated over the area of the face. This flux is

$$- \int_C \mathbf{C} \cdot \mathbf{n}_1 d\mathbf{s}$$

Since we are considering a small cube, we can approximate this integral by the

* The following development applies equally well to any relatively simple integral.

value of C , at the center of the face—which we call the *face value* of C —multiplied by the area of the face, $\Delta x \Delta y$:

$$\text{Flux out of } 1 = -C_1(1) \Delta y \Delta x$$

Similarly, for the flux out of face 2, we write

$$\text{Flux out of } 2 = C_2(2) \Delta y \Delta x.$$

Now $C_1(1)$ and $C_2(2)$ are, in general, slightly different. If they are small enough, we can write

$$C_2(2) = C_1(1) + \frac{\partial C}{\partial x} \Delta x.$$

There are, of course, more terms, but they will involve $(\Delta x)^2$ and higher powers, and so will be negligible if we consider only the limit of small Δx . So the flux through face 2 is

$$\text{Flux out of } 2 = \left[C_1(1) + \frac{\partial C}{\partial x} \Delta x \right] \Delta y \Delta x.$$

Summing up fluxes for faces 1 and 2, we get

$$\text{Flux out of 1 and 2} = \frac{\partial C}{\partial x} \Delta x \Delta y \Delta z.$$

The derivative should really be the value at the center of face 1; that is, at $(x, y = (x\Delta/2), z = (z\Delta/2))$. But at the limit of an infinitesimal cube, we make a negligible error if we evaluate it at the center (x, y, z) .

Applying the same reasoning to each of the other pairs of faces, we have

$$\text{Flux out of 3 and 4} = \frac{\partial C}{\partial y} \Delta x \Delta y \Delta z$$

and

$$\text{Flux out of 5 and 6} = \frac{\partial C}{\partial z} \Delta x \Delta y \Delta z.$$

The total flux through all the faces is the sum of these terms: Δx and Δy ,

$$\int_{\text{faces}} \mathbf{C} \cdot \mathbf{n} d\mathbf{a} = \left(\frac{\partial C}{\partial x} + \frac{\partial C}{\partial y} + \frac{\partial C}{\partial z} \right) \Delta x \Delta y \Delta z,$$

and the sum of the elements is just ΔV . After $\Delta x = \Delta y = \Delta z$, the volume of the cube. So we can say that, in an infinitesimal cube

$$\int_{\text{faces}} \mathbf{C} \cdot \mathbf{n} d\mathbf{a} = (\nabla \cdot \mathbf{C}) \Delta V. \quad (5.17)$$

We have shown that the outward flux from the surface of an infinitesimal cube is equal to the divergence of the vector multiplied by the volume of the cube. We now see the “meaning” of the divergence of a vector. The divergence of a vector at the point P is the flux—an outgoing “flow” of C —per unit volume, in the neighborhood of P .

We have connected the divergence of C to the flux of C out of an infinitesimal volume. For any finite volume we can do the same, as proven elsewhere: the total flux from a volume is the sum of the fluxes out of each part. We can then integrate the divergence over the entire volume. This gives us the theorem that the integral of the normal component of any vector over any closed surface can also be written as the integral of the divergence of the vector over the volume enclosed by the surface. This is often called the Gauss law.

Final word: Theorem,

$$\int_{\text{S}} \mathbf{C} \cdot \mathbf{n} d\mathbf{a} = \int_V \nabla \cdot \mathbf{C} dV, \quad (5.18)$$

where S is any closed surface and V is the volume inside it.

3-4 Heat conduction; the diffusion equation

Let's consider an example of the use of this theorem, just to get familiar with it. Suppose we take again the case of heat flow in, say, a metal. Suppose we have a simple situation in which all the heat has been previously put in and the body is just cooling off. There are no sources of heat, so that heat is conserved. Then how much heat is there inside some chosen volume at any time? It must be decreasing by just the amount that flows out of the surface of the volume. If our volume is a cube, we would write, following Eq. (3.17),

$$\text{Rate of loss} = \int_{\text{Surface}} \dot{q} \cdot \hat{n} d\sigma = -k \cdot A \Delta T. \quad (3.19)$$

This rate must equal the rate of loss of the heat inside the cube. If \dot{q} is heat per unit volume, the heat in the cube is $\rho A V$, and the rate of loss is

$$\frac{d}{dt} (\rho A V) = - \frac{\partial}{\partial x} \Delta T. \quad (3.20)$$

Comparing (3.19) and (3.20), we see that

$$-\frac{\partial}{\partial x} \Delta T = \dot{q}. \quad (3.21)$$

Take careful note of the ΔT in this equation. This form appears often in physics. It expresses a conservation law—here, the conservation of heat. We have imagined the same physics, due in another way in Eq. (3.13). There we have the differential form of a conservation equation, while Eq. (3.13) is the integral form.

We have obtained Eq. (3.21) by applying Eq. (3.11) to an infinitesimal cube. We can also go the other way. For a big volume V bounded by S , Gauss' law says that

$$\int_S \dot{q} \cdot \hat{n} d\sigma = \int_V \nabla \cdot \dot{q} dV. \quad (3.22)$$

Using (3.21), the integral on the right-hand side is found to be just $-k Q/dV$, and we have Eq. (3.13).

Now let's consider a different case. Imagine that we have a block of material and that inside it there is a very tiny hole in which some chemical reaction is taking place and generating heat. Or we could imagine this. There are some wires running through it, say copper, that is being heated by an electric current. We shall suppose that the heat is generated practically at a point, and let H represent the energy liberated per second at that point. We shall suppose that in the rest of the volume heat is conserved, and that the heat generation has been going on for a long time—so that now the temperature is no longer changing anywhere. The problem is: What does the heat mean? How like a current power is the heat? How much heat flow is there at each point?

We know that if we integrate the normal component of \dot{q} over a closed surface that encloses the source, we will always get H . All the heat that is being generated at the point comes out, goes out through the \dot{q} flow, since we have supposed that the flow is steady. We have the difficult problem of finding a vector field which, when integrated over any surface, always gives H . We can, however, find the field rather easily by taking a somewhat special surface. We take a sphere of radius R , centered at the source, and assume that the heat flow is radial (Fig. 3-6). Our intuition tells us that \dot{q} should be radial if the block of material is large, and we don't get too close to the source, and it should also have the same magnitude at x points on the sphere. You see that we are doing a certain amount of guess-work, usually called "physical intuition". In the mathematics, in order to find the answer,

when \dot{q} is to do just spherically symmetric, the integral of the normal component of \dot{q} over the area is very simple, because the normal component is just \dot{q} .

Fig. 3-6. In the region near a point source of heat, the heat flow is radially outward.

the magnitude of δ and b constant. The area over which we integrate is $4\pi R^2$. We have then that

$$\int_{\text{source}} \delta \cdot \mathbf{a} d\mathbf{x} = b \cdot 4\pi R^2 \quad (3.24)$$

(where b is the magnitude of δ). This integral should equal W , the rate at which heat is produced at the source. We get

$$W = \frac{b}{4\pi R} \cdot$$

or

$$b = \frac{W}{4\pi R} \cdot \tau_n \quad (3.25)$$

With b , as usual, a , represents a unit vector in the radial direction. Our result says that the proportionality W and a varies inversely as the square of the distance from the source.

The result we have just obtained applies in the heat flow in the vicinity of a point source of heat. Let's now try to find the equations that hold in the most general kind of heat flow. Here, keeping only the condition that heat is conserved. We will be dealing only with what happens at places outside of any sources or sinks (sites of heat).

The differential equation for the conduction of heat was derived in Chapter 2, according to Eq. (2.44)

$$\delta = -\kappa \nabla T \quad (3.26)$$

(Remember that this relationship is an approximation, but fairly good for some materials like metals). It is applicable, of course, only in regions of the material where there is no generation or absorption of heat. We derived above another relation, Eq. (3.21), that holds when heat is conserved. If we combine that equation with (3.26), we get

$$\begin{aligned} -\frac{\partial \delta}{\partial r} &= \mathbf{v} \cdot \delta = -\mathbf{v} \cdot (\kappa \nabla T), \\ \text{or} \\ \frac{\partial \delta}{\partial r} &= \kappa \mathbf{v} \cdot \nabla T = \kappa \nabla^2 T. \end{aligned} \quad (3.27)$$

If κ is a constant. Your common sense tells you that δ is proportional to heat in a unit volume and $\nabla^2 T = \nabla^2 \delta$ is the Laplacian operator.

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}.$$

If we now make your common assumption we can obtain a very interesting equation. We assume that the temperature of the material is proportional to the heat content per unit volume—that is, that the material has a definite specific heat. When this assumption is valid (as it often is), we can write

$$\delta_T = \kappa \Delta T$$

or

$$\frac{\partial \delta}{\partial r} = \kappa \frac{\partial^2 T}{\partial r^2} \quad (3.28)$$

The rate of change of heat is proportional to the rate of change of temperature. The constant of proportionality κ , is, here, the specific heat per unit volume of the material. Using Eq. (3.27) with (3.28), we get

$$\frac{\partial T}{\partial r} = \frac{\kappa}{c_v} \nabla^2 T. \quad (3.29)$$

We find that the coefficient of change of T —at every point—is proportional to the Laplacian of T , which is the second derivative of its spatial dependence. We have a differential equation—in x , y , z , and r —for the temperature T .

The differential equation (3.26) is called the heat diffusion equation. It is often Problem 43.

$$\frac{\partial T}{\partial t} = \alpha \nabla^2 T, \quad (3.29)$$

where α is called the diffusion constant, and is here equal to c/ρ .

The diffusion equation appears in many physical problems: in the diffusion of gases, in the diffusion of solutions, and so others. We have already discussed the physics of some of these phenomena in Chapter 43 of Vol. I. Now you have the complete equation that describes diffusion in the most general possible situation. At some later time we will take up ways of solving this diffusing equation to find how the temperature varies in particular cases. We can break now no longer off this business about water fiddle.

3-5. The circulation of a vector field

We wish now to look at the circulation in some other way we looked at the divergence. We obtained Green's theorem by considering the integral over a surface; although it was not obvious at the beginning that we were going to be dealing with the divergence. We did not know that we were supposed to integrate over a surface in order to get the divergence! It was not at all clear that this would be the result. And so with an apparently logical lack of justification, we shall calculate something else about a vector and show that it is related to it. This time we calculate what is called the circulation of a vector field. If C is any vector field, we take its component along a curve C and take the integral of this component all the way around a complete loop. The integral is called the circulation of the vector field around the loop. We have already established a line integral of C earlier in this chapter. Now we do the same kind of thing for any vector field C .

Let C be any closed loop in space—imagine, of course. An example is given in Fig. 3-7. The line integral of the tangential component of C around the loop is written as

$$\oint_C C \cdot d\mathbf{r} = \oint_C C \cdot ds. \quad (3.30)$$

You should note that the integral is taken all the way around, not from one point to another as we did before. The little circle on the integral sign is to remind us that the integral is to be taken all the way around. This integral is called the circulation of the vector field around the curve C . The name came originally from experiencing the circulation of a liquid. But the term—“circulation”—we have extended to apply to any field even when there is no material “circulating.”

Using the same kind of pure reason with the flux, we can show that the circulation around a loop is the sum of the circulations around two smaller loops. Suppose we break up our curve of Fig. 3-7 into two loops by joining two points (1) and (2) on the original curve by a new line that cuts across, as shown in Fig. 3-8. There are now two loops, T_1 and T_2 . T_1 is made up of C_1 , which is part of the original curve to the left of (1) and (2), plus C_2 , the “short cut.” C_2 is made up of the rest of the original curve plus the short cut.

The circulation around T_1 is the sum of an integral along C_1 and along C_2 . Similarly, the circulation around T_2 is the sum of two parts, one along C_3 and the other along C_4 . The integral along C_2 will cancel, for the curve C_2 , the opposite sign from what it has for C_1 , because the direction of travel is opposite—we must take both our line integrals with the same “sense” of travel.

Following the same kind of argument we used before, you can see that the sum of the two circulations or give just the line integral around the original curve T . The parts due to C_2 cancel. The circulation around the end part plus the circulation around the second part, or the single line around the inner line. We can continue the process of cutting the original loop into any number of smaller loops. When we add the circulations of the smaller loops, there is always a cancellation of the parts that are adjacent portions, and so however is equivalent to the circulation around the original single loop.

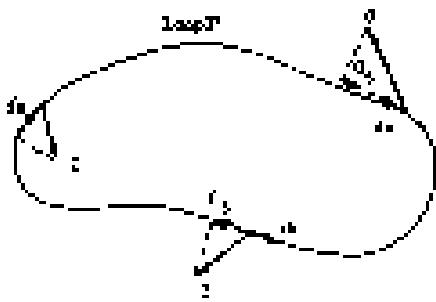

Fig. 3-7. The circulation of C around the curve C is the line integral of C , the tangential component of C .

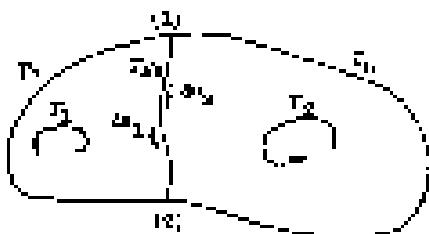

Fig. 3-8. The circulation around the whole loop is the sum of the circulations around the two loops $T_1 = T_a + T_b$ and $T_2 = T_c + T_d$.

Now let us suppose that the original loop is the boundary of some surface. Then, of course, an infinite number of surfaces which have the original loops as the boundary. One result will not, however, depend on which surface we choose. First, we break our original loop into a number of small loops. All lie on the surface we have chosen, as in Fig. 3-9. No matter what the shape of the surface, if we choose our small loops *small enough*, we can assume that each of the small loops will enclose an area which is essentially flat. Also, we can choose our small loops so that each is very nearly a square. Now we can calculate the circulation around the big loop C by finding the circulations around all of the little squares and then adding them up.

3-6 The circulation around a square; Stokes' theorem

How do we find the circulation for each little square? One question is: how is the square oriented to space? We could easily make the calculations if it had a special orientation. For example, if it were in one of the coordinate planes. Since we have not assumed anything about yet about the orientation of the coordinate axes, we can just as well choose the axes so that the four little squares we are concentrating on at the moment lie in the $x-y$ plane, as in Fig. 3-10. If our result is expressed in that orientation, we can say that it will be the same no matter what the particular orientation of the plane.

We want now to find the circulation of the field \mathbf{C} around our little square. It will be easy to do by integrating if we pass the square and through that the vector \mathbf{C} doesn't change much along any one side of the square. (The assumption is better the smaller the squares we are really taking, almost infinitesimal squares.) Starting at the point (x_1, y_1) —the lower-left corner of the figure—we go around it the direction indicated by the arrows. Along the first side—marked (1)—the tangential component is $C_x(1)$ and the distance is Δx . The first part of the integral is $C_x(1) \Delta x$. Along the second leg we get $-C_y(2) \Delta x$. Along the third, we get $-C_x(3) \Delta x$, and along the fourth, $-C_y(4) \Delta x$. The minus signs are necessary because we want the tangential component in the direction of travel. The whole line integral is then

$$\oint \mathbf{C} \cdot d\mathbf{s} = -C_x(1) \Delta x - C_y(2) \Delta y - C_x(3) \Delta x - C_y(4) \Delta y. \quad (3.11)$$

Now let's look at the first and third pieces. Together they are

$$[C_x(1) + C_x(3)] \Delta x. \quad (3.12)$$

You might think that in our approximation the difference is zero. That is true to the first approximation. We can be more accurate, however, and take into account the *rate* of change $\partial C_x / \partial x$. If we do, we may write

$$C_x(3) = C_x(1) + \frac{\partial C_x}{\partial x} \Delta x. \quad (3.13)$$

If we included the next approximation, it would involve terms in $(\Delta x)^2$, but since we still ultimately think of the limit as $\Delta x \rightarrow 0$, such terms can be neglected. Putting (3.13) together with (3.12), we find that

$$[C_x(1) + C_x(3)] \Delta x = -\frac{\partial C_x}{\partial x} \Delta x \Delta y. \quad (3.14)$$

The derivative due to our approximation is evaluated at (x, y) .

Similarly, for the other two terms in the circulation, we may write

$$C_y(2) \Delta y = C_y(4) \Delta y + \frac{\partial C_y}{\partial y} \Delta x \Delta y. \quad (3.15)$$

The circulation around our square is then

$$\left(\frac{\partial C_x}{\partial x} + \frac{\partial C_y}{\partial y} \right) \Delta x \Delta y. \quad (3.16)$$

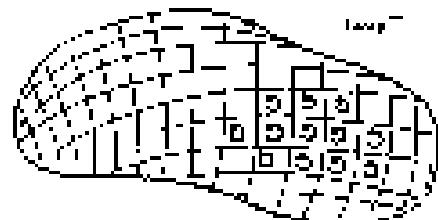

Fig. 3-9. Some surface bounded by the loop C is shown. The surface is divided into a number of small squares, each approximately a square. The circulation around C is the sum of the circulations around the little loops.

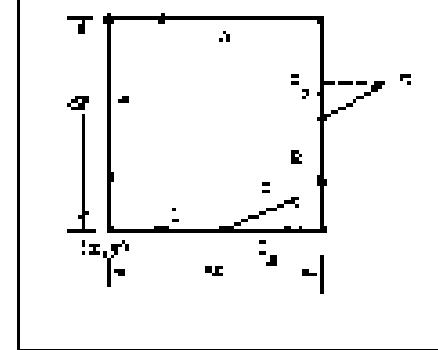

Fig. 3-10. Considering the circulation of \mathbf{C} around a unit square.

which is interesting because the two terms in the parentheses are just the *z*-component of the curl. Also, we may note that $\Delta \cdot \Delta p$ is the area of our square. So we can write our circulation (3-36) as

$$(\nabla \times C)_z \Delta p.$$

But the *z*-component really means the component normal to the surface element. We can, therefore, write the circulation around a differential square as a small vector sum:

$$\oint C \cdot d\ell = (\nabla \times C)_z \Delta p = (\nabla \times C) \cdot n \Delta p. \quad (3-37)$$

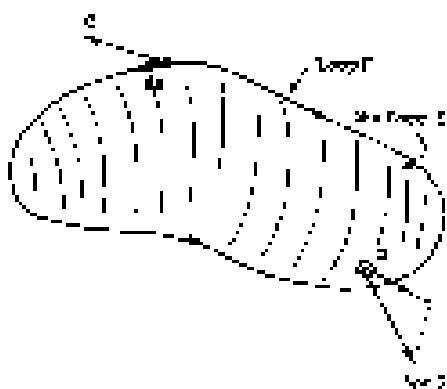

Fig. 3-11. The circulation of C around C is the surface integral of the *z*-component of $\nabla \times C$.

Our result for the circulation of any vector C around an infinitesimal square is the component of the curl of C normal to the surface, times the area of the square.

The circulation around any loop C can now be easily related to the curl of the vector field. We will do the loop with any convenient surface S , as in Fig. 3-11, and add the contributions from a set of "infinitesimal" squares in this surface. The sum can be written as an integral. Our result is a very useful theorem called Stokes' theorem (after M.L. Stokes).

Stokes' Theorem:

$$\oint_C C \cdot d\ell = \int_S (\nabla \times C) \cdot n d\ell, \quad (3-38)$$

where S is any surface bounded by C .

We must now speak about a convention of signs. In Fig. 3-10 the *z* axis would point toward you in a "fisted"→→→"right-handed"→→→system of axes. When we took our line integral with a "positive" sense of rotation, we found that the circulation was equal to the *z*-component of $\nabla \times C$. If we had gone around counter-clockwise, we would have gotten the opposite sign. Now here shall we know, in general, what direction to choose for the positive direction of the "normal" component of $\nabla \times C$? The "positive" normal must always be related to the sense of rotation, as in Fig. 3-11. It is indicated for the general case in Fig. 3-11.

One way of remembering the relationship is by the "right-hand rule". If you make the fingers of your right hand go around the curve C , with the fingertips pointing in the direction of the positive sense of $d\ell$, then your thumb points in the direction of the positive normal to the surface S .

3-7 Curl-free and divergence-free fields

We would like, now, to consider some consequences of our new theorem. Take first the case of a vector whose curl is everywhere zero. Then Stokes' theorem says that the circulation around any loop is zero. Now if we choose two paths (1) and (2) on a closed curve (Fig. 3-12), it follows that the surface integral of the tangential component from (1) to (2) is independent of which of the two possible paths is taken. We can, in fact, deform the integral from (1) to (2) over disjoint paths on the location of these poles - that is to say, it is a *conservative* of position only. This is analogous to what we learned in Chapter 14 of Vol. I, where we proved that if the integral along a closed loop of some quantity is always zero, then the integral can be represented as the difference of a function of the position of the two ends. This last statement we call the *law of a potential*. We just said, further, that this vector field was the gradient of this potential function (see Chap. 14, Sec. 17 of Vol. I).

It follows that any vector field whose curl is zero is equal to the gradient of some scalar function. That is, if $\nabla \times C = 0$, everywhere there is a vector field for which $C = \nabla \phi$ —a useful idea. We can, if we wish, describe this special kind of vector field by means of a scalar field.

Let's show something else. Suppose we have two paths (1) and (2) (Fig. 3-13) we take the gradient. The line integral of this vector along any curve has to be zero. Its line integral from point (1) to point (2) is $(\phi(2) - \phi(1))$. If (1) and (2) → 0

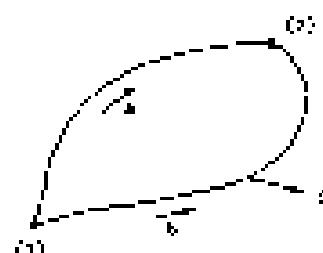

Fig. 3-12. If $\nabla \times C$ is zero, the circulation around the closed curve C is zero. The line integral of $C \cdot d\ell$ from (1) to (2) along C may be the same as the line integral along C .

and the second part, our Theorem 1, Eq. (1.6), tells us that the line integral is zero:

$$\oint_{\text{loop}} \mathbf{v} \cdot d\mathbf{l} = 0.$$

Using Stokes' Theorem, we can conclude the

$$\int_S \nabla \times (\mathbf{v}\mathbf{n}) \, dS = 0$$

over any surface. But if the integral is zero over any surface, the integral must be zero. So:

$$\nabla \times (\mathbf{v}\mathbf{n}) = 0, \text{ always.}$$

We proved the same result in Section 2.7 by vector algebra.

Let's look now at a special case in which we fill in a small loop T with a large surface S , as indicated in Fig. 3-11. We would like, in fact, to see what happens when the loop shrinks down to a point, so that the surface S ends up disappearing from the surface boundary of S . Now, if the vector \mathbf{C} is everywhere finite, the line integral around T must go to zero as we shrink the loop— \mathbf{v} is tangential to roughly perpendicular to the circumference of T , which goes to zero. According to Stokes' theorem, the surface integral of $(\nabla \times \mathbf{C})$ must also vanish. Furthermore, as we did the surface we add in contributes that cancel out what was there before. So we have a new theorem:

$$\int_S (\nabla \times \mathbf{C}) \cdot d\mathbf{S} = 0. \quad (3.39)$$

Fig. 3-11. Going to the limit of a closed surface, we find that the surface integral of $(\nabla \times \mathbf{C})$ must vanish.

Now this is interesting, because we already have a theorem about the surface integral of a vector field \mathbf{C} : such a surface integral is equal to the volume integral of the divergence of the vector, according to Gauss' theorem (Fig. 3-13). Gauss' theorem applied to $\nabla \times \mathbf{C}$ says

$$\int_{\text{volume}} (\nabla \times \mathbf{C}) \cdot d\mathbf{v} = \int_{\text{surface}} \mathbf{v} \cdot (\nabla \times \mathbf{C}) \, d\mathbf{S}. \quad (3.40)$$

So we conclude that the second integral must also be zero:

$$\int_{\text{surface}} \mathbf{v} \cdot (\nabla \times \mathbf{C}) \, d\mathbf{S} = 0, \quad (3.41)$$

and this is true for any vector field \mathbf{C} whatever. Since Eq. (3.41) is true for any volume, it must be true that at every point in space the divergence is zero. We have

$$\nabla \cdot (\mathbf{v} \times \mathbf{C}) = 0, \text{ always.}$$

But this is the same result we got from vector algebra in Section 2-7. Now we begin to see how everything fits together.

3-8 Summary

Let us summarize what we have learned about the vector calculus. There are really two main points of Chapters 2 and 3:

1. The operators $\partial/\partial x$, $\partial/\partial y$, and $\partial/\partial z$ can be considered as the three components of a vector operator ∇ , and the formulas which result from vector algebra by treating this operator as a vector are correct.

$$\nabla = \left(\frac{\partial}{\partial x}, \frac{\partial}{\partial y}, \frac{\partial}{\partial z} \right).$$

2. The difference of the values of a scalar field at two points is equal to the line integral of the tangential component of the gradient of that scalar along

any curve of all between the first and second points:

$$\psi(2) - \psi(1) = \int_{\text{any path}}^{(2)} \nabla \psi \cdot d\mathbf{r} \quad (2.42)$$

3. The surface integral of the normal component of an arbitrary vector over a closed surface is equal to the integral of the divergence of the vector over the volume interior to the surface:

$$\int_{\text{closed surface}} \mathbf{C} \cdot \mathbf{n} d\mathbf{S} = \int_{\text{volume}} \nabla \cdot \mathbf{C} dV \quad (2.43)$$

4. The line integral of the tangential component of an arbitrary vector around a closed loop is equal to the surface integral of the normal component of the curl of that vector over any surface which is bounded by the loop:

$$\int_{\text{closed loop}} \mathbf{C} \cdot d\mathbf{r} = \int_{\text{any surface}} (\nabla \times \mathbf{C}) \cdot \mathbf{n} d\mathbf{S} \quad (2.44)$$

Electrostatics

4-1 Statics

We begin now our detailed study of the theory of electromagnetism. All of electromagnetism is contained in the Maxwell equations.

Maxwell's equations:

$$\nabla \cdot E = \frac{\rho}{\epsilon_0}, \quad (4.1)$$

$$\nabla \times E = -\frac{\partial B}{\partial t}, \quad (4.2)$$

$$\nabla \cdot B = 0, \quad (4.3)$$

$$\nabla \times B = \frac{\mu_0}{\epsilon_0} J + \frac{J}{c}, \quad (4.4)$$

The situations described by these equations can be very complicated. We will consider first relatively simple situations, and soon how to handle them; next we take up more complicated ones. The easiest circumstance to treat is one in which nothing depends on the time, except the work done. All charges are permanently fixed —静止—, or if they do move, they move at a steady rate in a circuit (so ρ and J are constant in time). In these circumstances, all of the terms in the Maxwell equations which are derivatives of the field are zero. In this case, the Maxwell equations become:

Electricity:

$$\nabla \cdot E = \frac{\rho}{\epsilon_0}, \quad (4.5)$$

$$\nabla \times E = 0. \quad (4.6)$$

Magnetostatics:

$$\nabla \times B = \frac{J}{\epsilon_0 c^2}, \quad (4.7)$$

$$\nabla \cdot B = 0. \quad (4.8)$$

You will notice an interesting thing about this set of four equations. It can be separated into two parts. The electric field E appears only in the first two, and the magnetic field B appears only in the second two. The two fields are not fully uncoupled. This means that electricity and magnetism are distinct phenomena so long as charges and currents are static. The interdependence of E and B does not appear until there are changes in charges or currents, as when a condenser is charged, or a magnet moved. Only when there are sufficiently rapid changes so that the time derivatives in Maxwell's equations become significant, will E and B depend on each other.

Now if you look at the equations of statics you will see that the study of the two subjects we call **electrostatics** and **magnetostatics** is just from the point of view of learning about the mathematical properties of vector fields. Electrostatics is a field example of a vector field with zero divergence and a given direction. Magnetostatics is a field example of a field with zero divergence and a given curl. The more conventional way you may be thinking about electrostatics is a way of presenting

*Review Chapters 13 and 14, Vol. I,
Work and Potential Energy*

$$\epsilon_0 = \frac{1}{4\pi G} = 8.85 \times 10^{-12} \text{ coulombs}^2/\text{newton-meters}^2$$

The theory of electromagnetism is vector, first with electrodynamics and then we learn about the divergence, magnetostatics and the curl are taken up later. Finally, electricity and magnetism are put together. We have drawn to that will the incomplete history of vector calculus. Now we shall apply it to the special case of Electrodynamics, the law of E given by the first pair of equations.

We will begin with the simplest situation—cases in which the positions of all charges are specified. If we have only to study electromagnetism at this level (as we shall do in the next two chapters), it would be very simple to form, *exact* laws. Everything can be derived from Coulomb's law and some integration, as you will see. In many real electrostatic problems, however, we do not know initially where the charges are. We know only that they have distributed themselves in ways that depend on the properties of matter. The positions of the charges also depend on the A field, which in turn depends on the positions of the charges. These things can get quite complicated. If, for instance, a charged body is brought near a conductor or insulator, the electrons and protons in the body, either move or will move around. The charge density ρ (Eq. (4.5)) may not be zero, but we know about it from the charge that we brought up; but there will be other parts of the charge that have moved around in the conductor. And all of the charges move or move into account. One can get into some rather subtle and interesting problems. So although this chapter is to be on electrostatics, it will not cover the more beautiful and subtle parts of the subject. It will treat only the situation where we can assume that the positions of all the charges are known. Naturally, you should be able to do that case before you try to handle the other cases.

4-2 Coulomb's law: superposition

It would be logical to use Eqs. (4.3) and (4.6) as our starting points. It will be easier, however, if we can somewhere else and come back to these equations. The results will be equivalent. We will start with a law that we have called above Coulomb's law, which says that between two charges at rest there is a force directly proportional to the product of the charges and inversely proportional to the square of the distance between. The force is along the straight line from one charge to the other.

$$\text{Coulomb's law: } F_1 = \frac{1}{4\pi\epsilon_0} \frac{q_1 q_2}{r_{12}^2} \hat{v}_{12} = -F_2. \quad (4.9)$$

F_1 is the force on charge q_1 , v_{12} is the unit vector in the direction to q_2 . Since q_1 and q_2 is the distance between q_1 and q_2 . Therefore F_2 on q_2 is equal and opposite to F_1 .

The constant of proportionality, for historical reasons, is written as $1/4\pi\epsilon_0$. In the system of units which we use—the cgs system—it is defined as exactly 10^{-10} times the speed of light squared. Now since the speed of light is approximately 3×10^8 meters per second, the constant is approximately 9×10^9 , and the unit turns out to be newton-meter²/coulomb² or volt-meter per coulomb.

$$\begin{aligned} \frac{1}{4\pi\epsilon_0} &= 10^{-10} \quad (\text{by definition}) \\ &= 9.0 \times 10^9 \quad (\text{by experiment}). \end{aligned} \quad (4.10)$$

(Unit: newton-meter²/coulomb²,
or volt-meter per coulomb).

When there are more than two charges present—the only really interesting place—~~we~~ we supplement Coulomb's law with one other fact of nature: the force on one charge is the vector sum of the Coulomb forces from each of the other charges. This is so called "the principle of superposition." There is nothing to it in electrodynamics. If we combine the Coulomb law and the principle of superposition, there is nothing else. Equations (4.3) and (4.6)—the electrostatic equations—say no more than that.

When applying Coulomb's law, it is convenient to introduce the idea of an electric field. We say that the field $E(1)$ is the force per unit charge at \mathbf{r}_1 (the position of point charges). Dividing Eq. (4.9) by q_1 , we have for one-unit charge located at 1:

$$E(1) = \frac{1}{4\pi\epsilon_0} \frac{q_1}{r_{12}^2} \mathbf{e}_{12} \quad (4.11)$$

Now we consider that $E(1)$ describes something about the point (1) over if q_1 were not there—assuming that all other charges keep their same positions. We say, $E(1)$ is the electric field at the point (1).

The electric field E is a vector, so by Eq. (4.11) we really have three equations—one for each component. Writing out explicitly the x component, Eq. (4.11) becomes

$$E_x(x_1, y_1, z_1) = \frac{q_1}{4\pi\epsilon_0} \left[\frac{x_1 - x_2}{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2} \right] \mathbf{i} \quad (4.12)$$

and similarly for the other components.

If there are many charges present, the field E at any point (1) is a sum of the contributions from each of the other charges. Each term in the sum will look like Eq. (4.12) or (4.13). Letting q_j be the magnitude of the j th charge, and r_{ij} the displacement from q_j to the point (1), we write

$$\mathbf{E}(1) = \sum_j \frac{1}{4\pi\epsilon_0} \frac{q_j}{r_{ij}^2} \mathbf{e}_{ij}, \quad (4.13)$$

which means, of course,

$$E_i(x_1, y_1, z_1) = \sum_j \frac{1}{4\pi\epsilon_0} \frac{q_j(x_1 - x_j)}{(x_1 - x_j)^2 + (y_1 - y_j)^2 + (z_1 - z_j)^2} \quad (4.14)$$

and so on.

Often it is convenient to ignore the fact that charges come in packages like electrons and protons, and think of them as being spread out in volumes called "charge distributions," see figure 4.1. This is OK, as long as we are not interested in what is happening on too small a scale. We describe a charge distribution by the "charge density," $\rho(x_1, y_1, z_1)$. If the amount of charge ρ in a small volume dV located at the point (x_1, y_1, z_1) is $d\rho$, then ρ is defined by

$$d\rho = \rho(x) dV. \quad (4.15)$$

To use Coulomb's law with such a description, we replace the sums of Eqs. (4.13) or (4.14) by integrals over all volumes containing charges. Then we have

$$\mathbf{E}(1) = \frac{1}{4\pi\epsilon_0} \int_{\text{all}} \frac{\rho(\mathbf{r}') \mathbf{e}_{12}}{r_{12}^2} dV'. \quad (4.16)$$

Some people prefer to write

$$\mathbf{e}_{12} = \frac{\mathbf{r}_{12}}{r_{12}},$$

where \mathbf{r}_{12} is the vector displacement to (1) from (2), as shown in Fig. 4-1. The integral for \mathbf{E} is then written as

$$\mathbf{E}(1) = \frac{1}{4\pi\epsilon_0} \int_{\text{all}} \frac{\rho(\mathbf{r}') \mathbf{r}_{12}}{r_{12}^3} dV'. \quad (4.17)$$

When we start to evaluate something with these integrals, we usually have to write them out in explicit detail. For the x -component, in either Eq. (4.16) or (4.17), we would have

$$E_x(x_1, y_1, z_1) = \int_{\text{all}} \frac{(x_1 - x') \rho(x_1, y_1, z_1) dx' dy' dz'}{4\pi\epsilon_0 r_{12}^3 [(x_1 - x')^2 + (y_1 - y')^2 + (z_1 - z')^2]^{3/2}}. \quad (4.18)$$

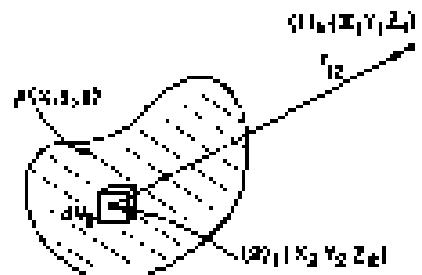

Fig. 4-1. The electric field \mathbf{E} at point (1), from a charge distribution, is obtained by an integral over the distribution. Point (1) could also be inside the distribution.

We are not going to use this formula much. We write it here only to emphasize the fact that we have completely solved all the diagnostic problems in which we know the locations of all of the charges. Given the charges, what are the fields? Answer: This is integral. So there is nothing to the subject: it is just a case of doing complicated integrals over three dimensions—strictly a job for a computing machine!

With our integrals we can find the field produced by a sheet of charge, finite line of charge, finite spherical shell of charge, or from any specified distribution. It is important to realize, as we go on to draw field lines, to talk about potentials, or to calculate divergences, that we already have the answer here. It is really a matter of it being somewhat easier to do an integral by some clever piece of work than by actually carrying it out. The question requires learning all sorts of straightforwards. In practice, it might be easier in most trying to be clever, and always to do the integral directly instead of trying to smart. We are, however, going to try to be smart about it. We shall go on to discuss some other features of the electric field.

4-3 Electric potential

First we introduce the idea of electric potential, which is related to the work done in carrying a charge from one point to another. There is some distribution of charge which produces an electric field. We ask: How much work is needed to carry a small charge from one place to another. The work done against the electrical forces in carrying a charge along some path is the negative of the component of the electrical force in the direction of the motion, integrated along the path. If we carry a charge from point a to point b ,

$$W = - \int_a^b F \cdot d\mathbf{r},$$

where F is the electrical force on the charge at each point, and $d\mathbf{r}$ is the differential vector displacement along the path. (See Fig. 4-2.)

It is more interesting for our purposes to consider the work that would be done in carrying one unit of charge. Then the force on the charge is numerically the same as the electric field. Calling the work done against electrical forces in this case "potential," we have

$$V(\text{unit}) = - \int_a^b E \cdot d\mathbf{r} \quad (4.19)$$

Now, in general, what we get with this kind of an integral depends on the path we take. So if the integral of (4.19) depended on the path from a to b , we could get work out of the field by carrying the charge to b along one path and then back to a on the other. We would go back along the path for which V is smaller and back along the other, paying off more work than we put in.

"There is nothing impossible." In principle, above getting energy out of a field, "Work," in fact, amounts to where it is possible. It could be that to you move a charge you produce forces on the other part of the "machinery." If the "machinery" moves against the force it would lose energy, thereby keeping the total energy in the work constant. For instance, however, there is no such "machinery." We know what the forces look on the geometry of the field lines. They are the Coulomb forces on the charges responsible for the field. If the other charges are fixed in position, so we assume in electrostatics only these last forces can do no work or harm. There is no way to get energy from them—provided, of course, that the principle of energy conservation works for electrostatic situations. We believe that it will work, but let's just review that it must follow from Coulomb's law of force:

We consider the work happens in the field due to a single charge q . Let point a be at the distance r_1 from q , and point b at r_2 . Now we carry a different charge, which we will call the "test" charge, and whose magnitude we choose to

Fig. 4-2. The work done in carrying a charge from a to b is the negative of the integral of $F \cdot d\mathbf{r}$ along the path taken.

so one take from a to b . Let's start with the easiest possible path to evaluate. We carry our test charge first from the left, then up a circle, then down, as shown in part (a) of Fig. 4-3. Since on the return, the path it is difficult to find the work done (otherwise we wouldn't have picked it). First, there is no work done at all on the path from a to b . The field is radial (from Coulomb's law), so it is parallel to the direction of motion. Next, on the path from b to a , the field is in the direction of motion and varies as $1/r^2$. Thus the work done by the test charge in carrying it from a to b would be

$$-\int_a^b \mathbf{F} \cdot d\mathbf{r} = -\frac{q}{4\pi\epsilon_0} \int_{r_0}^R \frac{dr}{r^2} = -\frac{q}{4\pi\epsilon_0} \left(\frac{1}{r_0} - \frac{1}{R} \right). \quad (4.20)$$

Now let's take another easy path. For instance, the one shown in part (b) of Fig. 4-3. It goes for awhile along surface of a circle, then radially outwards, then radially inwards. Every time we go along the circular parts, we do no work. Every time we go along the radial parts, we must just integrate $1/r^2$. Along the first radial stretch, we integrate from r_0 to r_1 , then along the next radial stretch from r_1 to r_2 , and so on. The sum of all these integrals is the same as a single integral directly from r_0 to R . We get the same answer for the path that we did for the first path, as listed. It is clear that we could get the same answer for any path which is made up of an arbitrary number of the same kinds of pieces.

What about smooth paths? What we get the same answer? We discussed this point previously in Chapter 13 of Vol. I. Applying the same arguments used there, we can conclude that work done in carrying a test charge from a to b is independent of the path.

$$\left[\Phi(\text{final}) - \Phi(\text{initial}) \right]_{a \rightarrow b} = - \int_a^b \mathbf{F} \cdot d\mathbf{r}.$$

Since the work done depends only on the endpoints, it can be represented as the difference between two numbers. We can see this in the following way. Let's choose a reference point P_0 and agree to evaluate our integral by using a path that always passes near enough to P_0 . Let $\phi(\mathbf{r})$ stand for the work done against the field by going from P_0 to point a , and let $\phi(\mathbf{r})$ be the work done in going from P_0 to point b (Fig. 4-3). The work in going to a from P_0 (or the way to b) is the negative of $\phi(a)$, so we have that

$$-\int_a^b \mathbf{F} \cdot d\mathbf{r} = \phi(b) - \phi(a). \quad (4.21)$$

Since only the difference in the function ϕ at our points is ever involved, we do not really have to specify the location of P_0 . Once we have chosen some reference point, however, a number ϕ is determined for any point in space; ϕ is then a scalar field. It is a function of x, y, z . We call this scalar function the *electrostatic potential* at any point.

Electrostatic potential:

$$\phi(\mathbf{r}) = - \int_{P_0}^{\mathbf{r}} \mathbf{E} \cdot d\mathbf{r}. \quad (4.22)$$

For convenience, we will often take the reference point at infinity. Then, for a single charge at the origin, the potential ϕ is given for any point (x, y, z) using Eq. (4.20):

$$\phi(x, y, z) = \frac{q}{4\pi\epsilon_0} \frac{1}{r}. \quad (4.23)$$

The electric field from several charges can be written as the sum of the electric field from the first, from the second, from the third, etc. When we integrate the sum to find the potential we get a sum of integrals. Each of the integrals is the

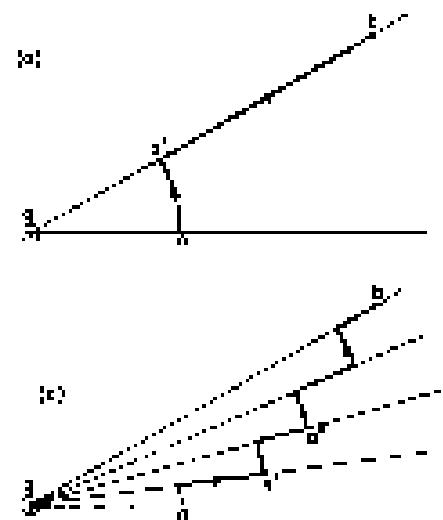

Fig. 4-3. In carrying a test charge from a to b the same work is done along either path.

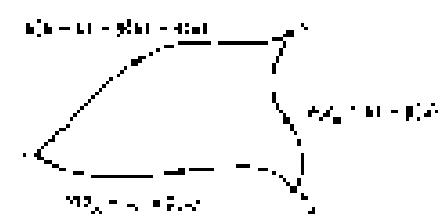

Fig. 4-4. The work done in going along any path from a to b is the negative of the work from some point P_0 to a plus the work from P_0 to b .

potential from one of the charges. We conclude that the potential ϕ from a lot of charges is the sum of the potentials from all the individual charges. There is a superposition principle also for potentials. Using the same kind of arguments by which we found the electric field from a group of charges, and for a distribution of charge, we can get the complete formulas for the potential ϕ at a point we call (1):

$$\phi(1) = \sum_j \frac{1}{4\pi\epsilon_0} \frac{q_j}{r_{1j}}, \quad (4.24)$$

$$\phi(1) = \frac{1}{4\pi\epsilon_0} \int_{V_{ext}}^1 \rho(2) dV_2. \quad (4.25)$$

Remember that the potential ϕ has a physical significance: it is the potential energy which a unit charge would have if brought to the specified place in space from some reference point.

4.4 $E = -\nabla\phi$

We discussed above ϕ ? Forces on charges are given by E , the electric field. The point is that E can be obtained easily from ϕ —it is so easy, in fact, as taking a derivative. Consider two points, one at x and one at $(x + dx)$, but both at the same y and z , and ask how much work is done in carrying a test charge from one point to the other. The path is along the horizontal line from x to $x + dx$. The work done is the difference in the potential at the two points:

$$\Delta W = \phi(x + dx, y, z) - \phi(x, y, z) = \frac{\partial \phi}{\partial x} dx.$$

But the work done against the field for the same path is

$$\Delta W' = -\int E \cdot dx = -E_x dx.$$

We see that

$$E_x = -\frac{\partial \phi}{\partial x}. \quad (4.26)$$

Similarly, $E_y = -\partial \phi / \partial y$, $E_z = -\partial \phi / \partial z$, or, summarizing with the notation of vector analysis,

$$\mathbf{E} = -\nabla\phi. \quad (4.27)$$

This equation is the differential form of Eq. (4.22). Any problem with spherical charges can be solved by computing the potential from (4.24) or (4.25) and using (4.27) to get the field. Equation (4.27) also agrees with what we found from vector calculus that for any scalar field ϕ

$$\int_{\gamma}^{\gamma'} \nabla\phi \cdot d\mathbf{l} = \phi(\gamma') - \phi(\gamma). \quad (4.28)$$

According to Eq. (4.27) the scalar potential ϕ is given by a three-dimensional integral similar to the one we had for E . Is there any advantage to computing ϕ rather than E ? Yes. There is only one integral for ϕ , while there are three integrals for E —because E is a vector. Furthermore, ϕ is usually a little easier to integrate than E_x/E^2 . It turns out in many practical cases that it is easier to calculate ϕ and then take the gradient to find the electric field, than it is to evaluate the three integrals for E . It is merely a potential answer.

There is also a deeper physical significance to the potential ϕ . We have shown that E in Coulomb's law is obtained from $E = -\nabla\phi$ if ϕ is given by (4.24). If ϕ is equal to the gradient of a scalar field, then we know from the vector calculus that the curl of E must vanish:

$$\nabla \times \mathbf{E} = 0. \quad (4.29)$$

But that is just our second fundamental equation of electrostatics, Eq. (4.6). We have shown that Coulomb's law gives an E field that satisfies that condition. So far, our finding is all right.

We had really generalized $\nabla \times E$ was zero before we defined the potential. We had shown that the work done around a closed path is zero. That is, that

$$\oint \mathbf{E} \cdot d\mathbf{s} = 0$$

for any path. We saw in Chapter 3 that for any such field $\nabla \times E$ must be zero everywhere. The electric field in electrostatics is an example of a curl-free field.

You can practice your vector calculus by proving that $\nabla \times E$ is zero in a different way—by computing the components of $\nabla \times E$ at the field at a point shown as given by Eq. (3.11). If you get zero, the superposition principle says you would get zero for the field of any charge distribution.

We should point out an important fact. For any field since the work done is independent of the path and from which a potential. If you think about it, the entire argument we made above to show that the work integral was independent of the path depended only on the fact that the field from a single charge was radial and spherically symmetric. If the non-dependence of the field on the distance was not $1/r^2$ —there could still be a dependence. The existence of a potential, and the fact that the curl of E is zero, comes really only from the symmetry and direction of the electrostatic forces. Because of this, Eq. (4.28)—or (4.29)—can contain only part of the laws of electricity.

4-6 The flux of E

We will now derive a field equation that depends specifically and exactly on the fact that the force law is inverse square. That the field varies inversely as the square of the distance seems, for some people, to be "fairly natural," because "that's the way things spread out." Take a light source with light spreading out, the amount of light that passes through a surface cut out by a cone with its apex at the center of the source—what happens the surface is placed? I must know if there is to be conservation of light energy. The density of light per unit area—the intensity—is proportional to the area cut by the cone, i.e., inversely as the square of the distance from the source. Comparing the electric field should vary inversely as the source of the distance for the same reason. But there is no such thing as the "source power" here. Nothing can say that the electric field measures the flow of something like light which must be conserved. (If we had a "model" of the electric field in which the electric field vector represented the direction and speed, say, the current, of some kind of little "bullets" which were flying out, and if our model required that these bullets were however that they could ever disappear once it was shot out of a source, then we might say that we can "see" that the inverse square law is necessary. On the other hand, there would necessarily be some mathematical way to express this "bullet" idea. If the electric field were like conserved bullets going out, then it would vary inversely as the source of the distance and we would be able to describe that behavior by an equation—which is purely mathematical. Now this is not true in this simple way, so long as we do not say that the electric field is made out of bullets, but rather that we are using a model to help us find the right mathematics.)

Suppose, instead, that we imagine for a moment, that the electric field did represent the flow of something that was conserved—everywhere, that is, except at charges. (It has to start somewhere!) We imagine that whenever it is flows out of a charge into the space around. If E were the vector of such a flow (as \mathbf{J} is for heat flow), it would have a $1/r^2$ dependence near a point charge. Now we wish to use this model to find out how to state the inverse square law in a deeper or more subtle way, rather than simply saying "inversely proportional." You may wonder why we should want to avoid the simple statement of such a simple law, and want instead to imply the same thing subtlety in a different way. Because it will turn out to be useful.

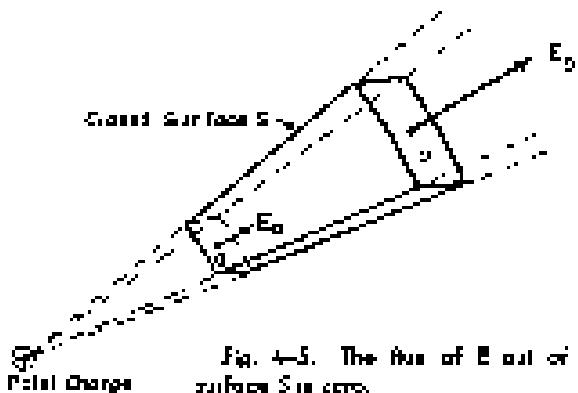

Fig. 4-5. The flux of E out of the surface S is zero.

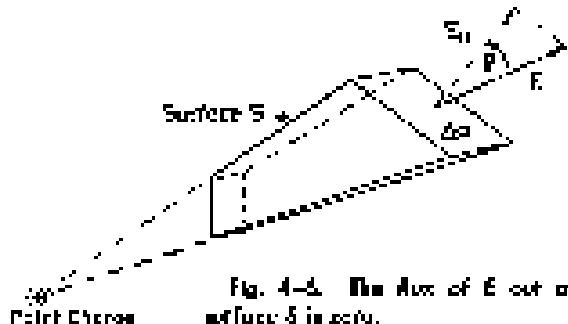

Fig. 4-6. The flux of E out of the surface S is zero.

We ask, "What is the "flux" of E out of an arbitrary closed surface in the neighborhood of a point charge?" First let's take an easy surface—the one shown in Fig. 4-5. If the E field is like it is now, the net flow out of this box should be zero. That is what we get; if by the "flux" from this surface we mean the surface integral of the normal component of E —that is, the flux of E on the radial faces, the normal component is zero. On the spherical faces, the normal component E_n is just the magnitude of E times the sine of the smaller face solid angle for the larger side. The magnitude of E increases as $1/r^2$, but the surface area is proportional to r^2 , so the product is independent of r . The flux of E into face a is just canceled by the flux out of face b . The total flux out of S is zero, which is to say that for this surface:

$$\int_S E_n d\sigma = 0. \quad (4-3)$$

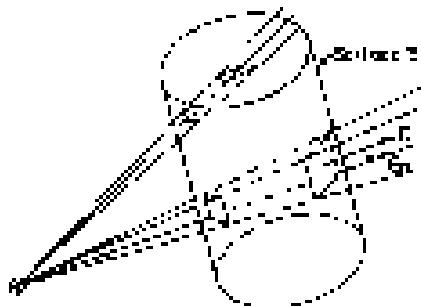

Fig. 4-7. Any volume can be thought of as completely made up of infinitesimal truncated cones. The flux of E from one end of each truncated segment is equal and opposite to the flux from the other end. The total flux over the surface S is therefore zero.

Next we note that the two end surfaces may be closed with respect to the radial line without changing the integral (4-3). Although it is true in general, for our purposes it is only necessary to show that this is true when the end surfaces are small, so that they subtend a small angle from the source—in fact, no retinocular angle. In Fig. 4-6 we show a surface S whose "ends" are tilted, but whose "ends" are tilted. The end surfaces represent small in the figure, but you are to imagine the situation for very small end surfaces. Since the field E will be sufficiently uniform over the surface that we can use just its value at the center, when we tilt the surface by an angle θ , the area is increased by the factor $1/\cos \theta$. But E_n , the component of E normal to the surface, is decreased by the factor $\cos \theta$. The product $E_n d\sigma$ is unchanged. The flux out of the whole surface S is still zero.

Now it is easy to see how the flux out of a volume enclosed by a surface S must be zero. Any volume can be thought of as made up of pieces, like that in Fig. 4-6. The surface will be subdivided completely into pairs of end surfaces, and opposite fluxes in and out of these end surfaces cancel by pairs. The total flux out of the surface will be zero. This idea is illustrated in Fig. 4-7. We have the completely general result that the total flux of E out of any surface S at the field of a point charge is zero.

Our proof works only if the surface S does not surround the charge. What would happen if the point charge were inside the surface? We could still divide our surface into pairs of ones that are matched by radial lines through the charge, as shown in Fig. 4-8. The fluxes through the two surfaces are still equal—by the same argument as before—but they have the same sign. The flux out of a surface that contains a charge is not zero. Then what is it? We can find out by a little trick. Suppose we "remove" the charge from the "inside" by surrounding the charge by a little surface S' totally inside the original surface S , as shown in Fig. 4-9. Now the volume enclosed between the two surfaces S and S' has no charge in it. The total flux out of this volume (including that through S') is zero, by the arguments we have given above. The arguments tell us, in fact, that the flux into the volume through S' is the same as the flux outward through S .

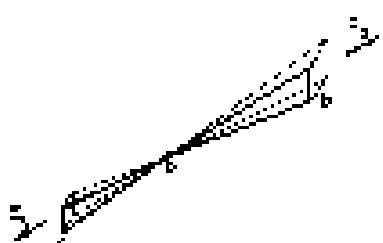

Fig. 4-8. If a charge is inside a surface, the flux out is not zero.

We can choose any surface we want for S' , so let's make it a sphere centered on the charge, as in Fig. 4-10. Then we can easily calculate the flux through it. If the radius of the little sphere is r , the value of E everywhere on its surface is

$$\frac{q}{4\pi r^2 \epsilon_0},$$

and is directed always normal to the surface. We find the total flux through S' if we multiply this normal component of E by the surface area:

$$\text{Flux through the surface } S' = \left(\frac{1}{4\pi \epsilon_0 r^2} q \right) (4\pi r^2) = \frac{q}{\epsilon_0}. \quad (4.31)$$

A number independent of the radius of the sphere! We know then that the flux outward through S is also q/ϵ_0 , or value independent of the shape of S as long as the charge q is inside.

We can state our conclusion as follows:

$$\int_{\text{surfaces } S} E_n dA = \sum_{\text{inside } S} q \quad (4.32)$$

Let's return to our "bullet" analogy and see if it makes sense. Our theorem says that the net flow of bullets through a surface is zero if the surface does not enclose the gun that shoots the bullets. If the gun is located in a surface, inside or outside and charges it is, the number of bullets passing through is the same as is given by the rate at which bullets are generated at the gun. It all seems quite reasonable for current bullets. But then the number will be anything more than we get simply by writing Eq. (4.32)! We can't be surprised in making that "bullet" do anything else can produce this new law. Also, that they start shooting bullets. That is why we prefer to represent the electrostatic field purely vectorially.

4-6 Gauss' law; the divergence of E

The last result, Eq. (4.32), was proved for a single point charge. Now suppose there are two charges, a charge q_1 at one point and a charge q_2 at another. The problem looks more difficult. The electric field whose normal component we integrate for the flux is the sum due to both charges. That is, if E_1 represents the electric field that would have been produced by q_1 alone, and E_2 represents the electric field generated by q_2 alone, the total electric field is $E = E_1 + E_2$. The flux through any closed surface S is

$$\int_S (E_{1n} + E_{2n}) dA = \int_S E_{1n} dA + \int_S E_{2n} dA. \quad (4.33)$$

The flux with both charges present is the flux due to a single charge plus the flux due to the other charge. If both charges are outside S , the flux through S is zero. If you integrate E and q_2 is suddenly there, the first integral goes to zero and the second integral gives q_2/ϵ_0 . If the surface encloses both charges, each will generate contribution and we have that the flux is $q_1 + q_2/\epsilon_0$. The general rule is clearly then the total flux out of a closed surface is equal to the total charge inside, divided by ϵ_0 .

Our result is an important general law of the electrostatic field, called Gauss' law.

$$\text{Gauss' law: } \int_{\text{closed surface } S} E_n dA = \frac{\text{sum of charges inside}}{\epsilon_0}. \quad (4.34)$$

$$\text{or} \quad \int_{\text{closed surface } S} E_n dA = \frac{Q_{\text{in}}}{\epsilon_0}, \quad (4.35)$$

$$\text{where:} \quad Q_{\text{in}} = \sum_{\text{inside } S} q_i. \quad (4.36)$$

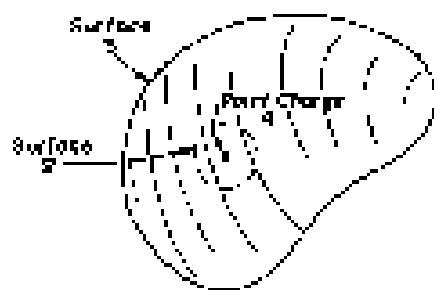

Fig. 4-9. The flux through S is the same as the flux through S' .

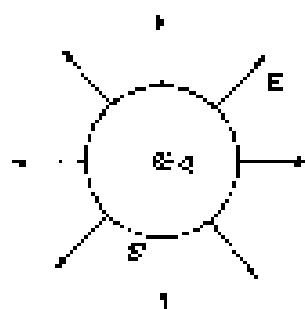

Fig. 4-10. The flux through a spherical surface enclosing a point charge q is q/ϵ_0 .

If we describe the location of charges in terms of a charge density ρ , we can consider that each infinitesimal volume dV contains a "point" charge ρdV . The sum over all charges is then the integral

$$Q_{\text{tot}} = \int_{\text{Volume}} \rho dV. \quad (4.37)$$

From our derivation you see that Gauss' law follows from the fact that the exponent in Coulomb's law is exactly two. A $1/r^2$ field, or any $1/r^n$ field with $n \neq 2$, would not give Gauss' law. So Gauss' law is just an expression in a different form of the Coulomb law of forces between two charges. In fact, working back from Gauss' law, you can derive Coulomb's law. The two are equivalent so long as we keep in mind the rule that the force between charges is radial.

We would now like to write Gauss' law in terms of derivatives. To do this, we apply Gauss' law to an infinitesimal cubical surface. We saw in Chapter 3 that the flux of E out of such a cube is $\nabla \cdot E$ times the volume dV of the cube. The charge inside of dV , by the definition of ρ , is equal to ρdV . So Gauss' law gives

$$\nabla \cdot E dV = \frac{\rho dV}{\epsilon_0},$$

or

$$\nabla \cdot E = \frac{\rho}{\epsilon_0}. \quad (4.38)$$

The differential form of Gauss' law is the first of the fundamental field equations of electrodynamics (Eq. 4.38). We have now shown that the two equations of electrostatics, Eqs. (4.5) and (4.6), are equivalent to Coulomb's law of force. We will now see the nice example of the use of Gauss' law. (We will soon refer to many more examples.)

4-7 Field of a sphere of charge

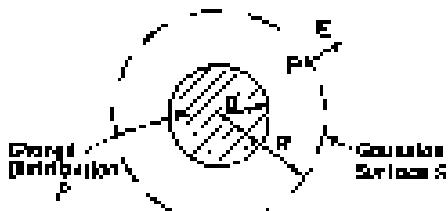

Fig. 4-11. Using Gauss' law to find the field of a uniform sphere of charge.

One of the difficult problems we had when we studied the theory of gravitational attraction was to prove that the force on a shell by a solid sphere of matter was the same as the surface of the sphere as it would be if the matter were concentrated on the surface. For many years Newton didn't make public his theory of gravitation, because he couldn't be sure this theory was true. He proved the theorem in Chapter 13 of Vol. I by doing the integral for the potential and then finding the gravitational force by using the gradient. Now we can prove the theorem in a much simpler fashion. Only this time we will prove the corresponding theorem for a uniform sphere of electrical charge. (Since the laws of electrodynamics are the same as those of gravitation, the same proof could be done for the gravitational field.)

We ask: What is the electric field E at a point P anywhere outside the surface of a sphere filled with a uniform distribution of charge? Since there is no "spur" direction, we can assume that E is everywhere directed away from the center of the sphere. We consider an imaginary surface that is spherical and concentric with the sphere of charge, and that passes through the point P (Fig. 4-11). For this surface, the flux outward is

$$\oint E_i dA = E \cdot 4\pi R^2.$$

Gauss' law tells us that this flux is equal to the total charge Q of the sphere (over ϵ_0):

$$E \cdot 4\pi R^2 = \frac{Q}{\epsilon_0},$$

or

$$E = \frac{1}{4\pi\epsilon_0} \frac{Q}{r^2}. \quad (4.39)$$

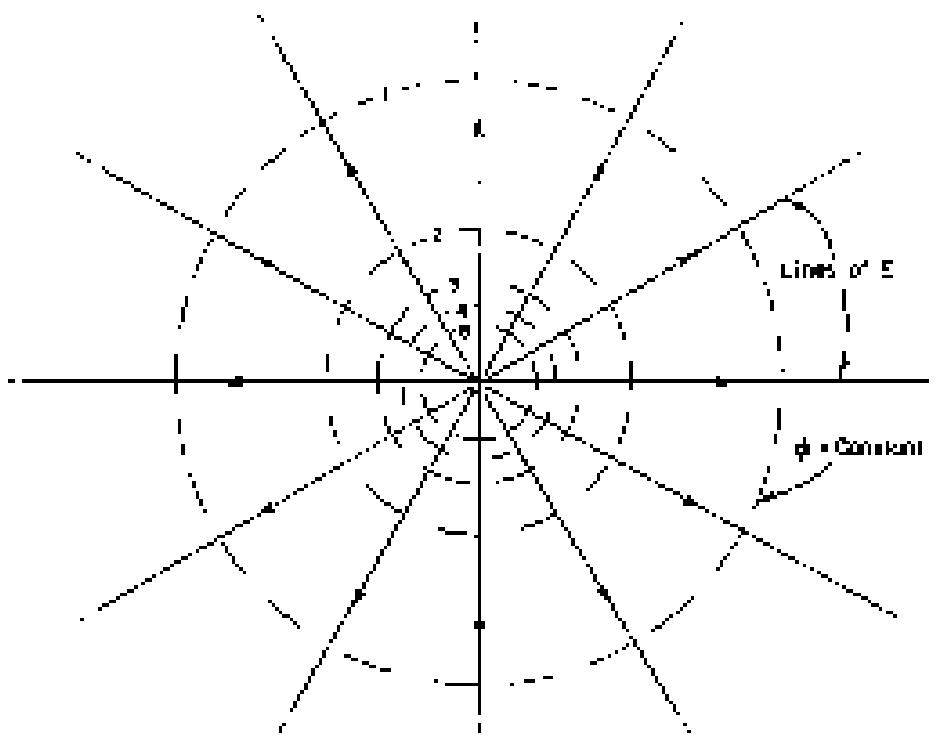

Fig. 4-12. Field lines and equipotential surfaces for a positive point charge.

which is the same formula we would have had a point charge q . We have proved Newton's problem more easily than by going the trigonal. This, of course, is false kind of reasoning—it has taken you some time to be able to understand Gauss' law, so you may think the new method has really been saved. But let you have used the theorem more and more, it begins to pay. It is a question of efficiency.

4-8 FIELD LINES; EQUIPOTENTIAL SURFACES

We would like now to give a geometrical description of the electric field. The two laws of electrostatics, one that the field is proportional to the charge inside and the other that the electric field is the gradient of a potential, can also be represented geometrically. We illustrate this with two examples.

First, we take the field of a point charge. We draw lines in the direction of the field—lines which are always tangent to the field, as in Fig. 4-12. These are called field lines. The lines show everywhere the orientation of the electric vector. But we also wish to represent the magnitude of the vector. We can do this now, for the strength of the electric field will be represented by the "density" of the lines. By this density we mean the number of lines per unit area through a surface perpendicular to the lines. With these two rules we can draw a picture of the electric field. For a point charge, the density of the lines must decrease as $1/r^2$. But the area of a spherical surface is proportional to the lines, so if radius increases as r^2 , so if we always keep the same number of lines for all distances from the charge, the density will remain proportional to the magnitude of the field. We can guarantee that there are the same number of lines at every distance if we make the lines be continuous. Since once a line is emitted from the charge, it never stops. In terms of the field lines, Gauss' law says that lines should start only at plus charges and stop at minus charges. The number where there is a charge q will be equal to q/e_0 .

Now, we can find a similar geometrical picture for the potential ϕ . The easiest way to represent the potential is to draw surfaces on which ϕ is a constant. We call them *equipotential surfaces*—surfaces of equal potential. Now, repeat the geometrical

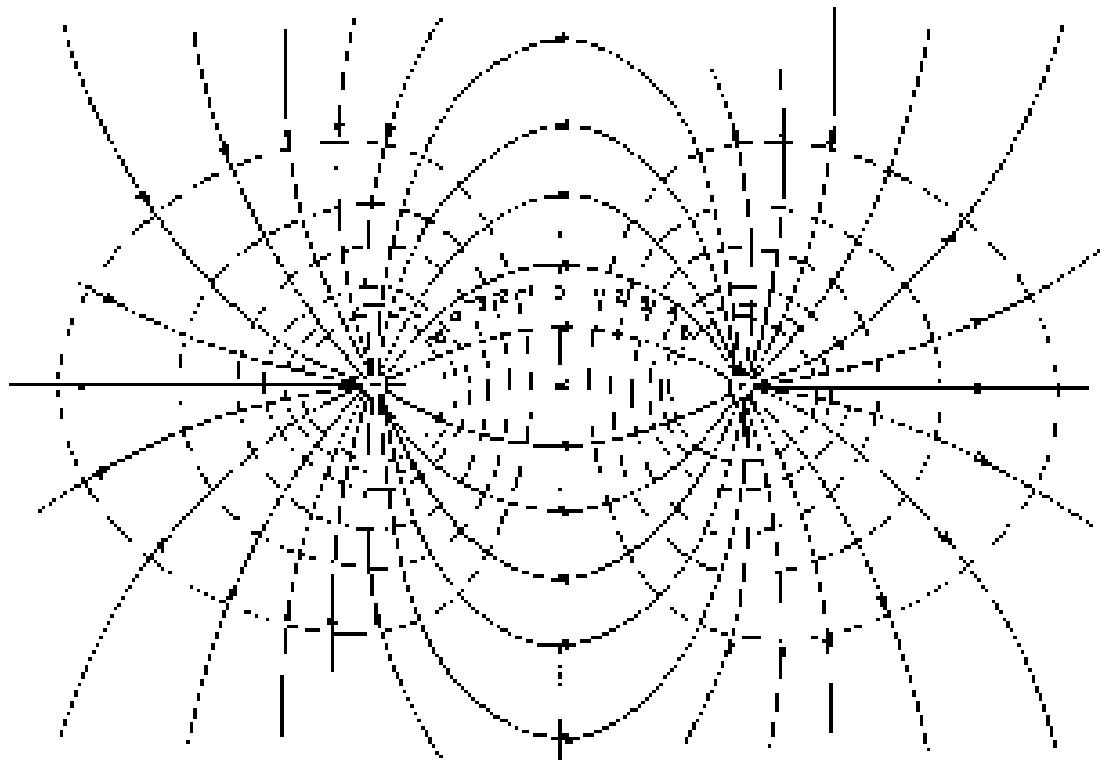

Fig. 4-12. Field lines and equipotential's for two equal and opposite point charges.

cal relationship of the equipotential surfaces to the field lines? The electric field is the gradient of the potential. The gradient is in the direction of the most rapid change of the potential, and is therefore perpendicular to an equipotential surface. If \mathbf{E} were not perpendicular to the surface, it would have a component to the surface. The potential would be changing in the surface, but then it wouldn't be an equipotential! The equipotential surfaces make them be everywhere at right angles to the electric field lines.

For a point charge q by itself, the equipotential surfaces are spheres centered on the charge. We have shown in Fig. 4-12 the interaction of these spheres with a plane through the charge.

As a second example, we consider the field near two equal charges, a positive one and a negative one. To get the field is easy. The field is the superposition of the fields from each of the two charges. So, we can take two point charges (Fig. 4-12) and superimpose them. It's possible! But we would have field lines meeting each other, and this is not possible, because \mathbf{E} can't have two directions at the same point. The disadvantage of the head-on picture is now obvious. By geometrical arguments it is impossible to analyze it a very simple way where the field lines go. From the two independent pictures, we can't get the combined picture. The principle of superposition, a simple and deep principle about electric fields, does not have, at the field-line picture, an easy representation.

The field-line picture has its uses, however, so we might still like to draw the picture for a pair of equal (but opposite) charges. If we calculate the field from Eq. (4.15) and the potentials from (4.23), we can draw the field lines and equipotential's. Figure 4-13 shows the result. But we first had to solve the problem *mathematically*!

Application of Gauss' Law

5-1 Electrostatics in Gauss' law plus...

There are two laws of electrostatics: that the flux of the electric field from a volume is proportional to the charge inside—Gauss' law, and that the circulation of the electric field is zero. \mathbf{E} is a gradient. From these two laws, all the predictions of electrostatics follow. But, in my view, this is unattractive in one sense, because there is only one with a certain amount of ingenuity, is another. In this chapter we will work through a number of calculations which can be made with Gauss' law alone. We will prove theorems and describe some effects, particularly in conductors, that can be understood very easily from Gauss' law. Gauss' law by itself cannot give the solution of any problem because the other law must be obeyed also. So when we use Gauss' law for the solution of particular problems, we will tend to add something to it. We will have to incorporate, for instance, some idea of how the field looks—based, for example, on arguments of symmetry. Or we may have to introduce specifically the idea that the field is the gradient of a potential.

5-2 Equilibrium in an electrostatic field

Consider first the following question: When can a point charge be in stable mechanical equilibrium in the electric field of a bar charge? As an example, imagine three negative charges at the corners of an equilateral triangle in a horizontal plane. Would a positive charge placed at the center of the triangle remain there? It will be simpler if we ignore gravity for the moment, although including it would not change the results. The force on the positive charge is zero, but is the equilibrium stable? Would the charge return to the equilibrium position if displaced slightly? The answer is no.

There are no points of stable equilibrium in any electrostatic field—except right on top of another charge. Using Gauss' law, it is easy to see why. First, since charges can be in equilibrium at any particular point P_1 , the field must be zero. Second, if the equilibrium is to be a stable one, we require that if we move the charge away from P_1 in any direction, there should be a restoring force directed opposite to the displacement. The electric field at all nearby points must be pointing inward—toward the point P_1 . But that is in violation of Gauss' law, if there is no charge at P_1 , as we can easily see.

Consider a tiny imaginary surface that encloses P_1 , as in Fig. 5-1. If the electric field everywhere in the vicinity is pointed toward P_1 , the surface integral of the normal component is certainly not zero. For the case shown in the figure, the flux through the surface must be a negative number. By Gauss' law, this the flux of electric field through any surface is proportional to the total charge inside. If there is no charge at P_1 , the field will have violated previous Gauss' law. It is impossible to balance a positive charge in empty space—at a point where there is no some negative charge. A positive charge can be in equilibrium if it is in the middle of a distributed negative charge. Of course, the negative charge distribution would have to be held in place by other non-electrical forces!

Our result has been negative for a point charge. Does this mean that, for a complicated arrangement of excesses held together in fixed relative positions—with rods, for example? We consider the question for two equal charges fixed on a rod. Is it possible that this combination can be in equilibrium in some electrostatic field? The answer is again no. The total force on the rod cannot be balancing for displacements in every direction.

Fig. 5-1. If P_1 were in position of stable equilibrium for a positive charge, the electric field everywhere in the neighborhood would point toward P_1 .

Call E the total force on the rod in its position. E is then a vector field. Following the argument just above, we conclude that at a position of static equilibrium, the divergence of E must be a negative number. But the total force on the rod is the first charge times the field at its position, plus the second charge times the field at its position:

$$E = q_1 E_x + q_2 E_y. \quad (3.1)$$

The divergence of E is given by

$$\nabla \cdot E = q_1 (\nabla \cdot E_x) + q_2 (\nabla \cdot E_y).$$

If each of the two charges q_1 and q_2 is in free space, both $\nabla \cdot E_x$ and $\nabla \cdot E_y$ are zero, and $\nabla \cdot E$ is zero—not negative, as would be required for equilibrium. You can see that an extension of the argument shows that no finite combination of any number of charges can have a position of static equilibrium in an electrostatic field in free space.

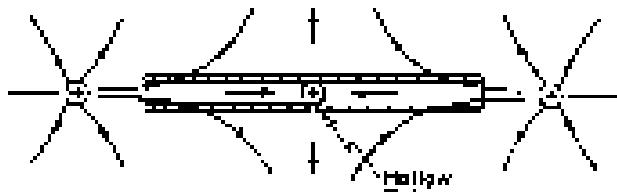

Fig. 3-2 A charge can be in equilibrium if there are mechanical constraints

Now we have not shown that equilibrium is forbidden if there are forces or other mechanical constraints. An example exists: a hollow tube in which a charge can move back and forth freely, but not sideways. It's very easy to derive an electric field that points toward both ends of the tube if it is allowed that the field has point intensity $q_1/q\pi r^2$ near the center of the tube. We simply place positive charges q at each end of the tube, as in Fig. 3-2. There remains now a equilibrium point even though the divergence of E is zero. The charge, of course, would not be in static equilibrium for sideways motion were it not for "non-electrical" forces from the tube walls.

3-3 Equilibrium with conduction

There is no simple spot in the field of a system of fixed charges. What about a system of charged conductors? Can a system of charged conductors produce a field that will have a static equilibrium point for a point charge? (We mean at a point other than on a conductor, of course.) You know that conductors have the property that charges do not freely travel in them. Perhaps when the point charge is displaced slightly, the other charges on the conductor will move in a way that will give a retarding force to the point charge. This answer is still doubtful; we have just given doesn't prove it. The proof for this case is more difficult, and we will only indicate how it goes.

First, we note that when charges redistribute themselves on the conductors, they can only do so if their motion decreases their total potential energy. (Some energy is lost, in fact, as they move in the conductor.) Now we have already shown that if the charges producing a field are stationary, there is, near any zero point P_0 in the field, some direction for which moving a point charge away from P_0 will decrease the energy of the system (since the forces are zero from P_0). Any redistribution of the charges on the conductors can only lower the potential energy until zero, so by the principle of virtual work, their motion will only increase the force in that particular direction away from P_0 , and not toward it.

Our conclusions do not mean that it is not possible to balance a charge by electrical forces. It is possible if one is willing to control the location or the sizes of the supporting charges with sufficient care. You know that a point charge on a point in a gravitational field is unstable, but this does not prove that it cannot be balanced on the end of a string. Similarly, a charge can be held in one spot by electric fields if they are suitable. But not with a *point*—that is, a static—system.

5-4 Stability of atoms

If charges could be held steady at position, it is surely not possible to keep the nuclei from being torn up of the negative charges (electrons) and pulled apart entirely by the law of electrostatics. Such a stable configuration is impossible; it would collapse!

It was suggested that the positive charge of an atom must be distributed uniformly in a sphere, and the negative charges, the electrons, could be at rest outside the positive charge, as shown in Fig. 5-3. This was the first atomic model, proposed by Thomson. But Rutherford concluded from the experiment of Geiger and Marsden that the positive charges were very much concentrated, in what he called the nucleus. Thus Thomson's static model had to be abandoned. Rutherford and Bohr then suggested that the equilibrium might be dynamic, with the electrons revolving in orbits, as shown in Fig. 5-4. The electrons would be kept from falling toward the nucleus by their orbital motion. We already know at least one difficulty with this picture. With such motion, the electrons would be accelerating (because of the circular motion) and would therefore be radiating energy. They would lose kinetic energy required to stay in orbit, and would spiral toward the nucleus. Again unstable!

The stability of the system is now explained in terms of quantum mechanics. The electrostatic forces pull the electron as close to the nucleus as possible, but the electron is compelled to stay several times over a distance given by the uncertainty principle. It is more confined in how small a space, so it would have a great uncertainty in momentum. Our rule assures that it would have a high expected energy, which it would get in excess from the Coulomb attraction. The net result is an electrical repulsion which differs from the model of Thompson — only it is not negative charge that is spread out (because the mass of the electron is so much smaller than the mass of the proton).

5-5 The field of a line charge

Gauss' law can be used to solve a number of electrostatic field problems involving a special symmetry—usually spherical, cylindrical, or plane symmetry. In the remainder of this chapter we will apply Gauss' law to a few such problems. The ease with which these problems can be solved may give the misleading impression that the method is very powerful, and that one should be able to go on to many other problems. It is unfortunately not so. One soon exhausts the list of problems that can be solved easily with Gauss' law. In later chapters we will develop more powerful methods for investigating electrostatic fields.

As our first example, we consider a system with cylindrical symmetry. Suppose that we have a very long, uniformly charged wire. By this we mean that electric charge is distributed uniformly along a indefinitely long straight line, with the charge λ per unit length. We wish to know the electric field. The problem can, of course, be solved by integrating the contribution to the field from every part of the line. We are going to do it using the gauging, by using Gauss' law and some guesswork. First, we assume that the electric field will be directed radially outward from the line. Any axial component from charges on one side would be accompanied by an equal and opposite force from charges on the other side. The result would only be a radial field. It also seems reasonable that the field should have the same magnitude at all points equidistant from the line. This is, however, (it is not necessary to prove, but it is true if space is symmetric)—as we believe it is.

We can use Gauss' law to see thisalog way. We consider an hemispherical surface in the shape of a cylinder intersecting with the line, as shown in Fig. 5-5. Around up a Gauss' law, the total flux of E from this surface is equal to the charge inside divided by ϵ_0 . Since the field is assumed to be zero outside the surface, the inward current density is the magnitude of the field. Let's call it E . Also let the radius of the cylinder be a , and its length be b (in your unit for convenience). The flux through the cylindrical surface is equal to E times the area of the surface, which is $2\pi r^2$. The flux through the two end faces is zero because the electric field is tan-

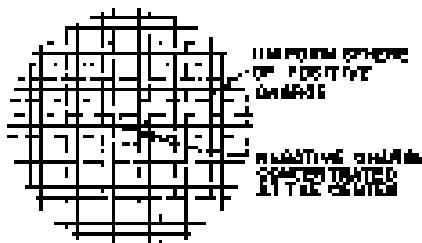

Fig. 5-3. The Thomson model of an atom.

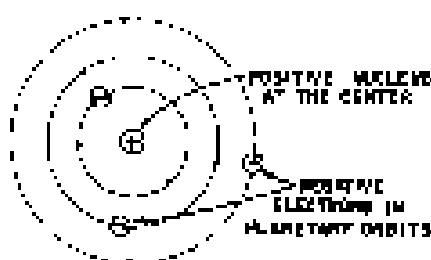

Fig. 5-4. The Rutherford-Bohr model of an atom.

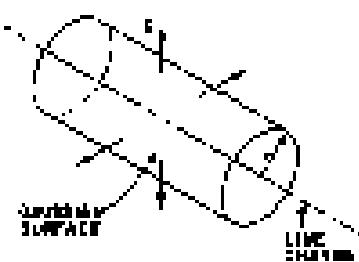

Fig. 5-5. A cylindrical Gaussian surface intersected with a line charge.

parallel to them. The total charge inside our surface is just λ , having the length of the surface as one axis. Gauss' law then gives

$$\begin{aligned} 1. \quad 2\pi r &= \lambda/4\epsilon_0, \\ 2. \quad E &= \frac{\lambda}{2\pi r \epsilon_0}. \end{aligned} \quad (5.2)$$

The electric field of a line charge depends inversely on the first power of the distance from the line.

5-6 A sheet of charges: two sheets

As another example, we can calculate the field from a uniform plane sheet of charge. Suppose that the sheet is infinite in extent and that the charge per unit area is σ . We are going to take another guess. Considerations of symmetry lead us to believe that the field direction is everywhere normal to the plane, and if no other fields from any other charges in the system, the field's magnitude must be the same (in magnitude) on each side. This time we choose for our Gaussian surface a rectangular box that cuts through the sheet, as shown in Fig. 5-6. The two faces parallel to the sheet will have equal areas, say A . The field is normal to these two faces, and parallel to the other four. The total flux is E times the area of the top face, plus E times the area of the opposite face—with no contribution from the other four faces. The total charge enclosed in the box is σA . Equating the sum to the charge outside, we have

$$EA - EA = \sigma A \frac{\epsilon_0}{\epsilon_0},$$

from which

$$E = \frac{\sigma}{2\epsilon_0}. \quad (5.3)$$

A simple but important result.

You may remember that the same result was obtained by an earlier chapter by an integration over the entire surface. Gauss' law gives, in this manner, much more quickly (although it is not as generally applicable as the earlier method).

We emphasize that this result applies only to the field due to the charges on the sheet. If there are other charges in the neighborhood, the total field near the sheet would be the sum of (5.3) and the field of the other charges. Gauss' law would then tell us only this:

$$E + E_s = \frac{\sigma}{\epsilon_0}, \quad (5.4)$$

where E_s and E are the fields directed outward on each side of the sheet.

The problem of two parallel sheets with equal and opposite charge densities, $+\sigma$ and $-\sigma$, is equally simple if we assume again that the distance between them is quite small. Either by superposing two solutions for a single sheet or by constructing a problem like that involving two sheets, it is easily seen that the field is zero outside of the two sheets (Fig. 5-7a). By considering a box that includes only one surface of the sheet, as in (b) or (c) of the figure, it can be seen that the field between the sheets must be twice what it is for a single sheet. The result is

$$E_{\text{between}}(\text{two sheets}) = \sigma/\epsilon_0. \quad (5.5)$$

$$E_{\text{outside}}(\text{two sheets}) = 0. \quad (5.6)$$

5-7 A sphere of charge: a spherical shell

We have already (in Chapter 4) used Gauss' law to find the field outside a uniformly charged spherical region. The same method can also give us the field at points inside the sphere. For example, the computation can be used to obtain a good approximation to the field inside an atomic nucleus. In spite of the fact that the protons in a nucleus repel each other, they are, because of the strong nuclear force, distributed fairly uniformly throughout the body of the nucleus.

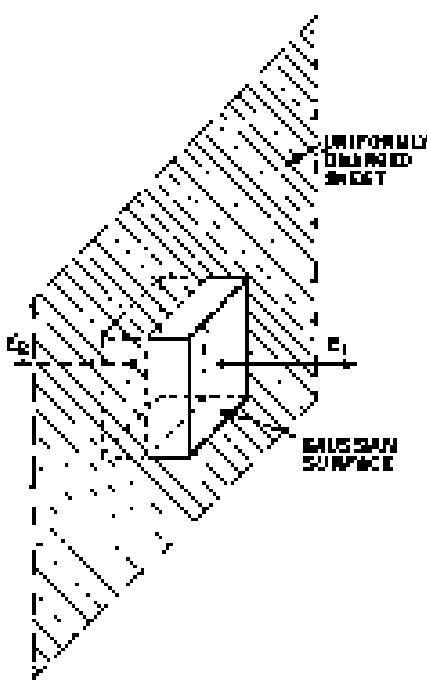

Fig. 5-6 The electric field near a uniformly charged sheet can be found by applying Gauss' law to an imaginary box.

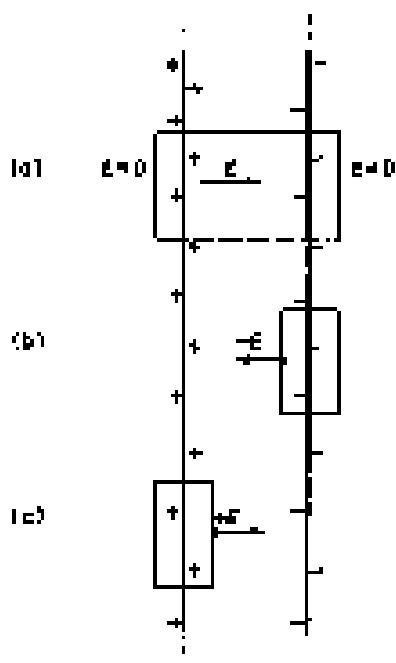

Fig. 5-7 The field between two charged sheets is σ/ϵ_0 .

Suppose that we have a sphere of radius R that uniformly contains charge. Let ρ be the charge per unit volume. Again, using arguments of symmetry, we assume the field to be radial and equal in magnitude at all points at the same distance from the center. To find the field at the distance r from the center, we take a spherical Gaussian surface of radius r ($r < R$), as shown in Fig. 5-8. The flux out of this surface is

$$4\pi r^2 E.$$

The charge inside our Gaussian surface is not volume: it's density ρ , or

$$4\pi r^3 \rho.$$

Using Gauss' law, it follows that the magnitude of the field is given by

$$E = \frac{\rho r}{\epsilon_0} \quad (r < R) \quad (5-7)$$

You can see that the formula gives the proper result for $r = R$. The electric field is proportional to the radius and is directed radially outward.

The arguments we have just given for a uniformly charged sphere can be applied also to a non-spherical shell of charge. Assuming that the shell is everywhere radially symmetric, one goes immediately from Gauss' law that the field outside the shell is zero. (A question is how inside the shell will there be no charge.)

5-8. Is the field of a point charge exactly $1/r^2$?

If we look in a little more detail at how the field inside the shell gets to be zero, we can see more clearly why it is that Gauss' law is true only because the coulomb force depends exactly on the inverse of the distance. Consider any point P inside a uniform spherical shell of charge. Suppose a small rectangular area $d\sigma_1$ and $d\sigma_2$ extends to the surface of the sphere, where it cuts out a small surface area $d\sigma_3$, as in Fig. 5-9. An equally symmetric cone discharging from the opposite side of the shell cuts off the surface area $d\sigma_4$. If the distance from P to each of the areas $d\sigma_1$ is r_1 , and r_2 , the areas are in the ratio

$$\frac{d\sigma_2}{d\sigma_1} = \frac{r_1^2}{r_2^2}.$$

(You can show this by geometry for any point P inside the shell.)

If the surface of the sphere is uniformly charging, the charging on each of the elements of area is proportional to the area, so

$$\frac{d\sigma_4}{d\sigma_1} = \frac{d\sigma_3}{d\sigma_1},$$

Coulomb's law then says that the magnitudes of the fields produced at P by these two surface elements are in the ratio

$$\frac{E_2}{E_1} = \frac{d\sigma_2/d\sigma_1}{r_1^2/r_2^2} = 1.$$

The fields cancel exactly. Since all parts of the surface can be paired off in the same way, the total field at P is zero. But you can see that it would not be so if the exponent of r in Coulomb's law were anything other than 2.

The validity of Gauss' law depends upon the inverse-square law of Coulomb. If the force law were not exactly the inverse square, it would not be true that the field inside a uniformly charged sphere would be zero by zero. For instance, if the force varied more steadily, like, say, the inverse cube of r , the portion of the surface which is nearer to an interior point would produce a field which is larger than that which is further away, resulting in a radial inward field for a positive surface

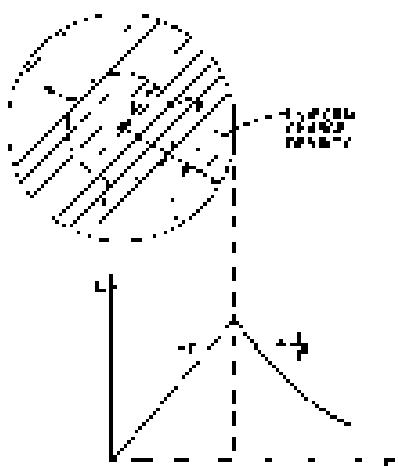

Fig. 5-8. Gauss' law can be used to find the field inside a uniformly charged sphere.

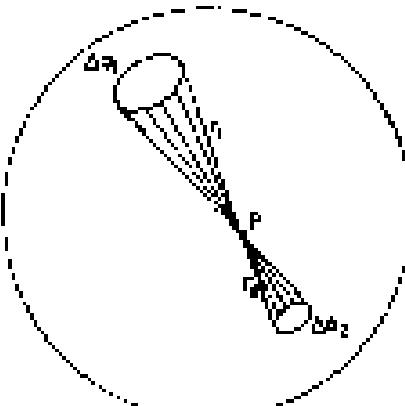

Fig. 5-9. The field is zero at any point P inside a spherical shell of charge.

charge. These conclusions suggest an elegant way of finding out whether the inverse square law is probably correct. We need only determine whether or not the field inside of a uniformly charged spherical shell is practically zero.

It is likely that such a method exists. It is usually difficult to measure a physical quantity to high precision - a one percent result may not be too difficult, but how would one go about measuring say, Coulomb's law to an accuracy of one part in a billion? It is almost certainly not possible with the best available techniques to measure the force between two charged objects with such an accuracy. But by determining only that the electric fields inside a charged sphere are smaller than some value we can make a highly accurate measurement of the correctness of Gauss' law, and hence of the inverse square dependence of Coulomb's law. What one does, in effect, is compare the force law in an ideal inverse-square system. Such comparisons of things that are equal, or nearly so, are usually the basis of the most precise physical measurements.

How shall we measure the field inside a charged sphere? One way is to try to charge an object by touching it to the inside of a spherical conductor. You know that if you touch a small metal ball to a charged object and then touch it to an electron gun the meter will become charged and the pointer will move from zero (Fig. 3-10a). The ball picks up charge because there are electric fields outside the charged sphere that cause charges to accumulate on the little ball. If you do the same experiment by touching the little ball to the inside of the charged sphere, you find that no charge is caused to the electron gun. With such an experiment you can easily show that the field inside is, at most, a few percent of the field outside, and that Gauss' law is at least approximately correct.

It appears that Huguenin's first slip was the due to neglect that the field inside a conducting shell is zero. The result seemed strange to him. When he reported his observation to Priestley, the latter suggested that it might be connected with an inverse square law, since it was known that a spherical shell of matter produced no gravitational field inside. But Coulomb didn't measure the inverse square dependence on it 'till years later, and Gauss' law came even later still.

Gauss' law has been checked carefully by putting an electron gun inside a large sphere and observing whether any deflections occur when the sphere is charged to a high voltage. A null result is always observed. Knowing the accuracy of the experimenter and the sensitivity of the meter, it is possible to compute the smallest field that would be observed. From this number it is possible to place an upper limit on the deviation of the exponent from two. If we write that the electrostatic force depends on $r^{-\alpha}$, we can place an upper bound on α . By this method Maxwell generalized that α was less than 1/10,000. The experiment was repeated and improved upon in 1936 by Plimpton and Laughlin. They found that Coulomb's exponent differs from two by less than one part in a billion.

Now that brings up an interesting question: How accurate do we know this Coulomb's law to be in various circumstances? The experiments we just described measure the dependence of the field on distance for clusters of some tens of millimeters. But what about the distances inside an atom - in the hydrogen atom, for instance, where we believe the electron is attracted to the nucleus by the same inverse square law? It is true that quantum mechanics must be used for the mechanical part of the behavior of the electron, but the force is the usual electrostatic one. In the simplification of the problem, the potential energy of an electron must be known as a function of distance from the nucleus, and Coulomb's law gives a potential whose values decrease with the first power of the distance. How accurately is the exponent known in such small distances? As a result of very careful measurements in 1911 by Faraday and Rutherford on the relative positions of the energy levels of hydrogen, we know that the exponent is correct up to one part in a billion in the atomic scale - that is, at distances of the order of one angstrom (10^{-8} centimeter).

The accuracy of the Rutherford measurements was possible again because of a physical "accident." Two of the states of a hydrogen atom are separated by near-almost identical energies only if the potential varies exactly as $1/r$. A measurement was made of the very slight difference in energies by finding

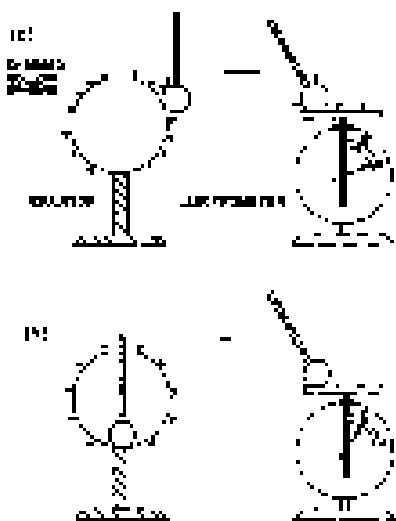

Fig. 3-10. The electric field is zero inside a closed conducting shell.

the frequency ν of the photons that are emitted or absorbed in the transition from one state to the other, using for the energy difference $\Delta E = h\nu$. Compton showed that a 2-wavelength had been impossibly different from what was observed if the exponent in the force law $1/r^2$ differed by as much as one part in a billion.

Is the same exponent correct at still greater distances? From measurements in stellar physics, it is found that there are electrostatic forces in atoms, nuclear distances about 10^{-15} centimeter—and that they fall very approximately as the inverse square. We can look at some of the evidence in a later chapter. Coulomb's law is, we know, still valid at least to some extent, in a range of the order of 10^{-12} centimeter.

How about 10^{-11} centimeters? This question can be investigated by bombarding protons with very energetic electrons and observing how they are scattered. Results indicate again an inverse law for the law of these distances. The electrical force seems to be about 10 times too weak at distances less than 10^{-11} centimeter. Now there are two possible explanations. One is that the Coulomb law does not work at such small distances; the proton is too big, perhaps, two electrons and two protons, and not point charges. Perhaps either the electron or proton, or both, is not a kind of a atom. Most physicists prefer, in fact, that the charge of the proton is smeared. We know that protons interact strongly with mesons. This implies that a proton will, from time to time, exist as a neutron with a π^+ meson around it. Such a configuration would last, on the average, about 10⁻²³ seconds of nuclear charge. We know from reasoning from a sphere of charge that $1/r^2$ all the way into the center. It is quite likely that the proton charge is smeared, but the charge of proton is at 10⁻¹¹ quite incomplete, so it may even be that Coulomb's law fails at very small distances. This question is still open.

One more point: The inverse square law is valid at distances like one meter and also at 10^{-10} m. But is the coefficient 1/4 $\pi\epsilon_0$ the same? The answer is you've had an answer of 1/4 per cent in my book.

We go back now to an important result that we obtained when we spoke of the experimental verification of Gauss' law. You may have wondered how the experiments of Maxwell or of Plimpton and Langford could give such an accuracy unless the spherical conductor they used was a perfect sphere. The accuracy of one part in a billion is really something to believe, and you might well ask what a tiny little tiny sphere, when was not perfect. There are going to be slight irregularities in any real sphere and if there are irregularities, will they not produce field inside? We wish to prove now that it is not necessary to have a perfect sphere. It is possible, in fact, to have then, is no field inside a closed wire coming shell of any shape. In other words, the experiments depended on $1/r^2$, but and nothing to do with the surface being a sphere (unless it is a sphere it is easier to calculate what the fields would be if the earth had been wrong), so we take up the stronger case. To show this, it is necessary to know some of the properties of electrical conductors.

3.9 The fields of a conductor

An electrical conductor is a solid, but containing many "free" electrons. The electrons can move around freely in the metal, but cannot leave the surface. In a metal there are so many free electrons that if any field will set large numbers of them in motion. First, the current of electrons will end up must be constantly set moving by external sources of energy, as the motion of the electrons will cause us they discharge the source producing the initial field. In "electronics" since then, we do not consider any finite amount of current (they will be considered later when we study magnetostatics) as electrons move only until they have arranged themselves to conduct an electric field everywhere inside the metal's body. (This usually happens in a very fraction of a second.) If now were say held left, the field would urge all more electrons to move, the only electric solution is that the field is everywhere zero inside.

Now consider the answer of a charged conducting object. (By "conductor" we mean in the metal itself). Since the metal is a conductor, no electric field can:

between, and on the gradient of the potential ϕ between. That means that E does not vary from point to point. Every conductor is an equipotential surface, and its surface is an equipotential surface. Since it is a conducting material the electric field is everywhere zero, the divergence of E is zero, and by Gauss' law the charge density in the interior of the conductor must be zero.

If there can be no charges in a conductor, how can it ever be charged? What do we mean when we say a conductor is "charged"? Where are the charges? The answer is that they reside on the surface of the conductor, where there are strong forces to keep them from leaving—they are not completely "free." When we study solid-state physics, we shall find that the excess charge of any conductor is on the average within one or two atomic layers of the surface. For our present purposes, it is accurate enough to say that if any charges per unit, or σ , a conductor it all accumulates on the surface, there is no charge in the interior of a conductor.

We note also that the electric field just outside the surface of a conductor must be normal to the surface. There can be no tangential component. If there were a tangential component, the electrons would move along the surface; there is no force perpendicular. Moving in another way, we know that the electric field lines must always go at right angles to an equipotential surface.

We can then, using Gauss' law, relate the field strength just outside a conductor to the density of the charge at the surface. For a Gaussian surface, we take a small cylindrical one half inside and half outside the surface, like the one shown in Fig. 5-11. There is a contribution to the total flux of E only from the side of the box toward the conductor. The field just outside the surface of a conductor is then

Outside a conductor:

$$E = \frac{\sigma}{\epsilon_0}, \quad (5.8)$$

where σ is the local surface charge density.

Why does a sheet of charge on a conductor produce a different field than a sheet of charge? In other words, why is (5.8) twice as large as (5.7)? The reason, of course, is that we have assumed that there are no "other" charges around. There must, in fact, be some to make $E = 0$ in the conductor. The charges in the immediate neighborhood of P will, from the surface in, in fact give a field $E_{ext} = \sigma/\epsilon_0$, and both fields sum outside the surface. But all the rest of the charge on the conductor "cooperates" to produce an additional field at the point P equal in magnitude to E_{ext} . The total field outside goes to zero and the total outside is $2E_{ext} = \sigma/\epsilon_0$.

5-10 The field in a cavity of a conductor

We come now to the problem of the hollow conductor—a conductor with a cavity. There is no field in the cavity, but what about in the cavity? We shall show that if the cavity is empty then there are no fields in it, no matter what the shape of the envelope of the cavity—say for this one in Fig. 5-12. Consider a gaussian surface, like S in Fig. 5-12, that encloses the cavity but stays everywhere in the conducting material. Everywhere on S the field is zero, and there is no flux through S since the total charge inside S is zero. For a spherical shell, one could then argue from symmetry that there could be no charge inside. But, in general, we can only say that there are equal amounts of positive and negative charge on the inner surface of the conductor π . There could be a positive surface charge on one part and a negative one somewhere else, as illustrated in Fig. 5-13. Such a thing cannot be ruled out by Gauss' law.

What really happens, of course, is that any equal and opposite charges on the inner surface would slide around to meet each other, cancelling out completely. We can show that they must cancel completely by using the fact that the circulation of E is always zero (conservation). Suppose there were charges on some parts of the inner surface. We know that there would have to be an equal number of opposite charges somewhere else. Now any line of E would have an end on the

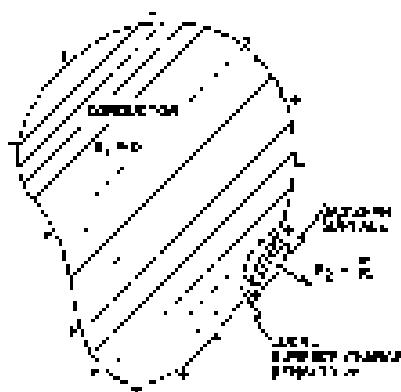

Fig. 5-11. The electric field just outside the surface of a conductor is proportional to the local surface density of charge.

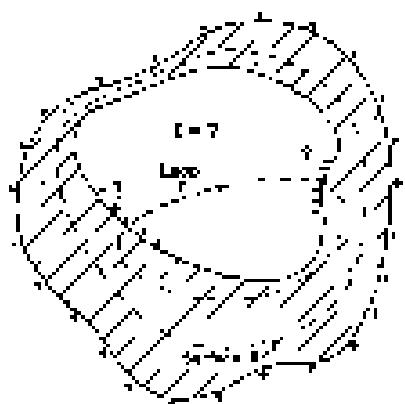

Fig. 5-12. What is the field in an empty cavity of a conductor, for any shape?

positive charge and end on the negative charge (since we are considering only the electric field, not free charges in the cavity). Now integrate a loop Γ that crosses the cavity along a line of force from some positive charge to some negative charge, and returns to its starting point via the conductor (as in Fig. 5-12). The integral along such a line of force from the positive to the negative charge would not be zero. The integral through the metal is zero, since $E = 0$. So we would have

$$\oint \mathbf{E} \cdot d\mathbf{s} \neq 0??$$

But the line integral of \mathbf{E} around any closed loop in an electric field is always zero. So there must be no fields inside the empty cavity, nor any charges on the inside surface.

You should notice carefully one important qualification we have made. We have always said "with an empty cavity." If there charged particles or some other conductors in the cavity, as in an insulator or in a metal conductor insulated from the outside, then there can be fields in the cavity. But then that is not an "empty" cavity.

We have shown that if a cavity is completely enclosed by a conductor, no static distribution of charges outside can ever produce any fields inside. This explains the principle of "shielding" electrical equipment by placing it in a metal can. (See some open cans can be used to show that no static distribution of charges inside a closed conductor can produce any fields outside. Shielding works both ways! In electrostatics—but not in varying fields—the fields on the two sides of a closed conducting shell are completely independent.)

Now you see why it was possible to check Coulomb's law to within a percent precision. The shape of the hollow shell need doesn't matter. It doesn't need to be spherical; it could be square. If Gauss' law is good, the field inside is always zero. Now you also understand why it is safe to sit inside the high voltage terminal of a million-volt Van de Graaff generator without worrying about getting a shock—because of Gauss' law.

The Electric Field in Various Configurations

6.1 Equations of the electrostatic potential

This chapter will describe the behavior of the electric field in a number of different configurations. It will provide some experience with solving the electric field behavior, and will develop some of the other related methods we shall use to study field distributions.

We begin by giving you the whole mathematical framework that describes the structure, the Maxwell equations for electrostatics:

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0}, \quad (6.1)$$

$$\nabla \times \mathbf{E} = 0. \quad (6.2)$$

In fact, we can combine these two equations. From the second equation, we know at once that we can describe the field as the gradient of a scalar field known as ϕ :

$$\mathbf{E} = -\nabla \phi. \quad (6.3)$$

We may, if you wish, completely bypass any geometric drawing in terms of the potential ϕ . We note, the differential relation that ϕ must obey is still satisfying Eq. (6.2), since

$$\nabla \cdot \mathbf{E} = -\frac{\partial}{\partial r}. \quad (6.4)$$

The divergence of the gradient of ϕ is the same as the divergence of \mathbf{E} :

$$\nabla \cdot \mathbf{E} = \nabla^2 \phi = \frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} \quad (6.5)$$

and so with Eq. (6.4) as

$$\nabla^2 \phi = -\frac{\rho}{\epsilon_0}. \quad (6.6)$$

The term $\nabla^2 \phi$ is called the *Laplacian*, and Eq. (6.6) is called the *Poisson* or *3D Poisson*. The entire subject of electrostatics, in this mathematical framework, is really a study of the solutions of Eq. (6.6) plus Eq. (6.1). Once ϕ is obtained by solving Eq. (6.6), we can find \mathbf{E} from Eq. (6.3).

We focus on the one special class of problem in which ϕ is given as a function of r , θ , ϕ , in that case the problem is almost trivial. If we already know the sinusoidal ϕ (6.6) for the given ρ , we have shown that \mathbf{E} is known at every point the scientific al point! This

$$\mathbf{E}(r) = \begin{cases} \frac{\partial \phi(r,\theta,\phi)}{\partial r} & \text{if } \rho \neq 0 \\ 0 & \text{if } \rho = 0 \end{cases} \quad (6.7)$$

where $\rho(r)$ is the charge density, $\phi(r,\theta,\phi)$ the relevant function of position (r,θ,ϕ) and \mathbf{E} is the field at between points (2) and (3). The solution of the differential equation (6.6) is nontrivial in many cases (see Chap. 7). The solution of (6.7) should be relatively trivial, provided you are many situations in physics that lead to equations like

$$\frac{d^2 \phi}{dr^2} = -\frac{\rho(r)}{\epsilon_0}, \quad (\text{something}) = \text{something else},$$

and Eq. (6.7) is a solution of the equation for any of these problems.

The solution of the next 10 problems is the majority of your assignment, and after the solutions of all the charges are known, the 3rd section of week 10 is a few examples.

6-1 The electric dipole

First, take two point charges, $+q$ and $-q$, separated by the distance d . Let the z -axis go through the charges, and pick the origin halfway between, as shown in Fig. 6-1. Then, using (4.24), the potential from the two charges is given by

$$\phi(x, y, z)$$

$$= \frac{1}{4\pi\epsilon_0} \left[\frac{q}{\sqrt{[z - (d/2)]^2 + x^2 + y^2}} + \frac{q}{\sqrt{[z + (d/2)]^2 + x^2 + y^2}} \right]. \quad (6.8)$$

We are not going to write out the formula for the electric field, but we can always calculate it once we have the potential. So we have solved the problem of two charges.

There is an important special case in which the two charges are very close together—which is to say that we are interested in the fields only at distances from the charges large in comparison with their separation. We call such a close pair of charges a *dipole*. Dipoles are very common.

A “dipole” antenna can often be approximated by two charges separated by a small distance if we don’t look at the field too close to the antenna. (We are usually interested in antennas with moving charges; then the equations of statics do not really apply, but for some purposes they are an adequate approximation.)

More important perhaps, are atomic dipoles. If there is an electric field in any material, the electrons and protons feel opposite forces and are displaced relative to each other. In a conductor, you remember, some of the electrons move to the surfaces, so that the field inside becomes zero. In an insulator the electrons cannot move very far; they are pulled back by the attraction of the nucleus. They do, however, shift a little bit. So although an atom, or molecule, remains neutral in an external electric field, there is a very tiny separation of its positive and negative charges and it becomes a microscopic dipole. If we are interested in the fields of these atomic dipoles in the neighborhood of ordinary-sized objects, we are normally dealing with distances large compared with the separations of the pairs of charges.

In some molecules the charges are somewhat separated even in the absence of external fields, because of the form of the molecule. In a water molecule, for example, there is a net negative charge on the oxygen atom and a net positive charge on each of the two hydrogen atoms, which are not placed symmetrically but as in Fig. 6-2. Although the charge of the whole molecule is zero, there is a charge distribution with a little more negative charge to one side and a little more positive charge on the other. This arrangement is certainly not as simple as two point charges, but when you look far away the system acts like a dipole. As we shall see a little later, the field at large distances is not sensitive to the fine details.

Let’s look then at the field of two opposite charges with a small separation d . If d becomes zero, the two charges are on top of each other, the two potentials cancel, and there is no field. But if they are not exactly on top of each other, we can get a good approximation to the potential by expanding the term ϕ in (6.8) in a power series in the small quantity d/r (using the binomial expansion). Keeping terms only to first order in d , we can write

$$\left(z - \frac{d}{2}\right)^2 \approx z^2 - zd,$$

It is convenient to write

$$x^2 + y^2 + z^2 = r^2.$$

Then

$$\left(z - \frac{d}{2}\right)^2 + x^2 + y^2 \approx r^2 - zd - r^2 \left(1 - \frac{zd}{r^2}\right).$$

and

$$\frac{1}{\sqrt{[z - (d/2)]^2 + x^2 + y^2}} \approx \frac{1}{\sqrt{r^2(1 - (zd/r^2))}} \approx \frac{1}{r} \left(1 - \frac{zd}{r^2}\right)^{-1/2}.$$

Using the binomial expansion again for $(1 - (zd/r^2))^{-1/2}$ and throwing away terms with higher powers than the square of d , we get

$$\frac{1}{r} \left(1 + \frac{1}{2} \frac{zd}{r^2} \right).$$

Similarly,

$$\frac{1}{\sqrt{(z + (d/2))^2 + r^2}} = \frac{1}{r} \left(1 - \frac{1}{2} \frac{zd}{r^2} \right).$$

The difference of these two terms gives for the potential

$$\phi(x, y, z) = \frac{1}{4\pi\epsilon_0} \frac{p}{r} \cos\theta. \quad (6.9)$$

The potential, and hence the field, which is its derivative, is proportional to qd , the product of the charge and the separation. This product is defined as the **dipole moment** of the two charges, for which we will use the symbol p (do not confuse with reaction/cm³):

$$p = qd. \quad (6.10)$$

Equation (6.9) can also be written as

$$\phi(x, y, z) = \frac{1}{4\pi\epsilon_0} \frac{p \cos\theta}{r}, \quad (6.11)$$

where $z/r = \cos\theta$, where θ is the angle between the axis of the dipole and the radius vector to the point (x, y, z) —see Fig. 6-1. The potential of a dipole decreases as $1/r^2$ for a given direction from the axis (which is for a point charge it goes as $1/r$). The electric field E of the dipole will then decrease as $1/r^3$.

We can put our formula into a vector form if we define p as a vector whose magnitude is p and whose direction is along the axis of the dipole, pointing from q_+ toward q_- . Then

$$\cos\theta = p \cdot e_r \quad (6.12)$$

where e_r is the unit radial vector (Fig. 6-2). We can also represent the point (x, y, z) by r . Then

$$\text{Dipole potential: } \phi(r) = \frac{1}{4\pi\epsilon_0} \frac{p \cdot e_r}{r^2} = \frac{1}{4\pi\epsilon_0} \frac{p \cdot r}{r^3}. \quad (6.13)$$

This formula is valid for a dipole with any orientation and position if r represents the vector from the dipole to the point of interest.

If we want the electric field of the dipole we can get it by taking the gradient of ϕ . For example, the component of the field is $-\partial\phi/\partial z$. For a dipole located along the z -axis we can use (6.9):

$$\begin{aligned} &= \frac{\partial\phi}{\partial z} = -\frac{2}{4\pi\epsilon_0} \frac{\partial}{\partial z} \left(\frac{z}{r^2} \right) = -\frac{1}{4\pi\epsilon_0} \frac{p \cdot 3z^2}{r^5}, \\ \text{or} \quad E_z &= \frac{p}{4\pi\epsilon_0} \frac{3 \cos^2\theta - 1}{r^5}. \end{aligned} \quad (6.14)$$

The x - and y -components are

$$E_x = \frac{p}{4\pi\epsilon_0} \frac{3xz}{r^5}, \quad E_y = \frac{p}{4\pi\epsilon_0} \frac{3yz}{r^5}.$$

These two can be combined to give one component directed perpendicular to the z -axis, which we will call the transverse component E_t :

$$E_t = \sqrt{E_x^2 + E_y^2} = \frac{p}{4\pi\epsilon_0} \frac{3x}{r^5} \sqrt{x^2 + y^2}$$

$$\text{or} \quad E_t = \frac{p}{4\pi\epsilon_0} \frac{3 \cos\theta \sin\theta}{r^5}. \quad (6.15)$$

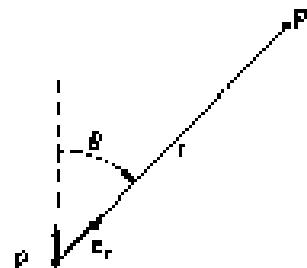

Fig. 6-2. Vector notation for a dipole.

The transverse component B_z is in the x - y plane and points directly away from the axis of the dipole. The total field, of course, is

$$\mathbf{B} = \sqrt{B_x^2 + B_z^2}.$$

The dipole field varies inversely as the cube of the distance from the dipole. On the axis, at $\theta = 0$, it is twice as strong as at $\theta = 90^\circ$. At each of these special angles the electric field has only a component, but of opposite sign at the two places (Fig. 6.4).

6-3 Remarks on vector equations

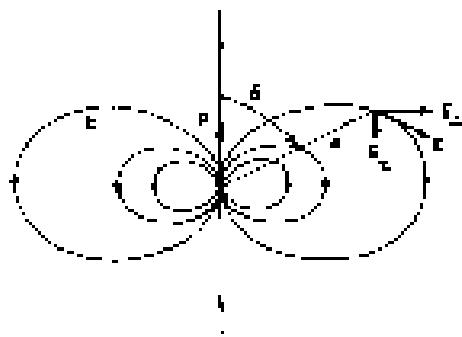

Fig. 6.4. The electric field of a dipole.

This is a good place to make a general remark about vector analysis. The fundamental parts can be expressed by scalar equations in a general form. But in making various calculations and analyses, it is always a good idea to choose the axes in some convenient way. Notice that when we were finding the potential of a dipole we chose the z -axis along the direction of the dipole, rather than at some arbitrary angle. This made the work much easier. But then we wrote the equation in vector form so that this would no longer depend on any particular coordinate system. After that, we were allowed to choose any coordinate system we wished, knowing that the relationships would still hold. It clearly does not make any sense to begin with an arbitrary coordinate system, if you are going to end up where you can change a new system for the particular problem—provided that the result can finally be expressed as a vector equation. So before you do take advantage of the fact that vector equations are independent of any coordinate system.

On the other hand, if you are trying to calculate the divergence of a vector, instead of just looking at $\nabla \cdot \mathbf{E}$ and wondering what it is, don't forget that it can always be expressed as

$$\frac{\partial E_x}{\partial x} + \frac{\partial E_y}{\partial y} + \frac{\partial E_z}{\partial z}.$$

If you can then work out the x , y , and z -components of the electric field and differentiate them, you will have the divergence. There often seems to be a feeling that there is something inelegant—some kind of deceit involved—in writing out the components; that somehow there ought always to be a way to do everything with the vector operators. There is often no advantage to it. The first time we encounter a particular kind of problem, it usually helps to write out the components to be sure we understand what is meant. There is nothing inelegant about putting numbers into equations, and nothing inelegant about substituting the derivatives for the fancy symbols. In fact, there is often a certain elegance in doing just that. Of course when you publish a paper in a professional journal it will look better—and be more easily understood—if you can write everything in vector form. Besides, it saves space.

6-4 The dipole potential as a gradient

We would like to point out a rather amazing thing about the dipole formula, Eq. (6.11). The potential can also be written as

$$\phi = -\frac{1}{4\pi\epsilon_0} \mathbf{p} \cdot \mathbf{r} \left(\frac{1}{r} \right), \quad (6.15)$$

If you calculate the gradient of $1/r$, you get

$$\nabla \left(\frac{1}{r} \right) = -\frac{x}{r^3} \mathbf{i} - \frac{y}{r^3} \mathbf{j} - \frac{z}{r^3} \mathbf{k},$$

and Eq. (6.16) is the same as Eq. (6.13).

How did we think of that? We just remembered that a/r^2 appeared in the formula for the field of a point charge, and that the field was the gradient of a potential which has a $1/r$ dependence.

There is a physical reason for being able to write the dipole potential in the form of Eq. (6.16). Suppose we have a point charge q at the origin. The potential at the point P at (x, y, z) is

$$\phi_0 = \frac{q}{r}.$$

(Let's leave off the $1/4\pi\epsilon_0$ which we make later; we can stick it in or not.) Now if we move the charge $+q$ up a distance Δz , the potential at P will change a little, by, say, $\Delta\phi_q$. How much is $\Delta\phi_q$? Well, it is just the amount that the potential would change if we were to leave the charge at the origin and move P downwards by the same distance Δz (Fig. 6-2). That is,

$$\Delta\phi_q = -\frac{\partial \phi_0}{\partial z} \Delta z,$$

where by Δz we mean the same as $d/2$. So, using $\phi = q/r$, we have that the potential from the positive charge is

$$\phi_+ = \frac{q}{r} - \frac{\partial}{\partial z} \left(\frac{q}{r} \right) \frac{d}{2}. \quad (6.17)$$

Applying the same reasoning for the potential from the negative charge, we can write

$$\phi_- = -\frac{-q}{r} + \frac{\partial}{\partial z} \left(\frac{-q}{r} \right) \frac{d}{2}. \quad (6.18)$$

The total potential is the sum of (6.17) and (6.18):

$$\begin{aligned} \phi &= \phi_+ + \phi_- = -\frac{\partial}{\partial z} \left(\frac{q}{r} \right) d \\ &= -\frac{\partial}{\partial z} \left(\frac{1}{r} \right) qd. \end{aligned} \quad (6.19)$$

For other orientation of the dipole, we could represent the displacement of the pos. charge by the vector Δr_+ . We should then write Eq. (6.17) as

$$d\phi = -\nabla\phi_0 \cdot d\mathbf{r}_+,$$

where $d\mathbf{r}$ is then to be replaced by $d/2$. Simplifying the derivation as before, Eq. (6.19) would then become

$$\phi = -\nabla \left(\frac{1}{r} \right) \cdot qd.$$

This is the same as Eq. (6.16), if we replace $qd \rightarrow p$, and put back the $1/4\pi\epsilon_0$. Looking at it another way, we see that the dipole potential, Eq. (6.13), can be interpreted as

$$\phi = -p \cdot \nabla \Phi_0, \quad (6.20)$$

where $\Phi_0 = 1/4\pi\epsilon_0 r$ is the potential of a unit point charge.

Although we can always find the potential of a known charge distribution by an integration, it is sometimes possible to save time by getting the answer with a clever trick. For example, one can often make use of the superposition principle. If we are given a charge distribution that can be made up of the sum of two distributions for which the potentials are already known, it is easy to find the desired potential by just adding the two known ones. One example of this is our derivation of (6.20), another is the following.

Suppose we have a spherical surface with a distribution of surface charge that varies as the cosine of the polar angle. The integration for this distribution is fairly messy. But, surprisingly, such a distribution can be analyzed by superposition. For imagine a sphere with a uniform volume density of positive charge, and another sphere with an equal uniform volume density of negative charge,

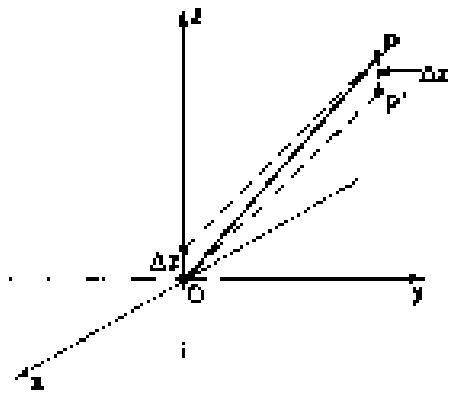

Fig. 6-2. The potential at P from a point charge at Δz above the origin is the same as the potential at $P'(\Delta z$ below $P)$ from the same charge at the origin

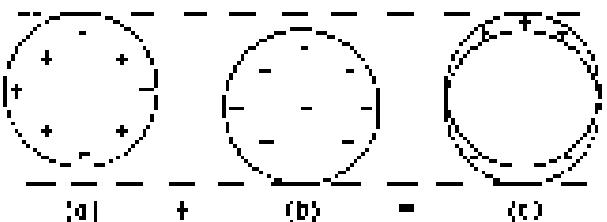

Fig. 6-3. Two uniformly charged spheres, superposed with a slight displacement, are equivalent to a Gaussian distribution of surface charge.

originally supposed to induce a negative test z , charge, sphere. If the left $+z$ sphere is displaced slightly with respect to the negative sphere, the tests of the elongated sphere would remain neutral, but a little positive dipole will appear on one side, and some negative charge will appear on the opposite side, as illustrated in Fig. 6-3. If the relative displacement d of the two spheres is small, the net charge is equivalent to a Gaussian charge (or a spherical surface), and the test charge density ρ_d is proportional to the cosine of the polar angle.

Now we want the potential from the distribution, we do not need to do an integral. We know that the potential from each of the spheres of charge q is for points outside the sphere the same as from a point charge. The two z -aligned spheres are like two point charges. The potential is just that of two z 's.

In this very simple case, but a charge distribution more general than a sphere, we can repeat this procedure.

$$\phi = \phi_{\text{point}}$$

where $\phi_{\text{point}} = kq/r$. This charge q is just that of a single sphere moment is

$$q = \frac{4\pi r^2}{3} \rho_d$$

It can also be shown that inside the sphere the field is constant with the value

$$E = \frac{2k}{3r_0}$$

In fact the angle from the positive z -axis, the electric field inside the sphere is in the original coordinate system. The example we have just considered is not as artificial as may appear; we will encounter it again in the theory of dielectrics.

6-6. The dipole approximation for an arbitrary distribution

The electric field appears in various dielectrics both in vacuum and in exterior. Suppose that we have an object that has a complicated distribution of charge like the water molecule (Fig. 6-2); and we are interested in it in the Coulomb way. Now it's not easy to get a fully satisfactory complete expression for the fields which is appropriate for distances large compared with the size a to be used.

We can think of a charge in symmetry to your charge q at a considerable distance, as shown in Fig. 6-7. (We can, if you like, replace q by $-q$; if you wish.) The two charges, let's call them q and q' , are separated by a distance d . From among q , q' , we can neglect

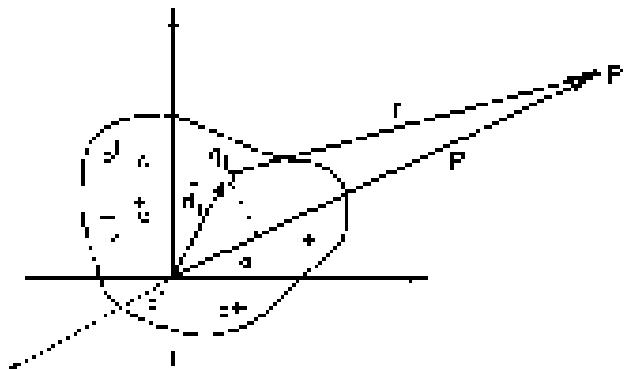

Fig. 6-7. Computation of the potential of a point P at a large distance from a set of charges.

In the middle of the pump of charges, ϕ_0 at is the potential at height R , but not at R , where it is much larger than the maximum ϕ_0^* . The potential from the whole distribution is given by

$$\phi = \frac{1}{4\pi\epsilon_0} \sum_i \frac{q_i}{r_i}, \quad (6.21)$$

where r_i is the distance from P to the charge q_i (the length of the vector $R - \vec{r}_i$). Now if the distance from the charge to P , the sum of all r_i 's, is enormous, each of the r_i 's can be approximated by R ; then term becomes q_i/R , and we can take $1/R$ out as a factor in front of the summation. This gives us the simple result

$$\phi = \frac{1}{4\pi\epsilon_0 R} \sum_i q_i = \frac{Q}{4\pi\epsilon_0 R}, \quad (6.22)$$

where Q is just the total charge of the whole object. This we find that far enough from any lump of charge, the field looks like a point charge. The result is not too surprising.

But what if there are equal numbers of positive and negative charges? Then the total charge Q of the object is zero. Taking my original case; in fact as we show, objects are usually neutral. The water molecule is neutral, but the charges are not all at one point, so if we are close enough we should be able to see some effect of the opposite charges. We need a better approximation than (6.21) for the potential from an arbitrary distribution of charge. A neutral object (Section 6.2) has $dipole$ fields but we are no longer interested in \vec{P} . We must make some approximation for ϕ at any point P at a large distance, as will differ from ϕ_0 in an excellent approximation by the proportion $1/d$ on R , as can be seen from Fig. 6.7. You should begin that ϕ is really to be over the d shown in the figure. In other words, if d is the first term in the expansion of R , then our next approximation to ϕ is

$$\phi = \bar{\phi} - d/\epsilon_0 \omega, \quad (6.23)$$

which we may write as $(1/d)\phi_0$, which shows $d/\epsilon_0 \omega$ is subtracted to our approximation to ϕ .

$$\bar{\phi}_i \approx \frac{1}{R} \left(1 + \frac{d_i}{\epsilon_0 \omega} \right). \quad (6.24)$$

Substituting this in (6.21), we get for the potential is

$$\phi = \frac{1}{4\pi\epsilon_0} \left(\frac{Q}{R} + \sum_i \omega_i \frac{d_i}{\epsilon_0 \omega} + \dots \right). \quad (6.25)$$

The three terms include the terms of higher order in $d/\epsilon_0 \omega$, but we have neglected. These, as well as the ones we have already obtained, are successive terms in an expansion of ϕ about $1/R$, about $1/d$ in powers of $d/\epsilon_0 \omega$.

The first term in (6.25) is what we get before; it drops out if the object is neutral. The second term depends on $1/d\omega$, just as for a dipole, but here, d we ignore

$$P = \sum_i q_i \vec{d}_i \quad (6.26)$$

as a property of the charge distribution. The second term of the potential (6.25) is

$$\delta = \frac{1}{4\pi\epsilon_0} \frac{d}{\omega^2}. \quad (6.27)$$

peculiarly difficult to work out. The quantity p is called the *dipole moment* of the distribution. It is a geometrical notion as its definition, and reduces to d for the special case of two point charges.

Our result is true far enough away from any pieces of charges, but if the whole neutral, the potential is a *long range* potential. It decreases as $1/d^2$ and varies as $\log d$ and its complete dependence on the dipole moment p of the distribution of charge. It is for these reasons that dipole fields are important, since the simple case of point charges is quite rare.

The water is electrically neutral, for example, and it has a rather strong dipole moment. The electric fields that result from this moment are responsible for some of the important properties of water. For many molecules, for example CO_2 , the dipole moment vanishes because of the symmetry of the molecule. For them we should expand still more accurately, containing another term in the potential which decreases as $1/R^3$, $1/m$, which is called a quadrupole potential. We will discuss such cases later.

6-6 The fields of charged conductors

We have now finished with the examples we wish to cover of situations in which the charge distributions is known from the start. It has been a problem without serious complications involving at most some integration. We turn now to an entirely new kind of problem: the determination of the fields near charged conductors.

Suppose that we have a situation in which a total charge Q is placed on an arbitrary conductor. Now we will not be able to say exactly where the charges are. They will spread out in some way on the surface. How can we know how the charges have distributed themselves on the surface? They must distribute themselves so that the potential of the surface is constant. If the surface were not an equipotential, there would be an electric field inside the conductor, and the charges would keep moving until it became zero. The general problem of this kind can be solved in the following way. We guess at a distribution of charge and calculate the potential. If the potential turns out to be constant everywhere on the surface, the problem is finished. If the surface is not an equipotential, we have guessed the wrong distribution of charges, and should guess again—carefully with an improved guess. This can go on forever, unless we are judicious about the successive guesses.

The question of how to guess at the distribution is mathematically difficult. Nature, of course, has time to do it; the charges push and pull until they all balance themselves. When we try to solve the problem, however, it takes us so long to make each trial that that method is very tedious. With an arbitrary group of conductors and charges the problem can be very complicated, and in general it cannot be solved without either elaborate numerical methods. Such numerical calculations, these days, are set up on a computing machine that will do the work for us, once we don't tell it how to proceed.

On the other hand, there are a lot of little practical cases where it would be just as feasible to find the answer by some simple device. Without trying, now, determine for me a conjecture. Frankly, I have a small list of cases where the answer can be obtained by reasoning it out of Nature by some trick or other. The first trick we will describe involves making use of something we have already obtained: the situations in which charges have specified locations.

6-7 The method of images

We have solved, for example, the field of two point charges. Figure 6-9 shows some of the field lines and equipotential surfaces we obtained by the manipulations in Chapter 5. Now consider the equipotential surfaces in Fig. 6-1. Suppose we were to shape a thin sheet of metal so that it just fits this surface. If we place it right at the surface and adjust its potential to the proper value, no one would ever know it was there, because nothing would be changed.

But notice! We have really solved a new problem. We have a situation in which the surface of a curved conductor with a given potential is placed next a point charge. If the metal sheet we place at the equipotential surface eventually closes on itself, for, in practice, if it goes far enough we have the kind of situation considered in Section 5-16, in which our space is divided into two regions, one inside and one outside a closed conducting shell. We found there that the fields in the two regions are quite independent of each other. So we would see the same fields outside our curved conductor no matter what is inside. We can even fill up

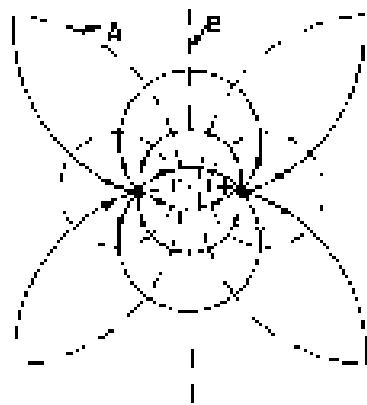

Fig. 6-9. The field lines and equipotential surfaces for two point charges

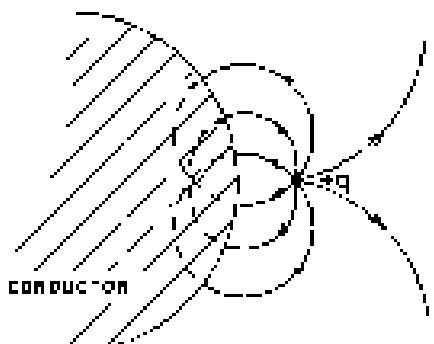

Fig. 6-4. The field outside a conductor shaped like the equipotential A of Fig. 6-9.

the whole inside with conducting material. We have found, therefore, the fields for the arrangement of Fig. 6-9. In the space outside the conductor the field is just like that of two point charges, as in Fig. 6-8. Inside the conductor, it is zero. Also—in it must be—the electric field just outside the conductor is normal to the surface.

Thus we can compute the fields in Fig. 6-9 by applying the field due to $+q$ in its ordinary point charge $-q$ at a suitable point. The point charge we "imagine" existing behind the conducting surface is called an *image charge*.

In books you can find long lists of solutions for hyperboloid-shaped conductors and more complicated looking things, and you wonder how anyone ever solved these terrible shapes. They were solved backwards! Someone solved a simple problem with given charges. He then saw that some equipotential surface showed up in a new shape, and he wrote a paper in which he pointed out that the field outside had particular properties described in a certain way.

6-8 A point charge near a conducting plane

As the simplest application of the use of this method, let's make use of the plane equipotential surface \mathcal{S} of Fig. 6-8. With it, we can solve the problem of a charge in front of a conducting sheet. We just cross out the left-hand half of the surface. The field lines for our solution are shown in Fig. 6-10. Notice that the plane sheet \mathcal{S} was halfway between the two charges, as in problem 1. We have solved the problem of a positive charge q in front of a given conducting sheet.

We have now solved for the total field, but what about the *induced charges* that are responsible for it? There are, in addition to our positive point charge, some induced negative charges on the conducting sheet that have been attracted by the positive charge (from large distances away). Now suppose that for some technical reason—or out of curiosity—you would like to know how the negative charges are distributed on the surface. You can find the surface charge density by using the result we worked out in Section 5-6 with Gauss' theorem. The normal com-

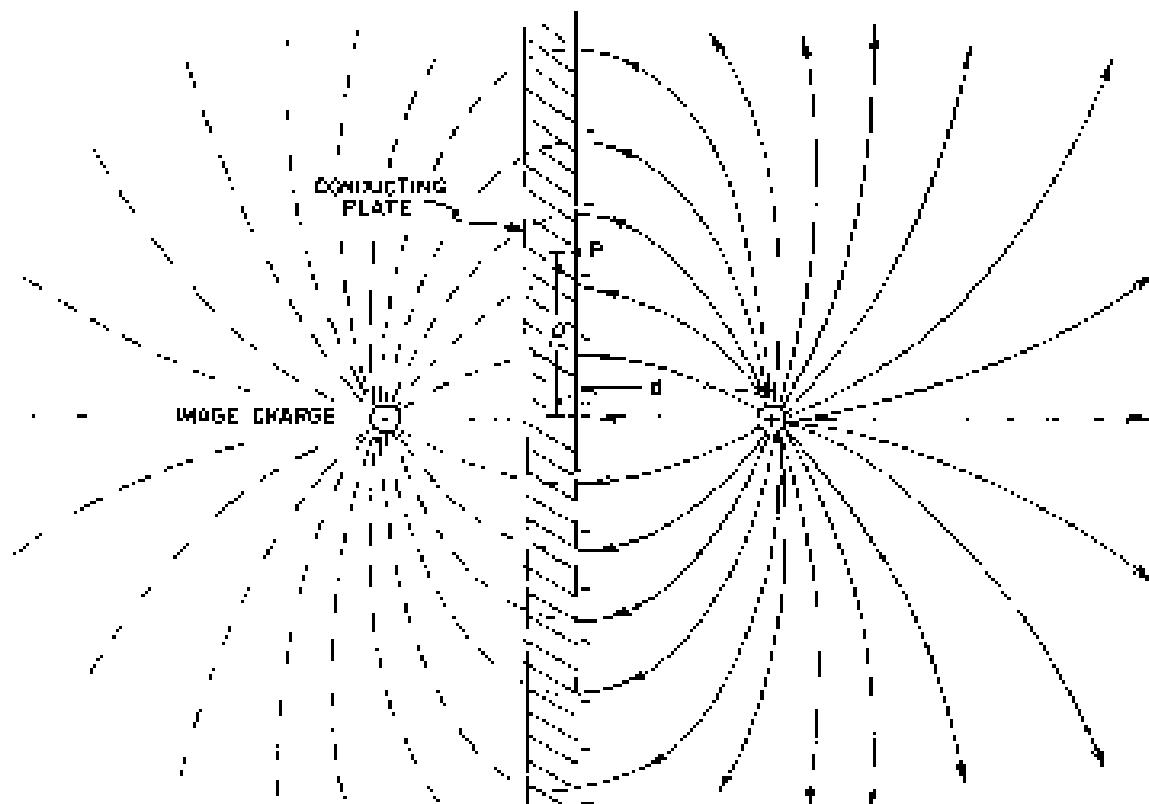

Fig. 6-10. The field of a charge near a plane conducting surface, found by the method of images.

point of the dielectric. The total surface density is equal to the density of surface charge σ , given by ϵ_0 . We can obtain the density of charge at any point on the sphere by looking forwards (from Eq. 6-10) to component of the electric field on the surface. We know that, because we know the field everywhere,

Consider a point P to be at distance r from the point charge. To reach the point charge (Eq. 6-10), the electric field at this point is normal to the surface and is directed inward. The component parallel to the surface of the field from the point charge is

$$E_r = \frac{q}{4\pi\epsilon_0 r^2} \frac{r^2}{r^2 + b^2} \quad (6-21)$$

To the left of P add the electric field produced by the negative surface charge. Then to the right the normal component (and hence all others) on the charge density σ at any point on the surface is

$$\sigma(r) = \sigma_0 \frac{b}{r} = -\frac{q}{4\pi\epsilon_0 r^2} \frac{r^2}{r^2 + b^2} \quad (6-22)$$

An interesting check on our work is to integrate over the whole surface. We find that the total induced charge is $-q$, as it should be.

One further question: Is there force on the point charge? This becomes there is an attraction from the induced negative surface charge on the plate. Now that we know what the surface charge is (from Eq. 6-22) we could compute the force on our positive point charge by integrating. Or we could know that the force acting on the positive charge is exactly the same as it would be were the negative image charge instead of the plate nearer the field. In the capillary case, the result is the same — no twin charges, but a force between the plates which is finite.

$$F = \frac{1}{4\pi\epsilon_0} \frac{q^2}{b^2 r^2} \quad (6-23)$$

We have found out how much more easily than by integrating over all the surface charges.

6-9 A point charge near a conducting sphere

What other problems deserve a little care & simple solution? The next most interesting is a sphere. Let's take the facts about a metal sphere which have charge q near it, as shown in Fig. 6-1. Now we may ask for a simple situation which gives a simple formula for calculating q exactly. If we took account of geometry people have already done, we find the somewhat surprising that the field of two equal point charges has an equipotential field as a sphere. That is we divide the field on R into q and charge $-q$ and pick the right value of R charge $-q$ must be on the upper hemisphere, free fit on sphere. Below, we're done with the following problem.

Assume that you want the equipotential surface to be a sphere of radius r with its center at a distance b from the charge q . Put a image charge of $-q$ at $y = -b$ along the y -axis from the origin to the center of the sphere, and at a distance a/b from the center. The sphere will be at zero potential.

The method used here stems from the fact that a sphere is the locus of points for whom the distances from two points are constant. Referring to Fig. 6-1, the condition at P from q and $-q$ is proportional to

$$\frac{q}{r_1} + \frac{q}{r_2}$$

The point P will thus satisfy a null point equation

$$\frac{r_1^2}{r} = -\frac{q}{r_1} \quad \text{or} \quad \frac{r_2^2}{r} = -\frac{q}{r_2}$$

If we place q' at the distance a' from the center, the ratio a'/r has the constant value a/b . Then if

$$\frac{a'}{r} = \frac{a}{b} \quad (6.31)$$

the sphere is an equipotential. Its potential is, in fact, zero.

What happens if we are interested in a sphere that is not at zero potential? That would be so only if total charge happens accidentally to be q . Of course if it is grounded, the charges induced on it would have to be just that. But what if it is insulated, and we have put no charge on it? Or if we know that the total charge Q has been put on it? Or just that it has a given potential not equal to zero? All these questions are easily answered. We can always find a point charge q'' on the center of the sphere. The sphere will remain an equipotential by superposition; only the magnitude of the potential will be changed.

If we have, for example, a conducting sphere which is initially uncharged and isolated from everything else, and we bring near to it the positive point charge q , the total charge of the sphere will remain zero. The solution is found by requiring a tiny charge q' as before, but in addition adding a charge q'' at the center of the sphere, according

$$q'' = -q' = \frac{q}{b} q. \quad (6.32)$$

The fields everywhere outside the sphere are given by the superposition of the fields of q , q' , and q'' . The problem is solved.

We can see now that there will be a force of attraction between the sphere and the point charge q . It is not zero even though there is no charge on the isolated sphere. What does the attraction come from? When you bring a positive charge up to a conducting sphere, the positive charge attracts negative charges to the side closest to itself, and these positive charges leave the surface of the body. The attraction by the positive charges causes the negative ion the positive charges, thus causing attraction. We can find out how large the attraction is by calculating the force on q by the field produced by q and q'' . The total force is the sum of the attractive force between q and q' ($= -kq_1q_2/q^2$) and the repulsive force between q and q'' ($= kq_1q_2/q^2$) of the distances b .

Those who were interested in followed by the following method, in which I was in. My labeling method is: taking powder, see who contains its self a particle is a "background" (or which may be interesting in the following incident). I imagined spheres, each having a total charge of $-q/2$ of the other with a total charge of $+Q$, are placed side-by-side facing each other. What is the force between them? The potential can be taken from a number of charges. One first approximates each sphere by a charge on its center. These charges will have image charges in the other sphere. The image charges will have charges, etc., etc. The solution is like the picture on the box of baking powder, and it converges pretty fast.

6-10 Condensers; parallel planes

We take up now another kind of a problem involving conductors. Consider two large metal plates which are parallel to each other and separated by a distance small compared with their width. Let's suppose that equal and opposite charges have been put on the plates. The charges on each plate will be attracted by the charges on the other plate, and the charges will spread out uniformly on the inner surfaces of the plates. The plates will have surface charge densities $+\sigma$ and $-\sigma$, respectively, as in Fig. 6-12. From Chapter 5 we know that the field between the plates is $\sigma/2\epsilon_0$, and that the field outside the plates is zero. The plates will have different potentials ϕ_1 and ϕ_2 . For convenience we will call the difference V ; it is often called the "voltage".

$$\phi_1 - \phi_2 = V$$

(Note well first that sometimes people use V for the potential, but we have chosen to use ϕ .)

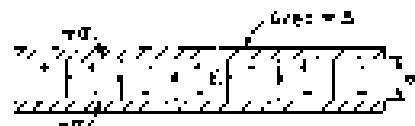

Fig. 6-12 A parallel plate condenser

The potential difference V is the work per unit charge required to bring a small charge from one plate to the other.

$$V = \frac{Q}{C} = \frac{\pi d^2}{4\epsilon_0 A} \cdot \frac{1}{d} Q, \quad (6.11)$$

where A/Q is the surface charge density on each plate, d is the distance between plates, and ϵ_0 is the dielectric constant.

We find that the voltage is proportional to the charge. Another proportionality between V and Q is found for any two conductors in space if there is a charge Q on one and an equal negative charge on the other. The potential difference between them due to the voltage will be proportional to the charge. (We are assuming no other external charges are nearby.)

Very this proves reciprocity, i.e., the superposition principle. Suppose we have the solution to one set of charges, and then we superimpose two such solutions. The charges are distributed, the fields are additive, and the work done in carrying a unit charge from one point to the other is also additive. Therefore the potential difference between two points is proportional to the charges. In particular, the potential difference between two points is proportional to the charges on them, assuming one grid of points. By symmetry of problem on the other side. That is they wrote

$$Q = \epsilon V,$$

where V is a constant. This coefficient of proportionality is called the capacity of the system of two conductors, or called a capacitor. (For a parallel-plate capacitor it is

$$C = \frac{A}{d} \quad (\text{per unit charge}). \quad (6.12)$$

This formula is not exact. Because the field is not truly uniform between the plates, as we assumed. The field does not just suddenly end at the edges of the plates, as shown in Figure 12. The field changes smoothly, as we have learned. There is a little curvature for the field lines; the edges of the plates, where the surface density, σ , is large, force the field lines to curve and bend outward with their impetus at the edges. (This is not illustrated in the sketch which is, however, the subject of techniques which we will not discuss here.) The result of such edge effects is that the average density is somewhat less than the edges of the plates. This means that the capacity of the plates is actually less than we computed. (We can compute exactly the average value of the field, however, in which case $C = A/d$ for the case of a cavity.) (In practice, however, by a factor of 3 or 4 the separation between the plates.)

We have talked about the case of two conductors only. Since, in general, there is more capacity of a single object, why say the more the capacity of a system of conductors? Well, everything is that the potential of a conductor is the sum of individual values. Therefore, there is a rule of superposition of capacities. If you have an infinite system of conductors, the aggregate capacity is ΣC_i , even in infinite system. One can also speak of capacities when there are three or more conductors. A discussion of such cases, however, defers.

Suppose now we wish to have a condenser with a very large capacity. We could get a large capacity by taking a very big distance or very small ϵ_0 . We could put waxed paper between sheets of aluminum foil and call it ϵ_0 . If we did it in plastic, we have a typical dielectric insulator. What you do not know is your insulating strength. It is very hard to characterize it. For example, an insulator has capacity as yet charged ... it may not be charged, that is the charge begins to escape into the air. But if you put the same charge on a conductor whose capacity is very large, the voltage drop would be low. Insulation would be small.

¹ Some people think it is good "superconducting" because it does not need any heat or cooling, or "heatless." We have defined it as the heatless terminology because it will more conveniently lead to the heatless laboratory experiments in the last chapter.

In many applications in electronic circuits, it is useful to have something which can absorb or deliver large quantities of charge without changing its potential much. A capacitor (or "capacitor") does just that. There are also many applications in electronic instruments and in computers where a capacitor is used to get a specified change in voltage in response to a particular change in charge. We have seen a similar application in Chapter 22, Vol. I, where we described the properties of resonant circuits.

From the definition of C , we see that its unit is one coulomb. This unit is also called a farad. Looking at Eq. (6.3), we see that one can express the units of C as farad/meter^2 , which is the unit most commonly used. Typical sizes of capacitors run from one micro-microfarad ($\sim 1 \text{ picofarad}$) to millifarads. Small condensers of a few picofarads are used in high-frequency tuned circuits, and capacitors up to hundreds or thousands of microfarads are found in power-supply filters. A pair of plates one square centimeter in area with a capacitance separation have a capacity of roughly one micro-microfarad.

6-11 High-voltage breakdown

We would like now to discuss qualitatively some of the characteristics of the fields around conductors. If we charge a conductor that is not a sphere, but instead has on it a point or a very sharp end, as, for example, the object sketched in Fig. 6-14, the field around the point is much higher than the field in the other regions. The reason is, qualitatively, that charges try to spread out as much as possible on the surface of a conductor, and the tip of a sharp point is as far away as it is possible to be from most of the surface. Some of the charges on the plate get pushed all the way to the tip. A relatively small amount of charge on the tip can still provide a large surface density; a high charge density means a high field, as we do.

The way to see that the fact is highest at those places on a conductor where the radius of curvature is smallest, is to consider the combination of a big sphere and a little sphere connected by a wire as shown in Fig. 6-15. It is somewhat simplified versions of the conductors of Fig. 6-14. The wire will have little influence on the fields outside, it is there to keep the spheres at the same potential. Now, if each ball has the same field at its surface? If the ball on the left has the radius a and carries a charge Q , its potential is about

$$\phi_1 = \frac{1}{4\pi\epsilon_0} \frac{Q}{a}$$

(Of course the presence of one ball changes the charge distribution on the other, so that the charges are not really spherically symmetric on either. But if we are interested only in an estimate of the fields, we can use the potential of a spherical charge.) If the smaller ball, whose radius is b , carries the charge q , its potential is about

$$\phi_2 = \frac{1}{4\pi\epsilon_0} \frac{q}{b}$$

But $a = \phi_1 \cdot \infty$

$$\frac{Q}{a} = \frac{q}{b}$$

On the other hand, the field at the surface (see Eq. 5.8) is proportional to the surface charge density, which is like the total charge over the radius squared. We get that

$$\frac{\Delta\phi}{\Delta r} = \frac{Q/a^2}{q/b^2} = \frac{b}{a}. \quad (6.5)$$

Therefore the field is higher at the surface of the small sphere. The fields are in the inverse proportion of the radii.

This result is technically very important, because air will break down if the electric field is too great. What happens is that a free charge (electron, or ion) somewhere in the air is accelerated by the field, and if the field is very great, the charge can pick up enough speed before it loses energy due to friction with

$$C_0 = \frac{1}{36\pi} \times 10^{-9} \text{ Farad/meter}$$

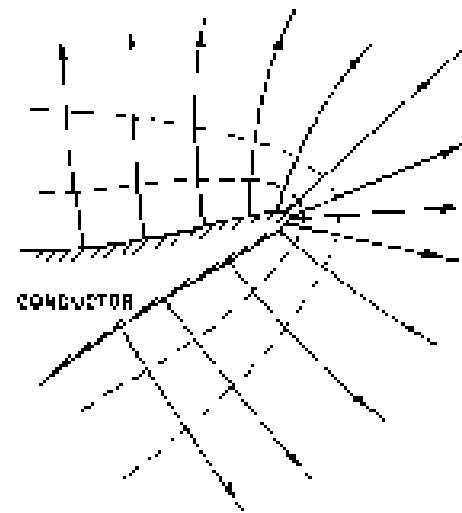

Fig. 6-14. The electric field near a sharp point on a conductor is very high.

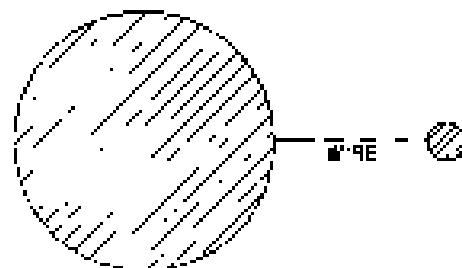

Fig. 6-15. The field of a pointed object can be approximated by that of two spheres of the same potential.

electron off that atom. As a result, more and more ions are produced. Their motion constitutes a discharge, or spark. If you want to charge an object to a high potential and not have it discharge itself by sparks in the air, you must be sure that the surface is smooth, so that there is no place where the field is abnormally large.

6-12 The field-emission microscope

There is an interesting application of the extremely high electric field which surrounds any sharp protuberance or a charged conductor. The field-emission microscope depends for its operation on the high fields produced at a sharp metal point.* It is built in the following way. A very fine needle, with a tip whose diameter is about .0001 cm., is placed at the center of an evacuated glass sphere (Fig. 6-16). The inner surface of the sphere is coated with a thin conducting layer of fluorescent material, and a very high potential difference is applied between the fluorescent coating and the needle.

Let's first consider what happens when the needle is negative with respect to the fluorescent coating. The field lines are highly concentrated at the sharp point. The electric field can be as high as 10 million volts per centimeter. In such intense fields, electrons are pulled out of the surface of the needle and accelerated across the potential difference between the needle and the fluorescent layer. When they arrive there they cause light to be emitted, just as in a television picture tube.

The electrons which arrive at a given point on the fluorescent surface are, to an excellent approximation, those which leave the other end of the radial field line, because the electrons will travel along the field line passing from the point to the surface. Thus we see on the surface spots due to passage of the tip of the needle. More precisely, we see a picture of the sensitivity of the surface of the needle. That is the case with which electrons can leave the surface of the metal tip. If the resolution were high enough, one could hope to resolve the positions of the individual atoms on the tip of the needle. With electrons, that resolution is not possible for the following reasons. First, there is quantum-mechanical diffraction of the electron waves which blur the image. Second, due to the internal motions of the electrons in the metal they have a small sideways initial velocity when they leave the needle, and this random sideways component of the velocity causes some smearing of the image. The combination of these two effects limits the resolution to 25 Å or so.

If, however, we reverse the polarity and introduce a small amount of helium gas into the bulb, much lighter resolutions are possible. When a helium atom collides with the tip of the needle, the intense field there strips an electron off the helium atom, leaving it positively charged. The positive ion is then accelerated outward along a field line to the fluorescent screen. Since the ionization is so much heavier than an electron, the quantum-mechanical wavelengths are much smaller. If the temperature T is not too high, the effect of the thermal velocities is also smaller than in the electron case. With an ionizing voltage of 1000 V, the resolution of the picture is obtained. It has been possible to obtain magnifications up to 2,000,000 times with the best field-ion microscopes, a magnification ten times greater than is obtained with the best electron microscopes.

Figure 6-17 is an example of the results which were obtained with a field-ion microscope, using a tungsten needle. The center of a tungsten atom invites a helium atom at a slightly different rate than the spaces between the tungsten atoms. The pattern of spots on the fluorescent screen shows the arrangement of the individual atoms on the tungsten tip. The reason the spots appear in rings can be understood by visualizing a large box of balls stacked in a rectangular array, representing the atoms in the metal. If you cut an approximately spherical section out of this box, you will see the ring pattern characteristic of the atomic structure. The field-ion microscope provided human beings with the means of seeing atoms for the first time. This is a remarkable achievement, considering the simplicity of the instrument.

The Electric Field in Various Circumstances (Continued)

7-1 Methods for finding the electrostatic field

This chapter is a continuation of our consideration of the characteristics of electric fields in various particular situations. We shall first describe some of the more elaborate methods for solving problems with conductors. It is not expected that these more advanced methods can be mastered at this time. Yet it may be of interest to have some idea about the kinds of problems that can be solved, using techniques that may be learned in more advanced courses. Then we take up two examples in which the charge distribution is neither fixed nor is carried by a conductor, but instead is determined by some other law of physics.

As we found in Chapter 6, the problem of the electrostatic field is fundamentally simple when the distribution of charges is specified; it requires only the evaluation of an integral. When there are conductors present, however, complications arise because the charge distribution on the conductors is not initially known; the charge must distribute itself on the surface of the conductor in such a way that the conductor is an equipotential. The solution of such problems is neither difficult nor simple.

We have looked at an indirect method of solving such problems, in which we find the equipotentials for some specified charge distribution and replace one of them by a conducting surface. In this way we can build up a catalog of special solutions for conductors in the shapes of spheres, planes, etc. The use of images, described in Chapter 6, is an example of an indirect method. We shall describe another in this chapter.

If the problem to be solved does not belong to the class of problems for which we can construct solutions by the indirect method, we are forced to solve the problem by a more direct method. The mathematical problem of the direct method is the solution of Laplace's equation,

$$\nabla^2 \phi = 0. \quad (7.1)$$

subject to the condition that ϕ is a suitable constant on certain boundaries—the surfaces of the conductors. Problems which involve the solution of a differential field equation subject to certain boundary conditions are called boundary value problems. They have been the object of considerable mathematical study. In the case of conductors having complicated shapes, there are no general analytical methods. Even such a simple problem as that of a charged cylindrical metal can elicit at both ends a beer can presents formidable mathematical difficulties. It can be solved only approximately, using numerical methods. The only general methods of solution are numerical.

There are a few problems for which Eq. (7.1) can be solved directly. For example, the problem of a charged conductor having the shape of an ellipsoid of revolution can be solved exactly in terms of known special functions. The solution for a thin disc can be obtained by letting the ellipsoid become infinitely oblate. In a similar manner, the solution for a needle can be obtained by letting the ellipsoid become infinitely prolate. However, it must be stressed that the only direct methods of general applicability are the numerical techniques.

Boundary value problems can also be solved by measurement of a physical quantity. Laplace's equation arises in many different physical situations: in steady-state heat flow, in irrotational fluid flow, in current flow in an extended medium,

7-1 Methods for finding the electrostatic field

7-2 Two-dimensional fields; functions of the complex variable

7-3 Plasma oscillations

7-4 Colloidal particles in air; closoxyne

7-5 The electrostatic field of a grid

and in the deflection of an elastic membrane. It is frequently possible to set up a physical model which is analogous to an electrical problem which we wish to solve. By the measurement of a suitable analogous quantity on the model, the solution to the problem of interest can be determined. An example of the analog technique is the use of the electrolytic tank for the solution of two-dimensional problems in electrodynamics. This works because the differential equation for the potential in a uniform conducting medium is the same as it is for a vacuum.

There are many physical situations in which the variations of the physical fields in one direction are zero, or can be neglected in comparison with the variations in the other two directions. Such problems are called two-dimensional; the field depends on two coordinates only. For example, if we place a long charged wire along the z -axis, then for points not too far from the wire the electric field depends on x and y , but not on z ; the problem is two-dimensional. Since in a two-dimensional problem $\partial/\partial z = 0$, the equation for ϕ in free space is

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0. \quad (7.2)$$

Because the two-dimensional equation is comparatively simple, there is a wide range of conditions under which it can be solved analytically. There is, in fact, a very powerful indirect mathematical technique which depends on a theorem from the mathematics of functions of a complex variable, and which we will now describe.

7-2 Two-dimensional fields; functions of the complex variable

The complex variable β is defined as

$$\beta = x + iy$$

(Do not confuse β with the z -coordinate, which we ignore in the following discussion because we assume there is no z -dependence of the fields.) Every point in x and y then corresponds to a complex number β . We can use β as a single (complex) variable, and with it write the usual kinds of mathematical functions $F(\beta)$. For example,

$$F(\beta) = \beta^2,$$

or

$$F(\beta) = 1/\beta^2,$$

or

$$F(\beta) = \beta \log \beta,$$

and so forth.

Given any particular $F(\beta)$ we can substitute $\beta = x + iy$, and we have a function of x and y , with real and imaginary parts. For example,

$$\beta^2 = (x + iy)^2 = x^2 - y^2 + 2ixy. \quad (7.3)$$

Any function $F(\beta)$ can be written as a sum of a pure real part and a pure imaginary part, each part a function of x and y :

$$F(\beta) = U(x, y) + iV(x, y), \quad (7.4)$$

where $U(x, y)$ and $V(x, y)$ are real functions. Thus from any complex function $F(\beta)$ two new functions $U(x, y)$ and $V(x, y)$ can be derived. For example, $F(\beta) = \beta^2$ gives us the two functions

$$U(x, y) = x^2 - y^2, \quad (7.5)$$

and

$$V(x, y) = 2xy. \quad (7.6)$$

Now we come to a marvelous mathematical theorem which is so delightful that we shall leave a proof of it for one of your courses in mathematics. (We should not reveal all the mysteries of mathematics, or that subject would

become zero (null). It is this. For any "ordinary function" (mathematicians will define it better) the functions U and V automatically satisfy the relations:

$$\frac{\partial U}{\partial x} = \frac{\partial V}{\partial y}, \quad (7.7)$$

$$\frac{\partial V}{\partial x} = -\frac{\partial U}{\partial y}. \quad (7.8)$$

It follows immediately that each of the functions U and V satisfy Laplace's equation:

$$\frac{\partial^2 U}{\partial x^2} + \frac{\partial^2 U}{\partial y^2} = 0, \quad (7.9)$$

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} = 0. \quad (7.10)$$

These equations are clearly true for the functions of (7.5) and (7.6).

Thus, starting with any arbitrary function, we can arrive at two functions $U(x, y)$ and $V(x, y)$, which are both solutions of Laplace's equation in two dimensions. Each function represents a possible electrostatic potential. We can pick one (arbitrary A) and it should represent some electric field problem—in fact, *too* problems, because U and V each represent solutions. We can write down as many solutions as we wish—by just making up functions—but we just have to find the problem that goes with each solution. It may sound backwards, but it's a possible approach.

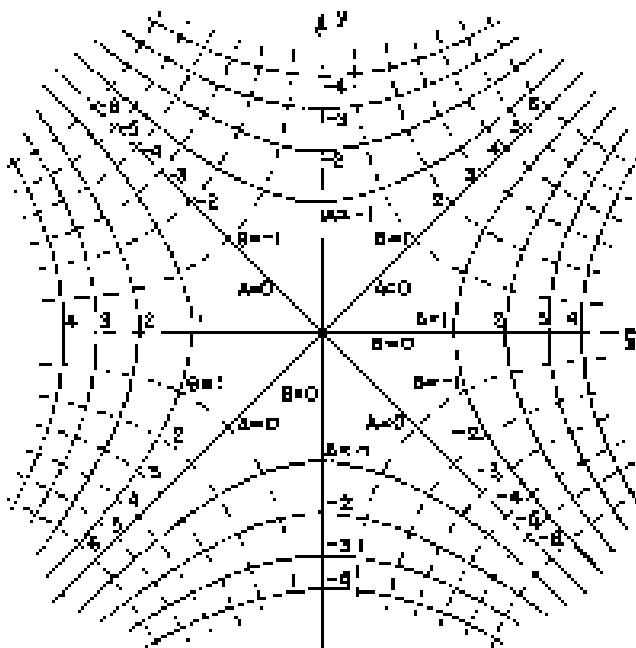

Fig. 7-1. Two sets of elliptical curves which can represent equipotentials in a two-dimensional electrostatic field.

As an example, let's see what physics the function $A(y) = y^2$ gives us. From (7.6) we get the two potential functions of (7.5) and (7.6). To see what problem the function y belongs to, we solve for the equipotential surfaces by setting $U = A$, a constant:

$$x^2 - y^2 = A.$$

This is the equation of a rectangular hyperbola. For various values of A , we get the hyperbolae shown in Fig. 7-1. When $A = 0$, we get the special case of diagonal straight lines through the origin.

Such a set of equipotentials corresponds to several possible physical situations. First, it represents the fine details of the field near the point halfway between two

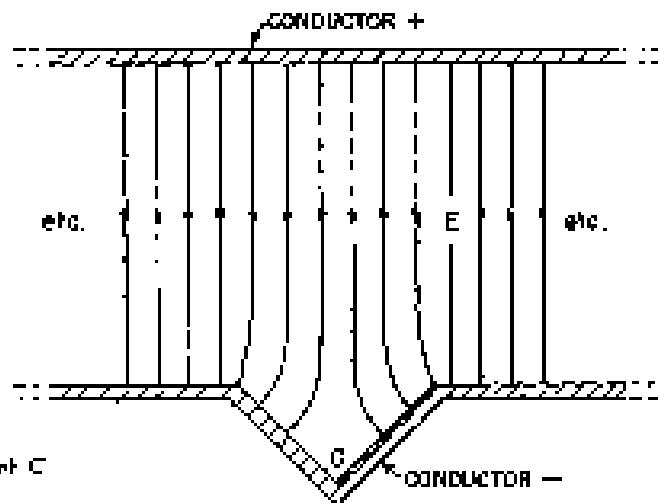

Fig. 7-2. The field near the point C
is the same as that in Fig. 7-1.

equal point charges. Second, it represents the field at an inside right-angle corner of a conductor. If we have two electrodes shaped like those in Fig. 7-2, which are held at different potentials, the field near the corner marked C will look just like the field above the origin in Fig. 7-1. The solid lines are the equipotentials, and the broken lines at right angles correspond to lines of E . Whereas at points of protruberances the electric field tends to be high, it tends to be low in dents or hollows.

The solution we have found also corresponds to that for a hyperbola-shaped electrode near a right-angle corner, or for two hyperbolae at suitable potentials. You will notice that the field of Fig. 7-1 has an interesting property. The x -component of the electric field, E_x , is given by

$$E_x = -\frac{\partial \phi}{\partial x} = -2x.$$

The electric field is proportional to the x distance from the axis. This fact is used to make devices (called quadrupole lenses) that are useful for focusing particle beams (see Section 29-9); the lens field is usually obtained by using four hyperbola-shaped electrodes, as shown in Fig. 7-3. For the electric field lines in Fig. 7-3, we have simply copied from Fig. 7-1 the set of broken-line curves that represent $V = \text{constant}$. We have a bonus! The curves for $V = \text{constant}$ are orthogonal to the ones for $\phi = \text{constant}$ because of the equations (7.7) and (7.8). Whenever we choose a function $F(z)$, we get from 7-1 and 7-2 both the equipotentials and field lines. And you will remember that we have solved either of these problems, depending on which set of curves we call the equipotentials.

As a second example, consider the function

$$F(z) = \sqrt{z}. \quad (7.11)$$

If we write

$$z = x + iy = \rho e^{i\theta},$$

where

$$\rho = \sqrt{x^2 + y^2}$$

and

$$\tan \theta = y/x,$$

then

$$F(z) = \rho^{1/2} e^{i\theta/2} \\ = \rho^{1/2} \left(\cos \frac{\theta}{2} + i \sin \frac{\theta}{2} \right).$$

From which

$$F(z) = \left[\left(\frac{x^2}{\rho} + \frac{y^2}{\rho} \right)^{1/2} + i \right]^{1/2} + i \left[\left(\frac{x^2}{\rho} + \frac{y^2}{\rho} \right)^{1/2} - x \right]^{1/2} \quad (7.12)$$

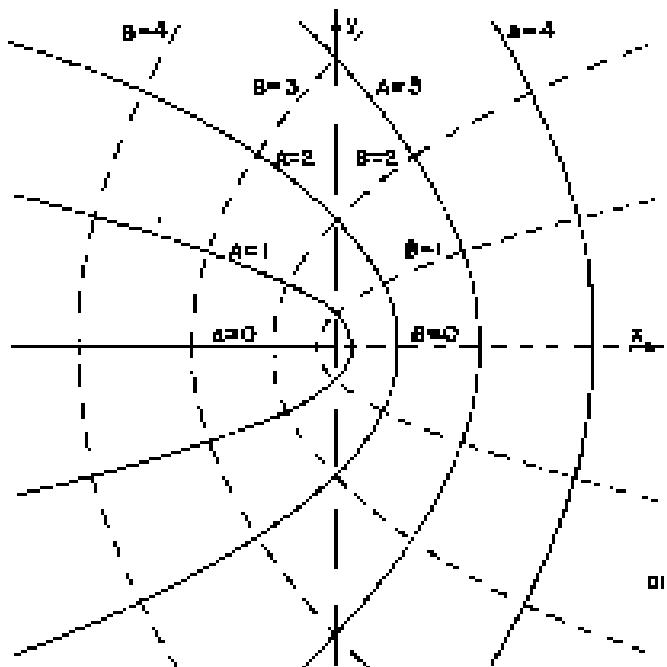

Fig. 7-4. Curves of constant $C(x,y)$ and $V(x,y)$ from Eq. (7.12).

The curves for $C(x,y) = A$ and $V(x,y) = B$, using \mathcal{U} and V from Eq. (7.12), are plotted in Fig. 7-4. Again, there are many possible situations that could be described by these fields. One of the most interesting is the field near the edge of a thin plate. If the line $R = 0$ —to the right of the x -axis—represents a thin charged plate, the field lines near it are given by the curves for various values of A . The physical situation is shown in Fig. 7-5.

Another example fits

$$P(1) = z^{1/2}, \quad (7.13)$$

which yields the field outside a rectangular corner

$$P(z) = \log z, \quad (7.14)$$

which yields the field for a unit charge, and

$$P(z) = 1/z, \quad (7.15)$$

which gives the field for the two-dimensional analog of an electric dipole, i.e., two parallel line charges with opposite volatilities, very close together.

We will not pursue this subject further in this course, but should emphasize that although the complex variable technique is often powerful, it is limited to two-dimensional problems; and also, it is an indirect method.

7.3 Plasma oscillations

We consider now some physical situations in which the field is determined, neither by fixed charges nor by charges on conducting surfaces, but by a combination of two physical phenomena. In other words, the field will be governed simultaneously by two sets of equations: (1) the equations from electromagnetism relating electric fields to charge distribution, and (2) an equation from another part of physics that determines the positions or motions of the charges in the presence of the field.

The first example that we will discuss is a dynamic one in which the motion of the charges is governed by Newton's laws. A simple example of such a situation occurs in a plasma, which is an ionized gas consisting of ions and free electrons distributed over a region in space. The ionosphere—the upper layer of the atmosphere—is an example of such a plasma. The ultraviolet rays from the sun knock

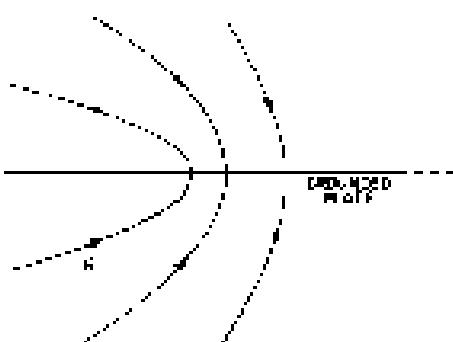

Fig. 7-5. The electric field near the edge of a thin grounded plate.

electrons off the molecules of the air, creating free electrons and ions—an ionized plasma. The positive ions are very much heavier than the electrons, so we may neglect the ionic motion; it is approximately zero at low temperature.

Let n_0 be the density of electrons in the undisturbed, equilibrium state. This must be equal to the density of positive ions, since the plasma is electrically neutral (after unbalance). Now we suppose that the electrons are somehow moved from equilibrium. One thing can happen. If the density of the electrons in one region is increased, they will repel each other and tend to return to their original equilibrium positions. As they return toward their original positions, they pick up kinetic energy, and instead of settling to rest in their equilibrium configuration, they overshoot the mark. They will oscillate back and forth. The situation is similar to what occurs in sound waves, in which the restoring force is the gas pressure. In a plasma, the restoring force is the electrical force on the electrons.

To simplify the discussion, we will consider only the case in which the electrons oscillate in one dimension, say x . Let's suppose that the electrons originally at $x = 0$, at time $t = 0$, displace themselves to equilibrium positions by a small amount of Δx . Since the electrons are nonrelativistic, their density n is, in general, being changed. The change in density is easily calculated. Referring to Fig. 7-6, the electrons initially contained between the two planes $x = 0$ and $x = \Delta x$ are moved and now occupy the interval between $x = -\Delta x$ and $x = \Delta x$. The number of electrons that were originally at $x = 0$ is proportional to $n_0 \Delta x$; the new number are now contained in the space whose width is $\Delta x + 2\Delta x$. The density has changed to

$$n = \frac{n_0 \Delta x}{\Delta x + 2\Delta x} = \frac{n_0}{1 + (2\Delta x/\Delta x)}. \quad (7.16)$$

If the change in density is small, we can write (using the binomial expansion for $(1 + x)^{-1}$)

$$n = n_0 \left(1 - \frac{\Delta x}{\Delta x}\right). \quad (7.17)$$

We assume that the positive ions do not move appreciably (in view of the much larger inertia), so their density remains n_0 . Each electron carries the charge $-e$, so the average charge density at any point is given by

$$\begin{aligned} \rho &= -e(n - n_0) \\ &= -en_0 \frac{\partial}{\partial x}. \end{aligned} \quad (7.18)$$

Let us now consider the differential, small for $\Delta x/\Delta x$.

The charge density is related to the electric field by Maxwell's equations, in particular,

$$\nabla \cdot \mathbf{D} = \frac{\rho}{\epsilon_0}. \quad (7.19)$$

If the problem is indeed one-dimensional (and if there are no other fields but the one due to the displacement of the electrons), the electric field E has a single component, E_x . Equation (7.19), together with (7.18), gives

$$\frac{\partial E_x}{\partial y} = \frac{\rho_0 \partial n_0}{\epsilon_0 \partial x}. \quad (7.20)$$

Integrating Eq. (7.20) gives

$$E_x = \frac{\rho_0}{\epsilon_0} x + K, \quad (7.21)$$

Since $E_x = 0$ when $x = 0$, the integration constant K is zero.

The force on an electron in the displaced position is

$$F_x = -\frac{\partial^2 \mathcal{H}}{\partial x^2} e. \quad (7.22)$$

a restoring force proportional to the displacement s of the electron. This leads to a harmonic oscillation of the electrons. The equation of motion of a displaced electron is

$$m_e \frac{d^2 s}{dt^2} = -\frac{\kappa_0 q_e^2}{\epsilon_0} s. \quad (7.23)$$

We find that s will vary harmonically. Its sinus variation will be $\propto \cos \omega t$, or—using the exponential notation of Vol. I—²

$$e^{i\omega t}. \quad (7.24)$$

The frequency of oscillation ω_p is determined from (7.23):

$$\omega_p^2 = \frac{\kappa_0 q_e^2}{\epsilon_0 m_e}, \quad (7.25)$$

and is called the plasma frequency. It is a characteristic number of the plasma.

When dealing with electron charges many people prefer to express their answers in terms of a quantity ϵ^2 defined by

$$\epsilon^2 = \frac{q_e^2}{4\pi\epsilon_0} \approx 2.3068 \times 10^{-24} \text{ newton-meter}^2. \quad (7.26)$$

Using this convention, Eq. (7.25) becomes

$$\omega_p^2 = \frac{4\pi e^2 n_e}{m_e}. \quad (7.27)$$

which is the form you will find in most books.

Thus we have found that a disturbance of a plasma will set up free oscillations of the electrons about their equilibrium positions at the natural frequency ω_p , which is proportional to the square root of the density of the electrons. The plasma electrons behave like a resonant system, such as those we described in Chapter 23 of Vol. I.

This natural resonance of a plasma has some interesting effects. For example, if our task is to propagate a radiowave through the ionosphere, our finds that it can penetrate only if the frequency is higher than the plasma frequency. Otherwise the signal is reflected back. We could use high frequencies if we wish to communicate with a satellite in space. On the other hand, if we wish to communicate with a radio station beyond the horizon, we must use frequencies lower than the plasma frequency, so that the signal will be reflected back to the earth.

Another interesting example of plasma oscillations occurs in nuclei. In a metal we have a contained plasma of positive ions, and free electrons. The density n_e is very high, so ω_p is also. But it should still be possible to observe the electron oscillations. Now, according to quantum mechanics, a harmonic oscillator with a natural frequency ω_p has energy levels which are separated by the the energy increment $\hbar\omega_p$. If, then, one shoots electrons through, say, an aluminum foil, and makes very careful measurements of the electron energies on the other side, one might expect to find that the electrons sometimes lost the energy $\hbar\omega_p$ to the plasma oscillations. This does indeed happen. It was first observed experimentally in 1956 that electrons which energies of a few hundred to a few thousand electron volts lost energy in incease when scattering from or going through a thin metal foil. The effect was not understood until 1953 when Hobbs and Pines* showed that the observations could be explained in terms of quantum excitations of the plasma oscillations in the metal.

7-4 Colloidal particles in an electrolyte

We turn to another phenomenon in which the actions of charges is governed by a potential that arises in part from the same charges. The resulting effects influence in an important way the behavior of colloids. A colloid consists of a suspension in water of small charged particles which, though microscopic, from an atomic point of view are still very large. If the colloidal particles were not charged, they would tend to coagulate into large lumps; but because of their charge, they repel each other and remain in suspension.

Now if there is also some salt dissolved in the water, it will be dissociated into positive and negative ions. (Such a solution of ions is called an electrolyte.) The negative ions are attracted to the colloid particles (assuming their charge is positive) and the positive ions are repelled. We will determine how the ions which surround such a colloidal particle are distributed in space.

To keep the ideas simple, we will again solve only a one-dimensional case. If we think of a colloidal particle as a sphere having a very large radius on an atomic scale, we can then treat a small part of its surface as a plane. (Whenever one is trying to understand a new phenomenon it is a good idea to take a somewhat oversimplified model; then, having understood the problem with that model, one is better able to proceed to tackle the more exact calculation.)

We suppose that the distribution of ions generates a charge density $\rho(x)$, and an electrical potential ϕ , related by the electrostatic law $\nabla^2\phi = -\rho/e$, or, for fields that vary in only one dimension, by

$$\frac{d^2\phi}{dx^2} = -\frac{\rho}{\epsilon_0}. \quad (7.25)$$

Now supposing there were such a potential $\phi(x)$, how would the ions distribute themselves in it? This we can determine by the principles of statistical mechanics. Our problem then is to determine ϕ so that the resulting charge density [from statistical mechanics (7.25)] satisfies (7.25).

According to statistical mechanics (see Chapter 46, Vol. II), particles in thermal equilibrium in a force field are distributed in such a way that the density n of particles at the position x is given by

$$n(x) = n_0 e^{-E(x)/kT}, \quad (7.26)$$

where $E(x)$ is the potential energy, k is Boltzmann's constant, and T is the absolute temperature.

We assume that the ions carry one electronic charge, positive or negative. At the distance x from the surface of a colloidal particle, a positive ion will have potential energy $q\phi(x)$, so that

$$E(x) = q\phi(x).$$

The density of positive ions, n_+ , is then

$$n_+(x) = n_0 e^{-q\phi(x)/kT}.$$

Similarly, the density of negative ions is

$$n_-(x) = n_0 e^{+q\phi(x)/kT}.$$

The total charge density is

$$\begin{aligned} \rho &= n_+ n_- = q n_-, \\ \rho &= q n_0 e^{-q\phi(x)/kT} e^{+q\phi(x)/kT}. \end{aligned} \quad (7.27)$$

Combining this with Eq. (7.25), we find that the potential ϕ must satisfy

$$\frac{d^2\phi}{dx^2} = -\frac{q\epsilon_0}{\epsilon_0} (e^{-q\phi(x)/kT} - e^{+q\phi(x)/kT}). \quad (7.28)$$

This equation is readily solved in general [multiply both sides by $2(\partial\phi/\partial x)$, and integrate with respect to x], but to keep the problem as simple as possible, we will consider here only the limiting case in which the potentials are small or the temperature T is high. The case where ϕ is small corresponds to a dilute solution. For these cases the exponent is small, and we can approximate

$$e^{16\pi\phi/kT} \approx 1 + \frac{8\pi\phi}{kT}. \quad (7.32)$$

Equation (7.31) then gives

$$\frac{d^2\phi}{dx^2} = + \frac{2\pi\sigma g^2}{\epsilon_0 kT} \psi(x). \quad (7.33)$$

Notice that this time the sign on the right is positive. The solutions for ϕ are not oscillatory, but exponential.

The general solution of Eq. (7.33) is

$$\phi = Ax^{-2/D} + Bx^{+2/D}, \quad (7.34)$$

with

$$D^2 = \frac{\epsilon_0 kT}{2\pi\sigma g^2}. \quad (7.35)$$

The constants A and B must be determined from the conditions of the problem. In our case, B must be zero; otherwise the potential would go to infinity for large x . So we have that

$$\phi = Ax^{-2/D}, \quad (7.36)$$

in which A is the potential at $x = 0$, the surface of the colloid particle.

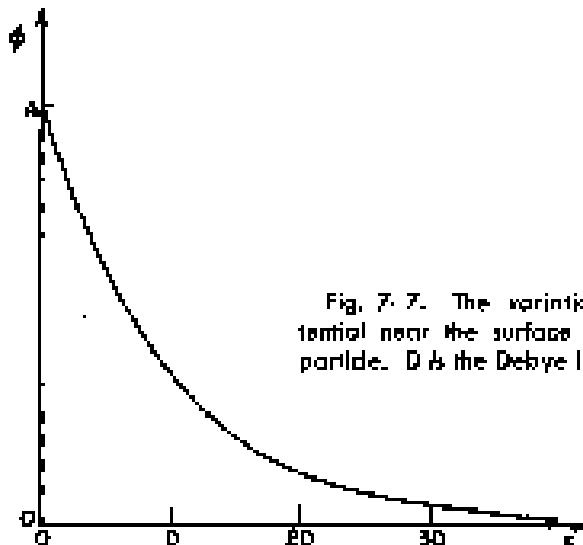

Fig. 7-7. The variation of the potential near the surface of a colloidal particle. D is the Debye length.

The potential decreases by a factor $1/e$ each time the distance increases by D , as shown in the graph of Fig. 7-7. The number D is called the Debye length, and is a measure of the thickness of the double layer surrounding a single charged particle in an electrolyte. Equation (7.36) says that the double layer thins with increasing concentration of the ions (n_i) or with decreasing temperature.

The constant A in Eq. (7.36) is easily obtained if we know the surface charge on the colloid particle. We know that

$$E_s = E_s(0) = \frac{f}{\epsilon_0}. \quad (7.37)$$

But E is also the gradient of ϕ :

$$E_s(0) = - \left. \frac{d\phi}{dx} \right|_0 = + \frac{A}{D}. \quad (7.38)$$

From which we get

$$A = \frac{\sigma D}{\epsilon_0}. \quad (7.39)$$

Using this result in (7.36), we find (by taking $\kappa = 0$) that the potential of the colloidal particle is

$$\phi(0) = \frac{\pi D}{\kappa_1}. \quad (7.40)$$

You will notice that this potential is the same as the potential difference across a condenser with a plate spacing D and a surface charge density σ .

We have said that the colloidal particles are kept apart by their electrical repulsion. But now we see that the field a little way from the surface of a particle is reduced by the ion sheath that collects around it. If the sheath get thin enough, the particles lose a good chance of knocking against each other. They will then stick, and the colloid will coagulate and precipitate out of the liquid. From our analysis, we understand why adding enough salt to a colloid should cause it to precipitate out. The process is called "salting out a colloid."

Another interesting example is the effect that a salt solution has on protein molecules. A protein molecule is a long complicated, and flexible chain of amino acids. The molecule has various charges on it, and it sometimes happens that there is a net charge, say negative, which is distributed along the chain. Because of mutual repulsion of the negative charges, the protein chain is kept stretched out. Now, if there are other similar chain molecules present in the solution, they will be kept apart by the same repulsive effects. We can, therefore, have a suspension of chain molecules in a liquid. But if we add salt to the liquid we change the properties of the suspension. As salt is added to the solution, increasing the Debye distance, the chain molecules can approach one another, and can also coil up. If enough salt is added to the solution, the chain molecules will precipitate out of the solution. There are many chemical effects of this kind that can be understood in terms of electrical forces.

7-5 The electrostatic field of a grid

As our last example, we would like to describe another interesting property of electric fields. It is one which is made use of in the design of electrical instruments, in the construction of vacuum tubes, and for other purposes. This is the character of the electric field near a grid of charged wires. To make the problem as simple as possible let us consider an array of parallel wires lying in a plane, the wires being infinitely long and with equal form spacing between them.

If we look at the field a large distance above the plane of the wires, we see a constant electric field, just as though the charge were uniformly spread over a plane. As we approach the grid of wires, the field begins to deviate from the uniform field; we find at large distances from the grid. We would like to estimate how close to the grid we have to be in order to see appreciable variations in the potential. Figure 7-5 shows a rough sketch of the equipotential surfaces at various distances from the grid. The closer we get to the grid, the larger the variations. As we travel parallel to the grid, we observe that the field fluctuates in a periodic manner.

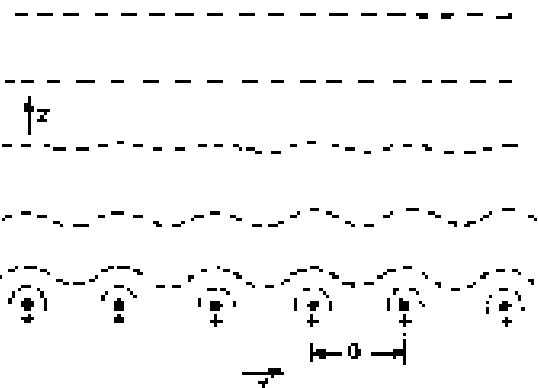

Fig. 7-5. Equipotential surfaces above a uniform grid of charged wires.

Now we have seen (Chapter 50, Vol. I) that any periodic quantity can be expressed as a sum of sine waves (Fourier's theorem). Let's see if we can find a suitable harmonic function that satisfies our field equations.

If the wires lie in the xz -plane and run parallel to the y -axis, then we might try terms like

$$\phi(x, z) = F_n(z) \cos \frac{2\pi n x}{a}, \quad (7.41)$$

where a is the spacing of the wires and n is the harmonic number. (We have assumed long wires, so there should be no variations with y .) A complete solution would be made up of a sum of such terms (for $n = 1, 2, 3, \dots$).

If this is to be a valid potential, it must satisfy Laplace's equation in the region above the wires (where there are no charges). That is,

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial z^2} = 0.$$

Trying this equation on the ϕ in (7.41), we find that

$$-\frac{4\pi^2 n^2}{a^2} F_n(z) \cos \frac{2\pi n x}{a} - \frac{d^2 F_n}{dx^2} \cos \frac{2\pi n x}{a} = 0. \quad (7.42)$$

or that $F_n(z)$ must satisfy

$$\frac{d^2 F_n}{dx^2} = -\frac{4\pi^2 n^2}{a^2} F_n. \quad (7.43)$$

So we must have

$$F_n = A_n e^{-k_n x}, \quad (7.44)$$

where

$$k_n = \frac{n}{2\pi a}. \quad (7.45)$$

We have found that if there is a Fourier component of the field of harmonic n , that component will decrease exponentially with a characteristic distance $x_0 = a/2\pi n$. For the first harmonic ($n = 1$), the amplitude falls by the factor $e^{-2\pi}$ (a large decrease) each time we increase x by one grid spacing a . The other harmonics fall off even more rapidly as we move away from the grid. We see that if we are only a few times the distance a away from the grid, the field is very nearly uniform, i.e., the oscillating terms are small. There would, of course, always remain the "zero harmonic" field

$$\phi_0 = -E_0 z$$

to give the uniform field at large z . For a complete solution, we would combine this term with a sum of terms like (7.41) with F_n from (7.44). The coefficients A_n would be adjusted so that the total sum would, when r is finite, give an electric field that would fit the charge density λ of the grid wires.

The method we have just developed can be used to explain why electrostatic shielding by means of a screen is often just as good as with a solid metal sheet. Except within a distance from the screen a few times the spacing of the screen wires, the fields inside a closed screen are zero. We see why copper screen (higher and cheaper than copper sheet) is often used to shield sensitive electrical equipment from external disturbing fields.

Electrostatic Energy

8-1 The electrostatic energy of charges. A uniform sphere

In the study of mechanics, one of the most interesting and useful discoveries was the law of the conservation of energy. The expressions for the kinetic and potential energies of a mechanical system helped us to discover connections between the states of a system at two different times without having to look into the details of what was occurring in between. We wish now to consider the energy of electrostatic systems. In electricity also the principle of the conservation of energy will be useful for discovering a number of interesting things.

The law of the energy of interaction in electrodynamics is very simple; we have, in fact, already discussed it. Suppose we have two charges q_1 and q_2 separated by the distance r_{12} . There is stored energy in the system, because a certain amount of work was required to bring the charges together. We have already calculated the work done in bringing two charges together from a large distance. It is

$$-\frac{q_1 q_2}{4\pi \epsilon_0 r_{12}}. \quad (8.1)$$

We also know, from the principle of superposition, that if we have many charges present, the total force on any charge is the sum of the forces from the others. It follows, therefore, that the total energy of a system of n number of charges is the sum of terms due to the mutual interaction of each pair of charges. If q_i and q_j are any two of the charges and r_{ij} is the distance between them (Fig. 8-1), the energy of that particular pair is

$$\frac{q_i q_j}{4\pi \epsilon_0 r_{ij}}. \quad (8.2)$$

The total electrostatic energy U is the sum of the energies of all possible pairs of charges:

$$U = \sum_{all \; i, j} \frac{q_i q_j}{4\pi \epsilon_0 r_{ij}}. \quad (8.3)$$

If we have a distribution of charge specified by a charge density ρ , the sum of Eq. (8.3) is, of course, to be replaced by an integral.

We shall concern ourselves with two aspects of this energy. One is the application of the concept of energy to electrostatic problems; the other is the evaluation of the energy in different ways. Sometimes it is easier to compute the work done for some special case than to evaluate the sum in Eq. (8.3) or the corresponding integral. As an example, let us calculate the energy required to assemble a sphere of charge with a uniform charge density. The energy is just the work done in gathering the charges together from infinity.

Imagine that we assemble the sphere by building up a succession of thin spherical layers of infinitesimal thickness. At each stage of the process, we gather a small amount of charge and put it in a thin layer from r to $r + dr$. We continue the process until we arrive at the final radius R (Fig. 8-2). If Q_r is the charge of the sphere when it has been built up to the radius r , the work done in bringing a charge dQ to it is

$$dU = \frac{Q_r dQ}{4\pi \epsilon_0 r}. \quad (8.4)$$

8-5 Energy in the electromagnetic field

8-6 The energy of a point charge

Review: Chapter 4, Vol. I, Conservation of Energy
Chapters 13 and 14, Vol. I.
Work and Potential Energy

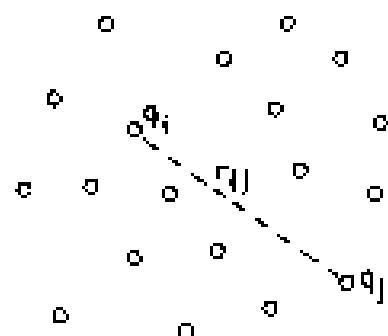

Fig. 8-1. The electrostatic energy of a system of particles is the sum of the electrostatic energy of each pair.

If the density of charge in the sphere is ρ , the charge Q_r is

$$Q_r = \rho \cdot \frac{4}{3} \pi r^3,$$

and the charge dQ is

$$dQ = \rho \cdot 4\pi r^2 dr.$$

Equation (8.4) becomes

$$dU = \frac{4\pi\rho^2 r^4 dr}{3\varepsilon_0}. \quad (8.5)$$

The total energy required to assemble the sphere is the integral of dU from $r = 0$ to $r = a$,

$$U = \frac{4\pi\rho^2 a^5}{15\varepsilon_0}. \quad (8.6)$$

Or if we wish to express the result in terms of the total charge Q of the sphere,

$$U = \frac{3}{5} \frac{Q^2}{4\pi\varepsilon_0 a^2}. \quad (8.7)$$

The energy is proportional to the square of the total charge and inversely proportional to the radius. We can also interpret Eq. (8.7) as saying that the average of $(1/r_{ij})$ for all pairs of points in the sphere is $3/5a$.

8-2 The energy of a condenser. Forces on charged conductors

We consider now the energy required to charge a condenser. If the charge Q has been taken from one of the conductors of a condenser and placed on the other, the potential difference between them is

$$V = \frac{Q}{C}, \quad (8.8)$$

where C is the capacity of the condenser. How much work is done in charging the condenser? Proceeding as for the sphere, we imagine that the condenser has been charged by transferring charge from one plate to the other in small increments dQ . The work required to transfer the charge dQ is

$$dU = V dQ.$$

Taking V from Eq. (8.8), we write

$$dU = \frac{Q dQ}{C}.$$

Or integrating from zero charge to the final charge Q , we have

$$U = \frac{1}{2} \frac{Q^2}{C}. \quad (8.9)$$

This energy can also be written as

$$U = \frac{1}{2} CV^2. \quad (8.10)$$

Recalling that the capacity of a conducting sphere (relative to infinity) is

$$C_{\text{sphere}} = 4\pi\varepsilon_0 a,$$

we can immediately get from Eq. (8.9) the energy of a charged sphere,

$$U = \frac{1}{2} \frac{Q^2}{4\pi\varepsilon_0 a}. \quad (8.11)$$

This, of course, is also the energy of a thin spherical shell of total charge Q and is just $5/6$ of the energy of a uniformly charged sphere, Eq. (8.7).

We now consider applications of the idea of electrostatic energy. Consider the following questions: What is the force between the plates of a condenser? Or what is the torque about some axis of a charged conductor in the presence of another with opposite charge? Such questions are easily answered by using our result Eq. (8.9) for electrostatic energy of a condenser, together with the principle of virtual work (Chapters 4, 13, and 14 of Vol. I).

Let's use this method for determining the force between the plates of a parallel-plate condenser. If we imagine that the spacing of the plates is increased by the small amount Δz , then the mechanical work done from the outside in moving the plates would be

$$\Delta W = F \Delta z, \quad (8.12)$$

where F is the force between the plates. This work must be equal to the change in the electrostatic energy of the condenser.

By Eq. (8.9), the energy of the condenser was originally

$$U = \frac{1}{2} \frac{Q^2}{C}.$$

The change in energy (if we do not let the charge change) is

$$\Delta U = \frac{1}{2} Q^2 \Delta \left(\frac{1}{C} \right). \quad (8.13)$$

Equations (8.12) and (8.13), we have

$$F \Delta z = - \frac{Q^2}{2C^2} \Delta C. \quad (8.14)$$

This can also be written as

$$F \Delta z = - \frac{Q^2}{2C^2} \Delta C. \quad (8.15)$$

The force, of course, results from the attraction of the charges on the plates, but we see that we do not have to worry so much about how they are distributed; everything we need is taken care of in the capacity C .

It is easy to see how the idea is extended to conductors of any shape, and for other components of the force. In Eq. (8.14), we replace Δ by the component we are looking for, and we replace Δz by a small displacement in the corresponding direction. Or if we have an electrode with a pivot and we want to know the torque τ , we write the virtual work as

$$\Delta W = \tau \Delta \theta,$$

where $\Delta \theta$ is a small angular displacement. Of course, $\Delta(1/C)$ must be the change in $1/C$ which corresponds to $\Delta \theta$. We could, in this way, find the torque on the movable plates in a variable condenser of the type shown in Fig. 8-3.

Returning to the special case of a parallel-plate condenser, we can use the formula we derived in Chapter 6 for the capacity:

$$\frac{1}{C} = \frac{\epsilon_0 A}{d}, \quad (8.16)$$

where A is the area of each plate. If we increase the separation by Δz ,

$$\Delta \left(\frac{1}{C} \right) = \frac{\Delta z}{\epsilon_0 d}.$$

From Eq. (8.14) we get that the force between the plates is

$$F = \frac{Q^2}{2\epsilon_0 d^2}. \quad (8.17)$$

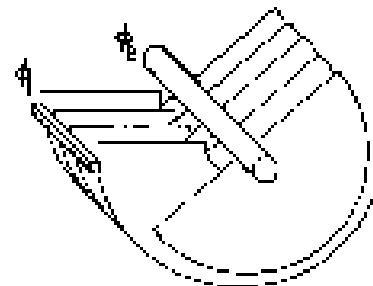

Fig. 8-3. What is the torque on a variable capacitor?

Let's look at Eq. (3.17) a little more closely, and see if we can tell how the force varies. To do this, let's integrate implicitly we write

$$Q = \sigma A.$$

Eq. (3.17) can be rewritten as

$$F = \frac{1}{2} Q \frac{\sigma}{\epsilon_0}.$$

Or, since the electric field between the plates is

$$E_s = \frac{\sigma}{\epsilon_0},$$

then

$$F = \frac{1}{2} Q E_s. \quad (3.18)$$

One would immediately guess that the force acting on one plate is the charge Q on the plate times the field acting on the charge. But we have a surprising answer of ourself. The reason is that E_s is not the field of the charges. If we imagine that the charge at the surface of the plate occupies a thin layer, as indicated in Fig. 3-1, the field will vary from zero at the outer boundary of the layer to E_s in the space outside of the plate. The average field acting on the surface charge is $E_s/2$. That is why the factor one-half is in Eq. (3.18).

You should notice that in computing the virtual work we have assumed that the charge on the conductor was constant. That it was not electrically connected to other objects, and so the total charge could not change.

Suppose we had imagined that the conductor was held at a constant potential difference as we made the virtual displacement. Then we should have taken

$$U = \frac{1}{2} C V^2$$

and in place of Eq. (R.15) we would have had

$$\Delta U = \frac{1}{2} C V^2 \Delta C,$$

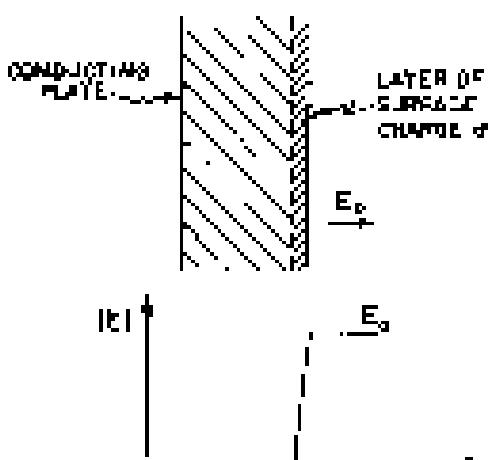

which gives a force equal in magnitude to the one in Eq. (3.18) (because $V = (1/C)$), but with the opposite sign! Surely the force between the condenser plates doesn't reverse in sign as we disassemble it from its charging source. Also, we know that two plates with opposite electrical charges must attract. The principle of virtual work has been incorrectly applied in the second case: we have not taken into account the virtual work done on the charging source. That is, to keep the potential constant at V as the capacity changes, a charge $V \Delta C$ must be supplied by a source of charge. But this charge is supplied at a potential V , so the work done by the electrical system which keeps the potential constant is $V^2 \Delta C$. The mechanical work δU plus this electrical work $V^2 \Delta C$ together make up the change in the total energy $\frac{1}{2} V^2 \Delta C$ of the condenser. Therefore $F \delta u$ is $-V^2 \Delta C$, as before.

3.3 The electrostatic energy of an ionic crystal

We now consider an application of the concept of electrostatic energy in atomic physics. We cannot easily measure the forces between atoms, but we are often interested in the energy differences between one atomic arrangement and another, as, for example, the energy of a chemical change. Since atomic forces are basically electrical, chemical energies are in large part just electrostatic energies.

Let's consider, for example, the electrostatic energy of an ionic lattice. An ionic crystal like NaCl consists of positive and negative ions which repel each other if they get too close. They attract sufficiently until they begin to touch; then there is a resultant force which goes up very rapidly if we try to push them closer together.

For our first approximation, therefore, we imagine a set of rigid spheres that represent the atoms in a salt crystal. The structure of the lattice has been determined by x-ray diffraction. It is a cubic lattice like a three-dimensional

checkerboard. Figure 8-5 shows a cross-sectional view. The spacing of the ions is 2.81 Å ($\sim 2.81 \times 10^{-8}$ cm).

If our picture of this system is correct, we should be able to check it by asking the following question: How much energy will it take to pull all these ions apart—that is, to separate the crystal completely into ions? This energy should be equal to the heat of vaporization of NaCl plus the energy required to dissociate the molecules into ions. This total energy to separate NaCl to ions is determined experimentally to be 7.92 electron volts per molecule. Using the conversion

$$1 \text{ ev} = 1.602 \times 10^{-19} \text{ joule},$$

and Avogadro's number for the number of molecules in a mole,

$$N_A = 6.02 \times 10^{23},$$

the energy of vaporization can also be given as

$$W = 7.92 \times 10^3 \text{ joules/mole}.$$

Physical chemists prefer to use energy units the kilocalorie, which is 4190 joules; so that 1 ev per molecule is 23 kilocalories per mole. A chemist would then say that the dissociation energy of NaCl is

$$W = 183 \text{ kcal/mole}.$$

Can we obtain this chemical energy theoretically by computing how much work it would take to pull apart the crystal? According to our theory, this work is the sum of the potential energies of all the pairs of ions. The easiest way to figure out this sum is to pick out a particular ion and compute its potential energy with each of the other ions. That will give us twice the energy per ion, because the energy belongs to the pair of charges. If we want the energy to be associated with one particular ion, we should take half the sum. But we really want the energy per molecule, which contains two ions, so that the sum we compute will give directly the energy per molecule.

The energy of an ion with one of its nearest neighbors is e^2/a , where $e^2 = q^2/4\pi\epsilon_0$, and a is the inter-ion spacing between ions. (We are considering monovalent ions.) This energy is 5.12 ev, which we already see is going to give us a result of the correct order of magnitude. But it is still a long way from the full sum of terms we need.

Let's begin by summing all the terms from the ions along a straight line. Considering that the ion marked Na in Fig. 8-5 is very special now, we shall consider first those ions on a horizontal line with it. There are two nearest Cl ions with negative charges, each at the distance a . Then there are two positive ions at the distance $2a$, etc. Calling the energy of this sum U_1 , we write

$$\begin{aligned} U_1 &= \frac{e^2}{a} \left(-\frac{1}{1} - \frac{2}{2} - \frac{2}{3} - \frac{2}{4} + \dots \right) \\ &= -\frac{2e^2}{a} \left(1 - \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + \dots \right). \end{aligned} \quad (8.19)$$

The series converges slowly, so it is difficult to evaluate numerically, but it is known to be equal to $-\ln 2$. So

$$U_1 = -\frac{2e^2}{a} \ln 2 = -1.389 \frac{e^2}{a}. \quad (8.20)$$

Now consider the next adjacent line of ions above. The nearest is negative and at the distance a . Then there are two positives at the distance $\sqrt{2}a$. The next pair are at the distance $\sqrt{3}a$, the next at $\sqrt{5}a$, and so on. So for the whole line we get the series

$$\frac{e^2}{a} \left(-\frac{1}{1} + \frac{2}{\sqrt{2}} + \frac{2}{\sqrt{3}} - \frac{2}{\sqrt{5}} + \dots \right). \quad (8.21)$$

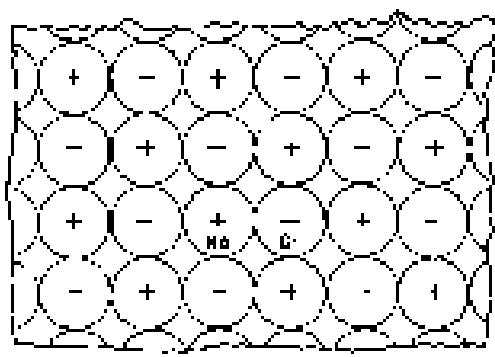

Fig. 8-5

Fig. 8-5. Cross section of a salt crystal on an atomic scale. The checkerboard arrangement of Na and Cl ions is the same in the two cross sections perpendicular to the one shown. (See Vol. I, Fig. 1-7.)

There are, over such lines; above, below, in front, and in back. Then there are the four lines which are the nearest lines on diagonals, and so on and on.

If you work patiently through for all the lines, and then take the sum, you find that the grand total is

$$U = 1.747 \frac{e^2}{a}$$

which is just somewhat more than what we obtained in (9.20) for the first line. Using $e^2/a = 5.12$ ev, we get

$$U = 8.94 \text{ ev.}$$

Our answer is about 10% above the experimentally observed energy. It shows that our idea that the whole lattice is held together by electrical Coulomb forces is fundamentally sound. This is the first time that we have obtained a specific property of a macroscopic substance from a knowledge of atomic physics. We will do much more later. The subject that tries to understand the behavior of bulk matter in terms of the laws of atomic behavior is called solid-state physics.

Now what about the error in our calculation? Why is it not exactly right? It is because of the repulsion between the ions at close distances. They are not perfectly rigid spheres, so when they are close together they are partly squashed. They are not very soft, so they squash only a little bit. Some energy, however, is used in deforming them, and when the ions are pulled apart this energy is released. The actual energy needed to pull the ions apart is a little less than the energy that we calculated; the repulsion helps in overcoming the electrostatic attraction.

Is there any way we can make an allowance for the contribution? We could if we knew the law of the repulsive force. We are not ready to analyze the details of this repulsive mechanism, but we can get some idea of its characteristics from atomic large-scale measurements. From a measurement of the compressibility of the whole crystal, it is possible to obtain a quantitative idea of the law of repulsion between the ions and therefore of its contribution to the energy. In this way it has been found that this contribution must be 1/9.4 of the contribution from the electrostatic attraction and, of course, of opposite sign. If we subtract this contribution from the pure electrostatic energy, we obtain 7.99 ev for the dissociation energy per molecule. It is much closer to the observed result of 7.92 ev, but still not in perfect agreement. There is one more thing we haven't taken into account: we have made no allowance for the kinetic energy of the crystal vibrations. If a correction is made for this effect, very good agreement with the experimental number is obtained. The ideas are then correct; the major contribution to the energy of a crystal like NaCl is electrostatic.

9-4 Electrostatic energy in nuclei

We will now take up another example of electrostatic energy in atomic physics, the electrical energy of atomic nuclei. Before we do this we will have to discuss some properties of the main forces (called nuclear forces) that build the protons and neutrons together in a nucleus. In the early days of the discovery of nuclei—and of the neutrons and protons that make them up—it was hoped that the law of the strong, nonelectrical part of the force between, say, a proton and another proton would have some simple law, like the inverse square law of electricity. For such was had determined this law of force, and the corresponding force between a proton and a neutron, and a neutron and a neutron, it would be possible to describe theoretically the complete behavior of these particles in nuclei. Therefore a big program was started for the study of the scattering of protons, in the hope of finding the law of force between them; but after thirty years of effort, nothing simple has emerged. A considerable knowledge of the force between proton and proton has been accumulated, but we find that the force is as complicated as it can possibly be.

What we mean by "as complicated as it can be" is that the force depends on as many things as it possibly can.

First, the force is not a simple function of the distance between the two protons. At large distances there is no attraction, but at closer distances there is a repulsion. The distance dependence is a complicated function, still imperfectly known.

Second, the force depends on the orientation of the protons' spins. The protons have a spin, and any two interacting protons may be spinning with like or against movements in the same direction or in opposite directions. And the force is different when the spins are parallel from what it is when they are antiparallel, as in (a) and (b) of Fig. 8-6. The difference is quite large; it is not a small effect.

Third, the force is considerably different when the separation of the two protons is in the direction parallel to their spins, as in (c) and (d) of Fig. 8-6, than it is when the separation is in a direction perpendicular to the spins, as in (e) and (f).

Fourth, the force depends, as it does in magnetism, on the velocity of the protons, only much more strongly than in magnetism. And this velocity-dependent force is not a relativistic effect; it is strong even at speeds much less than the speed of light. Furthermore, this part of the force depends on other things besides the magnitude of the velocity. For instance, when a proton is moving near another proton, the force is different when the orbital motion has the same direction of rotation as the spin, as in (e) of Fig. 8-6, than when it has the opposite direction of rotation, as in (f). This is called the "spin-orbit" part of the force.

The force between a proton and a neutron and between a neutron and a neutron are also equally complicated. To this day we do not know the machinery behind these forces—that is to say, any simple way of understanding them.

There is, however, one important way in which the nuclear forces are simpler than they could be. That is that the nuclear force between two neutrons is the same as the force between a proton and a neutron, which is the same as the force between two protons! If, in any nuclear situation, we replace a proton by a neutron (or vice versa), the nuclear interactions are not changed. The "fundamental reason" for this equality is not known, but it is an example of an important principle that can be extended also to the interaction laws of other strongly interacting particles—such as the π -mesons and the "strange" particles.

This fact is nicely illustrated by the locations of the energy levels in similar nuclei. Consider a nucleus like B^{11} (boron-eleven), which is composed of five protons and six neutrons. In the nucleus the eleven particles interact with one another in a most complicated dance. Now, there is one configuration of all the possible interactions which has the lowest possible energy; this is the normal state of the nucleus, and is called the ground state. If the nucleus is disturbed (for example, by being struck by a high-energy proton or other particle) it can be put into any number of other configurations, called excited states, each of which will have a characteristic energy that is higher than that of the ground state. In nuclear physics research, such as is carried on with Van de Graaff generators (for example, in Caltech's Kelling and Sloan Laboratories), the energies and other properties of these excited states are determined by experiment. The energies of the fifteen lowest-known excited states of B^{11} are shown in a two-dimensional graph on the left half of Fig. 8-7. The lowest horizontal line represents the ground state. The first excited state has an energy 2.14 Mev higher than the ground state, the next an energy 4.46 Mev higher than the ground state, and so on. The study of nuclear physics attempts to find an explanation for this rather complicated pattern of energies; there is as yet, however, no complete general theory of such nuclear energy levels.

If we replace one of the neutrons in B^{11} with a proton, we have the nucleus of an isotope of carbon, C^{12} . The energies of the lowest sixteen excited states of C^{12} have also been measured; they are shown in the right half of Fig. 8-7. (The broken lines indicate levels for which the experimental information is questionable.)

Looking at Fig. 8-7, we see a striking similarity between the patterns of the energy levels in the two nuclei. The first excited states are about 2 Mev above the ground states. There is a large gap of about 2.3 Mev to the second excited state, then a small jump of only 0.5 Mev to the third level. Again, between the fourth and fifth levels, a big jump; but between the fifth and sixth a tiny separation of the

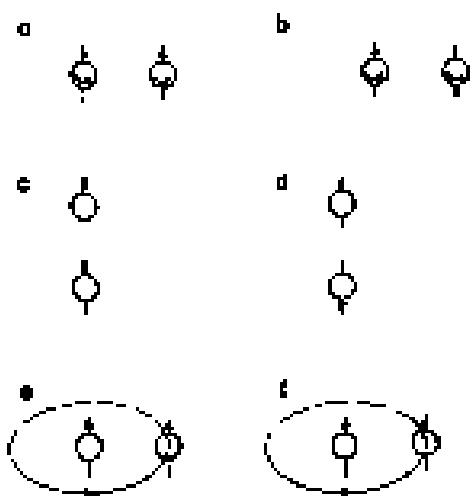

Fig. 8-6. The force between two protons depends on every possible parameter.

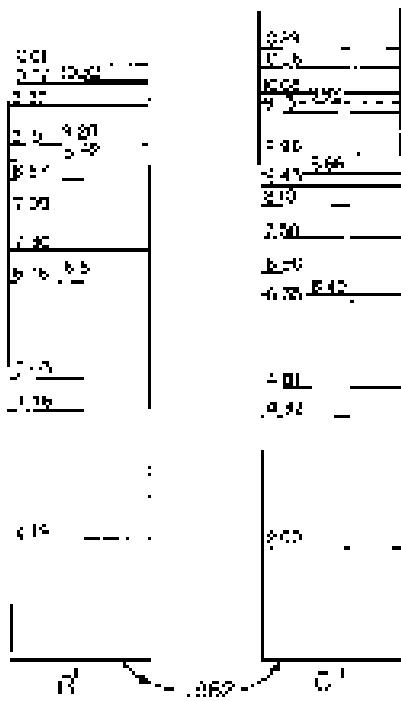

Fig. 8-7. The energy levels of B^{11} and C^{12} (energies in Mev). The ground state of C^{12} is 1.982 Mev higher than that of B^{11} .

order of 0.1 Mev. And so on. After about the tenth level, the correspondence seems to become bad, but can still be seen if the levels are labeled with their other defining characteristics—for instance, their angular momentum and what they do to lose their extra energy.

The striking similarity of the patterns of the energy levels of B^{11} and C^{11} is surely not just a coincidence. It must reveal some physical law. It shows, in fact, that even in the complicated situation in a nucleus, replacing a neutron by a proton makes very little change. This can mean only that the neutron-nucleus and proton-nucleus forces must be nearly identical. Only then would we expect the nuclear configurations with five protons and six neutrons to be the same as with six protons and five neutrons.

Notice that the properties of these two nuclei tell us nothing about the neutron-proton force; there are the same number of neutron-proton combinations in both nuclei. But if we compare two other nuclei, such as C^{14} , which has six protons and eight neutrons, with N^{14} , which has seven of each, we find a similar correspondence of energy levels. So we can conclude that the p-p, n-n, and p-n forces are identical in all their complexities. There is an unexpected principle in the laws of nuclear forces. Even though the force between each pair of nuclear particles is very complicated, the force between the three possible different pairs is the same.

But there are some small differences. The levels do not correspond exactly; also, the ground state of C^{11} has an absolute energy (its mass) which is higher than the ground state of B^{11} by 1.982 Mev. All the other levels are also higher in absolute energy by this same amount. So the forces are not exactly equal. But we know very well that the complete forces are not exactly equal; there is an electrostatic force between two protons because each has a positive charge, while between two neutrons there is no such electrical force. Can we perhaps explain the differences between B^{11} and C^{11} by the fact that the electrical interaction of the protons is different in the two cases? Perhaps so; the remaining minor differences in the levels are caused by electrical effects? Since the nuclear forces are so much stronger than the electrical force, electrical effects would have only a small perturbing effect on the energies of the levels.

In order to check this idea, or rather to find out what the consequences of this idea are, we first consider the difference in the ground-state energies of the two nuclei. To take a very simple model, we suppose that the nuclei are spheres of radius r (to be determined), containing Z protons. If we remember that a nucleus is like a sphere with uniform charge density, we would expect the electrostatic energy (from Eq. 8.7) to be

$$U = \frac{3}{5} \frac{(Zq_r)^2}{4\pi\epsilon_0 r}, \quad (8.22)$$

where q is the elementary charge of the proton. Since Z is five for B^{11} and six for C^{11} , their electrostatic energies would be different.

With such a small number of protons, however, Eq. (8.22) is not quite correct. If we compute the electrical energy between all pairs of protons, considered as points which we assume to be nearly uniformly distributed throughout the sphere, we find that in Eq. (8.22) the quantity Z^2 should be replaced by $Z(Z - 1)$, so the energy is

$$U = \frac{3}{5} \frac{Z(Z - 1)q^2}{4\pi\epsilon_0 r} = \frac{3}{5} \frac{Z(Z - 1)e^2}{r}. \quad (8.23)$$

If we knew the nuclear radius r , we could use (8.23) to find the electrostatic energy difference between B^{11} and C^{11} . But let's do the opposite; let's instead use the observed energy difference to compute the radius, assuming that the energy difference is all electrostatic in origin.

That is, however, not quite right. The energy difference of 1.982 Mev between the ground states of B^{11} and C^{11} includes the rest energies—that is, the energy $m c^2$ of all the particles. In going from B^{11} to C^{11} , we replace a neutron by a proton, which has less mass. So part of the energy difference is the difference in the rest energies of a neutron and a proton, which is 0.784 Mev. The difference,

to be accounted for by electrostatic energy, is thus more than 1.982 Mev; it is
 $1.982 + 0.784 = 2.766$ Mev.

Using this energy in Eq. (8.23), for the radius of either B^{11} or C^{11} we find

$$r = 3.12 \times 10^{-12} \text{ cm.} \quad (8.24)$$

Does this number have any meaning? To see whether it does, we should compare it with atomic size determinations of the radius of these nuclei. For example, we can make another measurement of the radius of a nucleus by seeing how it scatters beta particles. From such measurements it has been found, in fact, that the density of matter in all nuclei is nearly the same, i.e., their volumes are proportional to the number of particles they contain. If we let A be the number of protons and neutrons in a nucleus (a number very nearly proportional to its mass), it is found that its radius is given by

$$r = A^{1/3} r_0 \quad (8.25)$$

where

$$r_0 = 1.2 \times 10^{-12} \text{ cm.} \quad (8.26)$$

From these measurements we find that the radius of a B^{11} (or a C^{11}) nucleus is expected to be

$$r = (1.2 \times 10^{-12})(11)^{1/3} = 2.7 \times 10^{-12} \text{ cm.}$$

Comparing this result with (8.24), we see that our assumptions that the energy difference between B^{11} and C^{11} is electrostatic is fairly good; the discrepancy is only about 15% (not bad for our first nuclear computation!).

The reason for the discrepancy is probably the following. According to the current understanding of nuclei, an even number of nuclear particles—in the case of B^{11} , five neutrons together with five protons—make a kind of core; when one more particle is added to this core, it revolves around the outside to make a new spherical nucleus, rather than being absorbed. If this is so, we should have taken a different electrostatic energy for the additional proton. We should have taken the excess energy of C^{11} over B^{11} to be just

$$\frac{Z_p e^2}{4\pi \epsilon_0 r},$$

which is the energy needed to add one more proton to the outside of the core. This number is just 5/6 of what Eq. (8.21) predicts, so the new prediction for the radius is 5/6 of (8.24), which is in much closer agreement with what is directly measured.

We can draw two conclusions from this agreement. One is that the electrical laws appear to be working at dimensions as small as 10^{-12} cm. The other is that we have verified the remarkable coincidence that the nonelectrical part of the forces between proton and proton, neutron and neutron, and proton and neutron are all equal.

8-5 Energy in the electrostatic field

We now consider other methods of calculating electrostatic energy. They can all be derived from the basic relation Eq. (8.3), the sum, over all pairs of charges, of the mutual energies of each charge-pair. First we wish to write an expression for the energy of a charge distribution. As usual, we consider that each volume element dV contains the element of charge ρdV . Then Eq. (8.3) should be written

$$U = \frac{1}{2} \int_{\text{all space}} \frac{\rho(1)\rho(2)}{4\pi \epsilon_0 r_{12}} dV_1 dV_2. \quad (8.27)$$

Notice the factor $\frac{1}{2}$, which is introduced because in the double integral over dV_1 and dV_2 we have counted all pairs of charge elements twice. (There is no convenient way of writing an integral that keeps track of the pairs so that each pair is counted only once.) Next we notice that the integral over dV_2 in (8.27) is just the potential at (1). That is,

$$\int \frac{\rho(2)}{4\pi\epsilon_0 r_{12}} dV_2 = \phi(1),$$

so that (8.27) can be written as

$$U = \frac{1}{2} \int \rho(1)\phi(1) dV_1.$$

Or, since the point (2) no longer appears, we can simply write

$$U = \frac{1}{2} \int \rho\phi dV. \quad (8.28)$$

This equation can be interpreted as follows. The potential energy of the charge ρdV is the product of this charge and the potential at the same point. The total energy is therefore the integral over $d\rho dV$. But there is again the factor $\frac{1}{2}$. It is still required because we are counting energies twice. The mutual energies of two charges is the charge of one times the potential at it due to the other. Or, it can be taken as the second charge times the potential at it from the first. Thus for two point charges we would write

$$U = q_1\phi(1) = q_1 \frac{q_2}{4\pi\epsilon_0 r_{12}}$$

or

$$U = q_2\phi(1) = q_2 \frac{q_1}{4\pi\epsilon_0 r_{12}}.$$

Notice that we could also write

$$U = \frac{1}{2}(q_1\phi(1) + q_2\phi(1)). \quad (8.29)$$

The integral in (8.28) corresponds to the sum of both terms in the brackets of (8.29). That is why we need the factor $\frac{1}{2}$.

An interesting question is: Where is the electrostatic energy located? One might also ask: Who cares? What is the meaning of such a question? If there is a pair of interacting charges, the combination has a certain energy. Do we need to say that the energy is located at one of the charges or the other, or in both, or in between? These questions may not make sense because we really know only that the total energy is conserved. The idea that the energy is located somewhere is not necessary.

Yet suppose that it did make sense to say, in general, that energy is located at a certain place, as it does for heat energy. We might then extend our principle of the conservation of energy with the idea that if the energy in a given volume changes, we should be able to account for the change by the flow of energy into or out of that volume. You realize that our early statement of the principle of the conservation of energy is still perfectly all right if some energy disappears at one place and appears somewhere else far away without anything passing (that is, without any special phenomena occurring) in the space between. We are, therefore, now discussing an extension of the idea of the conservation of energy. We might call it a principle of the local conservation of energy. Such a principle would say that the energy in any given volume changes only by the amount that flows into or out of the volume. It is indeed possible that energy is conserved locally in such a way. If it is, we would have a much more detailed law than the simple statement of the conservation of total energy. It does turn out that in nature energy is conserved locally. We can find formulas for where the energy is located and how it travels from place to place.

There is also a physical reason why it is imperative that we be able to say where energy is located. According to the theory of gravitation, all mass is a source

of gravitational attraction. We also know, by $E = mc^2$, that mass and energy are equivalent. All energy is, therefore, a source of gravitational force. If we could not locate the energy, we could not locate all the mass. We would not be able to say where the sources of the gravitational field are located. The theory of gravitating would be incomplete.

If we restrict ourselves to electrostatics there is really no way to tell where the energy is located. The complete Maxwell equations of electrodynamics give us much more information (although even then the answer is, strictly speaking, not unique). We will therefore discuss this question in detail again in a later chapter. We will give you now only the result for the particular case of electrostatics. The energy is located in space, where the electric field is. This seems reasonable because we know that when charges are accelerated they radiate electric fields. We would like to say that when light or radio waves travel from one point to another, they carry their energy with them. But there are no charges in the waves. So we would like to locate the energy where the electromagnetic field is and not at the charges from which it comes. We thus describe the energy, not in terms of the charges, but in terms of the fields they produce. We can, in fact, show that Eq. (8.28) is numerically equal to

$$U = \frac{\epsilon_0}{2} \int E \cdot E dV. \quad (8.30)$$

We can then interpret this formula as saying that when an electric field is present, there is located in space an energy whose density (energy per unit volume) is

$$\epsilon = \frac{\epsilon_0}{2} E \cdot E = \frac{\epsilon_0 E^2}{2}. \quad (8.31)$$

This idea is illustrated in Fig. 8-8.

To show that Eq. (8.30) is consistent with our laws of electrodynamics, we begin by introducing into Eq. (8.28) the relation between ρ and ϕ that we obtained in Chapter 6:

$$\rho = -\epsilon_0 \nabla^2 \phi.$$

We get

$$U = -\frac{\epsilon_0}{2} \int \phi \nabla^2 \phi dV. \quad (8.32)$$

Writing out the components of the integrand, we see that

$$\begin{aligned} \phi \nabla^2 \phi &= \phi \left(\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} \right) \\ &= \frac{\partial}{\partial x} \left(\phi \frac{\partial \phi}{\partial x} \right) - \left(\frac{\partial \phi}{\partial x} \right)^2 + \frac{\partial}{\partial y} \left(\phi \frac{\partial \phi}{\partial y} \right) - \left(\frac{\partial \phi}{\partial y} \right)^2 + \frac{\partial}{\partial z} \left(\phi \frac{\partial \phi}{\partial z} \right) - \left(\frac{\partial \phi}{\partial z} \right)^2 \\ &= \nabla \cdot (\phi \nabla \phi) - (\nabla \phi) \cdot (\nabla \phi). \end{aligned} \quad (8.33)$$

Our energy integral is then

$$U = \frac{\epsilon_0}{2} \int (\nabla \phi) \cdot (\nabla \phi) dV = \frac{\epsilon_0}{2} \int \nabla \cdot (\phi \nabla \phi) dV.$$

We can use Gauss' theorem to change the second integral into a surface integral:

$$\int_{V_{ext}} \nabla \cdot (\phi \nabla \phi) dV = \int_{S_{ext}} (\phi \nabla \phi) \cdot n d\sigma. \quad (8.34)$$

We evaluate the surface integral in the case that the surface goes to infinity (so the volume integrals become integrals over all space), supposing that all the charges are located within some finite distance. The simple way to proceed is to take a spherical surface of enormous radius R whose center is at the origin of coordinates. We know that when we are very far away from all charges, ϕ varies as $1/R$ and $\nabla \phi$ as $1/R^2$. (Both will decrease even faster with R if there are no

Fig. 8-8. Each volume element $dV = dx dy dz$ in an electric field contains the energy $(\epsilon_0/2)E^2 dV$.

charge in the distribution is zero.) Since the surface area of the large sphere increases as R^2 , we see that the surface integral falls off as $(1/R)(1/R^2)R^2 = (1/R)$ as the radius of the sphere increases. So if we include all space in our integration ($R \rightarrow \infty$), the surface integral goes to zero and we have that

$$U = \frac{\epsilon_0}{2} \int_{\text{all space}} (\nabla \phi) \cdot (\nabla \phi) dV = \frac{\epsilon_0}{2} \int_{\text{all space}} E \cdot E dV. \quad (8.35)$$

We see that it is possible for us to represent the energy of any charge distribution as being the integral over all energy density located in the field.

8-6 The energy of a point charge

Our new relation, Eq. (8.35), says that even a single point charge q will have some electrostatic energy. In this case, the electric field is given by

$$E = \frac{q}{8\pi\epsilon_0 r^2} \hat{r}.$$

So the energy density at the distance r from the charge is

$$\frac{\epsilon_0 E^2}{2} = \frac{q^2}{32\pi\epsilon_0 r^4}.$$

We can take for an element of volume a spherical shell of thickness dr and area $4\pi r^2$. The total energy is

$$U = \int_{r=0}^{\infty} \frac{q^2}{8\pi\epsilon_0 r^4} 4\pi r^2 dr = -\frac{q^2}{8\pi\epsilon_0} \frac{1}{r} \Big|_{r=0}^{\infty}. \quad (8.36)$$

Now the limit as $r \rightarrow \infty$ gives no difficulty. But for a point charge we are supposed to integrate down to $r = 0$, which gives an infinite integral. Equation (8.35) says that there is an infinite amount of energy in the field of a point charge, although we began with the idea that there was energy only between point charges. In our original energy formula for a collection of point charges (Eq. 8.3), we did not include any interaction energy of a charge with itself. What has happened is that when we went over to a continuous distribution of charge in Eq. (8.27), we counted the energy of interaction of every infinitesimal charge with all other infinitesimal charges. The same account is included in Eq. (8.35), so when we apply it to a finite point charge, we are including the energy it would take to assemble that charge from infinitesimal parts. You will notice, in fact, that we would also get the result in Eq. (8.36) if we used our expression (8.11) for the energy of a charged sphere and let the radius tend toward zero.

We must conclude that the idea of treating the energy in the field is inconsistent with the assumption of the existence of point charges. One way out of the difficulty would be to say that elementary charges, such as an electron, are not points but are really small distributions of charge. Alternatively, we could say that there is something wrong in our theory of electricity at very small distances, or with the idea of the local conservation of energy. These are difficulties with older point of view. These difficulties have never been overcome; they exist to this day. Sometime later, when we have discussed some additional ideas, such as the interaction in an electromagnetic field, we will give a more complete account of these fundamental difficulties in our understanding of nature.

Electricity in the Atmosphere

9-1 The electric potential gradient of the atmosphere

On an ordinary day over flat closed country, or over the sea, as one goes upward from the surface of the ground the electric potential increases by about 100 volts per meter. Thus there is a vertical electric field E of 100 volts/m in the air. The sign of the field corresponds to a negative charge on the earth's surface. This means that midday the potential at the height of your nose is 200 volts higher than the potential at your feet! You might ask: "Why don't we just stick a pair of electrodes one in the air one meter apart and use the 100 volts to power our electric lights?" Or you might wonder: "If there is really a potential difference of 200 volts between my nose and my feet, why is it I don't get a shock when I go out into the street?"

We will answer the second question first. Your body is a relatively good conductor. If you are in contact with the ground, you and the ground will tend to make one equipotential surface. Ordinarily, the equipotentials are parallel to the surface, as shown in Fig. 9-1(a), but when you are there, the equipotentials are distorted, and the field looks somewhat as shown in Fig. 9-1(b). So you still have very nearly zero potential difference between your head and your feet. There are no charges that come from the earth to your head, changing the field. Some of them may be discharged by ions collected from the air, but the current of these is very small because air is a poor conductor.

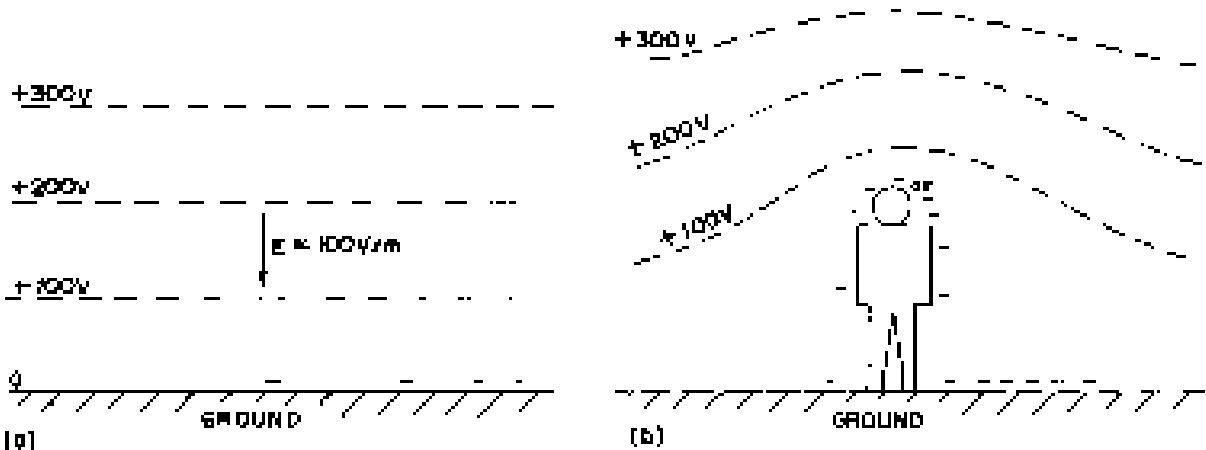

Fig. 9-1. (a) The potential distribution above the earth. (b) The potential distribution near a man on open flat ground.

How can we measure such a field if the field is changed by putting something there? There are several ways. One way is to place an insulated conductor at some distance above the ground and leave it there until it is at the same potential as the air. If we leave it long enough, the very small conductivity in the air will let the charges leak off (or move the conductor until it comes to the potential of its world). Then we can bring it back to the ground, and measure the shift of its potential as we do so. A faster way is to let the conductor be a bucket of water with a small leak. As the water drops out, it carries away any excess charges and the bucket will approach the same potential as the air. (The charges, as you know, reside on the surface, and as the drops come off "pieces of surface" break off.) We can measure the potential of the bucket with an electrometer.

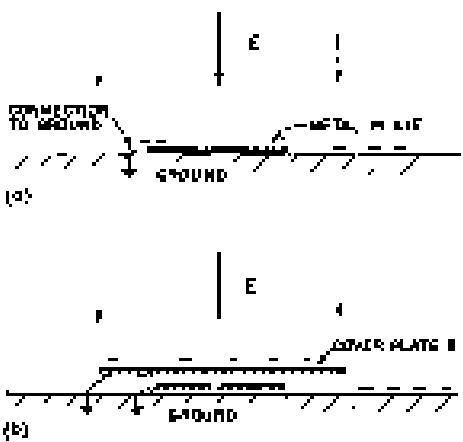

Fig. 9-2. (a) A grounded metal plate will have the same surface charge as the earth. (b) If the plate is connected with a grounded conductor it will have no surface charge.

There is another way to directly measure the potential gradient. Since there is an electric field, there is a surface charge on the earth ($\sigma = \epsilon_0 E$). If we place a flat metal plate at the earth's surface and ground it, negative charges appear on it (Fig. 9-2a). If this plate is now covered by another grounded conducting cover *B*, the charges will appear on the cover, and there will be no charges on the original plate *A*. If we measure the charge that flows from plate *A* to the ground (by, say, a galvanometer in the grounding wire) as we cover it, we can find the surface charge density that was there, and therefore also find the electric field.

Horing suggested how we can measure the electric field in the atmosphere, we now continue our description of it. Measurements show, first of all, that the field continues to exist, but gets weaker, as one goes up to high altitudes. By about 50 kilometers, the field is very small, so most of the potential change (the integral of *E*) is at lower altitudes. The total potential difference from the surface of the earth to the top of the atmosphere is about 400,000 volts.

9-2 Electric currents in the atmosphere

Another thing that can be measured, in addition to the potential gradient, is the current in the atmosphere. The current density is small—about 10 micromilli-amperes/cm² square meter parallel to the earth. The air is evidently not a perfect insulator, and because of this conductivity, a small current—caused by the electric field we have just been describing—goes from the sky down to the earth.

Why does the atmosphere have conductivity? Here and there among the air molecules there is an ion—a molecule of oxygen, say, which has acquired an extra electron, or perhaps lost one. These ions are not steady us single molecules; because of their electric field they usually accumulate a few other molecules around them. Each ion then becomes a little lump which, along with other lumps, drifts in the field—moving slowly upward or downward—making the observed current. Where do the ions come from? It was first guessed that the ions were produced by the radioactivity of the earth. (It was known that the radiation from radioactive materials would make air conducting by ionizing the air molecules.) Particles like β -rays coming out of the atomic nuclei are moving so fast that they tear electrons from the atoms, leaving ions behind. This would imply, of course, that if we were to go to higher altitudes, we should find less ionization, because the radioactivity is all in the dirt on the ground—in the traces of radium, uranium, potassium, etc.

To test this theory, some physicists carried an experiment up in balloons to measure the ionization of the air (Tess, in 1912) and discovered that the opposite was true—the ionization per unit volume increased with altitude! (The apparatus was like that of Fig. 9-3. The two plates were charged periodically to the potential *V*. Due to the conductivity of the air, the plates slowly discharged; the rate of discharge was measured with the electrometer.) This was a most mysterious result—the most dramatic finding in the entire history of atmospheric electricity. It was so dramatic, in fact, that it required a branching off of an entirely new subject—cosmic rays. Atmospheric electricity itself remained less dramatic. Ionization was evidently being produced by something from outside the earth: the investigation of this source led to the discovery of the cosmic rays. We will not discuss the subject of cosmic rays here, except to say that they maintain the supply of ions. Although the ions are being swept away all the time, new ones are being created by the cosmic-ray particles coming from the outside.

To be positive, we must say that besides the ions made of molecules, there are also other kinds of ions. Tiny pieces of dirt, like extremely fine bits of dust, float in the air and become charged. They are sometimes called "nuclei." For example, when a wave breaks in the sea, little bits of spray are thrown into the air. When one of these drops evaporates, it leaves an infinitesimal crystal of NaCl floating in the air. These tiny crystals can then pick up charges and become ions; they are called "tiny ions."

The small ions—these turned by cosmic rays—are the most mobile. Because they are so small, they move rapidly through the air—with a speed of about 1 g-t

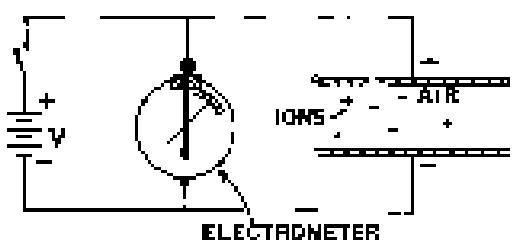

Fig. 9-3. Measuring the conductivity of air due to the motion of ions.

cm/sec in a field of 100 volts/meter, or 1 volt/cm. The much bigger and heavier ions move much more slowly. It turns out that if there are many "nuclei," they will pick up the charges from the small ions. Thus, since the "large ions" move so slowly in a field, the total conductivity is reduced. The conductivity of air, therefore, is quite variable, since it is very sensitive to the amount of "dirt" there is in it. There is much more of such dirt over land—where the winds can blow up dust or where man, through air blends of pollution into the air—than there is over water. It is not surprising that from day to day,风 can move to movement. From place to place, the conductivity near the earth's surface varies enormously. The voltage gradient observed at any particular place on the earth's surface also varies greatly because roughly the same current flows down from high altitudes in different places, and the varying conductivity near the earth results in a varying voltage gradient.

The conductivity of the air due to the drifting of ions also increases rapidly with altitude. For two reasons. First of all, the ionization from cosmic rays increases with altitude. Secondly, as the density of air goes down, the mean free path of the ions increases, so that they can travel farther in the electric field before they have a collision--resulting in a rapid increase of conductivity as one goes up.

Although the electric current-density in the air is only a few microamperes per square meter, there are very many square meters on the earth's surface. The total electric current reaching the earth's surface at any time is very nearly constant at 1800 amperes. This current, of course, is "positive"—it carries plus charges to the earth. So we have a voltage supply of 400,000 volts with a current of 1800 amperes—a power of 700 megawatts!

With such a large current coming down, the negative charge on the earth should soon be discharged. In fact, it should take only about half an hour to discharge the entire earth. But the atmospheric electric field has already lasted more than a half-hour since its discovery. How is it maintained? What maintains the voltage? And between what and the earth? There are many questions.

The earth is negative, and the potential in the air is positive. If you go high enough, the conductivity is so great that horizontally there is no more chance for voltage variations. The air, for the scale of times that we are talking about, becomes effectively a conductor. This occurs at a height in the neighborhood of 50 kilometers. This is not as high as what is called the "ionosphere," in which there are very large numbers of ions produced by photoelectricity from the sun. Nevertheless, for our discussions of atmospheric electricity, the air becomes sufficiently conductive at about 50 kilometers that we can imagine that there is practically a perfect conducting surface at this height, from which the currents come down. Our picture of the situation is shown in Fig. 9-4. The problem is: How is the positive charge maintained there? How is it pumped back? Because if it comes down to the earth, it has to be pumped back somehow. That was one of the greatest puzzles of atmospheric electricity for quite a while.

Each piece of information we can get should give a clue or, at least, tell you something about it. Here is an interesting phenomenon: If we measure the current (which is more stable than the potential gradient) over the sea, for instance, or in careful conditions, and average very carefully so that we get rid of the irregularities, we discover that there is still a daily variation. The average of many measurements over the oceans has a variation with time roughly as shown in Fig. 9-5. The current varies by about -15 percent, and it is largest at 7:00 p.m. in London. The strange part of the thing is that no matter where you measure the current—in the Atlantic Ocean, the Pacific Ocean, or the Arctic Ocean—it is at its peak value when the clocks in London say 7:00 p.m.! All over the world the current is at its maximum at 7:00 p.m. London time and it is at a minimum at 4:00 a.m. London time. In other words, it depends upon the absolute time on the earth, not upon the local time at the place of observation. In one respect this is not mysterious; it checks with our idea that there is a very high conductivity laterally at the top, because that makes it impossible for the voltage difference from the ground to the top to vary locally. Any potential variations should be worldwide, as indeed they are. What we now know, therefore, is that the voltage at the "top" surface is dropping and rising by 15 percent with the absolute time on the earth.

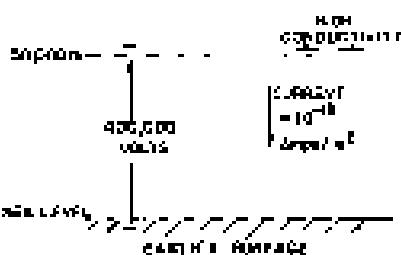

Fig. 9-4. Typical electrical conditions in a clear atmosphere.

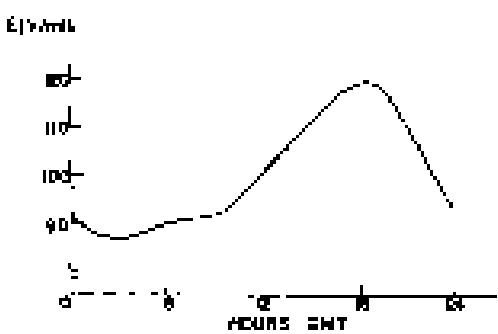

Fig. 9-5. The average daily variation of the atmospheric potential gradient on a clear day over the oceans, referred to Greenwich Time.

9-3 Origin of the atmospheric currents

We must now talk about the source of the large negative currents which must be flowing from the "top" to the surface of the earth to keep charging it up negatively. Where are the batteries that do this? The "battery" is shown in Fig. 9-3. It is the thunderstorm and its lightning. I assume that the bolts of lightning is a sort "discharge" the generator we have been talking about (or you might at first guess). Lightning storms carry negative charges to the earth. When a lightning bolt strikes, it carries it's negative charges to the earth in large amounts. It is the thunderstorms throughout the world that are charging the earth with an average of .800 amperes, which is then being discharged through regions of fair weather.

There are about 1,800 thunderstorms per day all over the earth, and we can think of them as batteries pumping the electricity to the upper layer and down to us by the voltage difference. Then take into account the geography of the earth. There are thunderstorms in the savannah in Brazil, tropical thunderstorms in Africa, and so forth. People have made estimates of how much lightning is striking world wide at any time, and perhaps needless to say, their estimates more or less agree with the voltage difference measurements: the total amount of thunderstorm activity is highest on the whole earth at about 7:00 p.m. in London. However, the thunderstorm estimates are very difficult to make out were made only after it was known that the sunspot should have occurred. These things are very difficult, because we don't have enough observers on the seas and over all parts of the world to count the number of the infections accurately. But these people who think they "got it right" obtain the result, that there is a peak in the activity at 7:00 p.m. Greenwich Mean Time.

Fig. 9-3. The mechanism that generates the atmospheric electric field. (Photo by William L. Widmayer.)

In order to understand how these batteries work, we will look at a thunderstorm in detail. What is going on inside a thunderstorm? We will describe this insofar as it is known. As we get into this marvelous phenomenon of real nature—instead of the idealized spheres of perfect conductors inside of other spheres that we can solve so neatly—we discover that we don't know very much. Yet it is really quite exciting. Anyone who has been in a thunderstorm has enjoyed it, or has been frightened, or at least has had some emotion. And in those places in nature where we get an emotion, we find that there is generally a corresponding complexity and mystery about it. It is not going to be possible to describe exactly how a thunderstorm works, because we do not yet know very much. But we will try to describe a little bit about what happens.

9-4 Thunderstorms

In the first place, an ordinary thunderstorm is made up of a number of "cells" fairly close together, but almost independent of each other. So it is best to analyze one cell at a time. By a "cell" we mean a region with a limit area in the horizontal direction in which all of the basic processes occur. Usually there are several cells side by side, and in each one above the same thing is happening, although perhaps with a different timing. Figure 9-7 indicates in an idealized fashion what such a cell looks like in the early stage of the thunderstorm. It turns out that in a certain place in the air, under certain conditions which we shall describe, there is a general rising of the air, with higher and higher velocities near the top. As the warm, moist air at the bottom rises, it cools and condenses. In the figure the little crosses indicate snow and the dots indicate rain, but because the updraft currents are great enough and the drops are small enough, the snow and rain do not come down at this stage. This is the beginning stage, and not the real thunderstorm yet—in the sense that we don't have anything happening at the ground. At the same time that the warm air rises, there is an entrainment of air from the sides—an imperfect point which was neglected for many years. Thus it is not just the air from below which is rising, but also a certain amount of other air from the sides.

Why does the air rise like this? As you know, when you go up in altitude the air is colder. The ground is heated by the sun, and the re-radiation of heat to the sky comes from water vapor high in the atmosphere; so at high altitude the air is cold—very cold—whereas lower down it is warm. You may say, "Then it's very simple. Warm air is lighter than cold; therefore the combination is automatically unstable and the warm air rises." Of course, if the temperature is different at different heights, the air is unstable thermodynamically. Let it itself fall slowly long, the air would all come to the same temperature. But it is not left to itself; the sun is always shining (during the day). So the problem is indeed not one of thermodynamic equilibrium, but of mechanical equilibrium. Suppose we plot, as in Fig. 9-8—the temperature of the air against height above the ground. In ordinary circumstances we would get a decrease along a curve like the one labeled (a); as the height goes up, the temperature goes down. How can the atmosphere be stable? Why doesn't the hot air below simply rise up into the cold air? The answer is this: if the air were to go up, its pressure would go down, and if we consider a particular parcel of air going up, it would be expanding adiabatically. (There would be no heat coming in or out because in the large dimensions considered here, there isn't time for much heat flow.) Thus the parcel of air would cool as it rises. Such an adiabatic process would give a temperature-height relationship like curve (b) in Fig. 9-8. Any air which rose from below would be cooler than the environment it goes into. Thus there is no reason for the hot air below to rise; if it were to rise, it would cool to a lower temperature than the air already there, would be heavier than the air there, and would just want to come down again. On a good, bright day with very little humidity there is a certain rate at which the temperature in the atmosphere falls, and this rate is, in general, lower than the "maximum stable gradient," which is represented by curve (b). The air is in stable mechanical equilibrium.

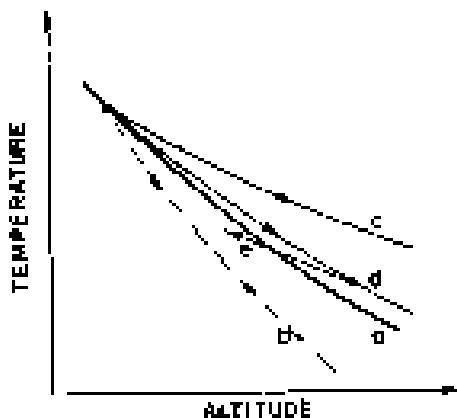

Fig. 9-8. Atmospheric temperature. (a) Static atmosphere; (b) adiabatic cooling of dry air; (c) adiabatic cooling of wet air; (d) wet air with some mixing of ambient air.

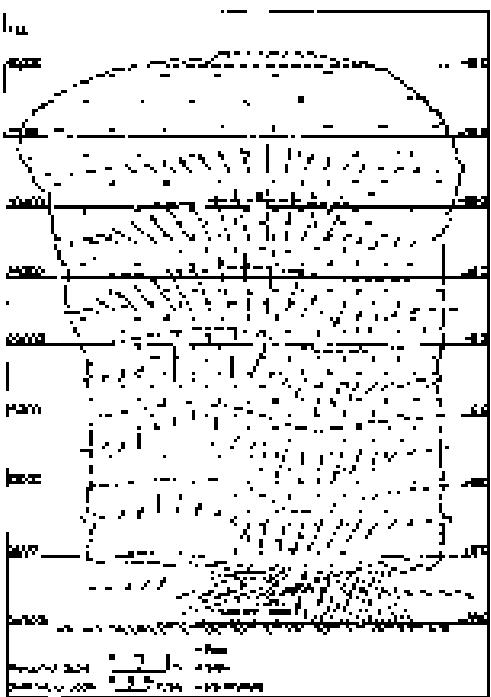

Fig. 9-9. A mature thunderstorm cell.
[From U.S. Department of Commerce Weather Bureau Report, June 1949.]

On the other hand, if we think of a parcel of air that contains a lot of water vapor being carried up into the air, its adiabatic cooling curve will be different. As it expands and cools, the water vapor in it will condense, and the condensing water will liberate heat. Moist air, therefore, does not cool nearly as much as dry air does. So if air that is wetter than the average starts to rise, its temperature will follow a curve like (c) in Fig. 9-8. It will cool off somewhat, but will still be warmer than the surrounding air at the same level. If we have a region of warm moist air and something starts it rising, it will always find itself lighter and warmer than the air around it and will continue to rise until it gets to successive heights. This is the mechanism that makes the air in the thunderstorm cell rise.

For many years the thunderstorm cell was explained simply in this manner, but then measurements showed that the temperature of the cloud at different heights was not nearly as high as indicated by curve (c). The reason is that as the moist air "bubble" goes up, it carries air from the environment and it cools off by it. The temperature-versus-height curve looks more like curve (d), which is much closer to the original curve (a) than to curve (c).

After the convection just described gets under way, the cross section of a thunderstorm cell looks like Fig. 9-9. We have what is called a "mother" thunderstorm. There is a very rapid updraft which, in this stage, goes up to about 10,000 to 15,000 meters—sometimes even much higher. The thunderheads, with their condensation, climb way up out of the general cloud bank, carried by an updraft that is usually about 60 miles an hour. As the water vapor is forced up and condenses, it forms tiny drops which are rapidly cooled to temperatures below zero degrees. They should freeze, but do not freeze immediately—they are "supercooled." Water and other liquids will usually cool well below their freezing points before crystallizing if there are no "nuclei" present to start the crystallization process. Only if there is some small pieces of material present, like a tiny crystal of NaCl, will the water drop freeze into a little piece of ice. Then the equilibrium is such that the water drops evaporate and the ice crystals grow. Thus at a certain point there is a rapid disappearance of the water and a rapid buildup of ice. Also, there may be direct collisions between the water drops and the ice—collisions in which the supercooled water droplets stick to the ice crystals, which causes it to suddenly crystallize. So at a certain point in the cloud expansion there is a rapid accumulation of large ice particles.

When the ice particles are heavy enough, they begin to fall through the rising air—they get too heavy to be supported any longer by the updraft. As they come down, they draw a little air with them and start a downdraft. And surprisingly enough, it is easy to see that once the downdraft is started, it will maintain itself. The air now drives itself down!

Notice that the curve (d) in Fig. 9-8 for the actual distribution of temperature in the cloud is not as steep as curve (c), which applies to wet air. So if we have wet air falling, its temperature will drop with the slope of curve (c) and will go below the temperature of the environment if it goes down far enough, as indicated by curve (e) in the figure. The moment it does this, it is denser than the environment and begins to fall rapidly. You say, "That is perpetual motion. First, you argue that the air should rise, and when you have it up there, you argue equally well that the air should fall!" But it isn't perpetual motion. When the situation is unstable and the warm air should rise, then clearly something has to replace the warm air. It is equally true that cold air coming down would energetically replace the warm air, but you realize that what is coming down is not the original air. The early arguments, that had a particular cloud without entrainment going up and then coming down, had some kind of a puzzle. They needed the twin to maintain the downdraft—an argument which is hard to believe. As soon as you realize that there is a lot of original air mixed in with the rising air, the thermodynamic argument shows that there can be a descent of the cold air which was originally at some great height. This explains the picture of the active thunderstorm sketched in Fig. 9-9.

As the air comes down, rain begins to come out of the bottom of the thunderstorm. In addition, the relatively cold air spreads out after it arrives at the earth's surface. So just before the rain comes there is a certain little cold wind that gives

is a forewarning of the oncoming storm. In the storm itself there are rapid and irregular gusts of air, there is an enormous turbulence in the clouds, and so on. But basically we have an updraft, then a downdraft—in general, a very complicated process.

The moment at which precipitation starts is the same moment that the large downdraft begins and is the same moment, in fact, when the electrical phenomena arise. Before we describe lightning, however, we can finish the story by looking at what happens to the thunderstorm cell after about one-half an hour to an hour. The cell looks as shown in Fig. 9-10. The updraft stops because there is no longer enough warm air to maintain it. The downward precipitation continues for a while, the last little bits of water come out, and things get quieter and quieter—although there are small ice crystals left way up in the air. Because the winds at very great altitude are in different directions, the top of the cloud visually spreads into an anvil shape. The cell comes to the end of its life.

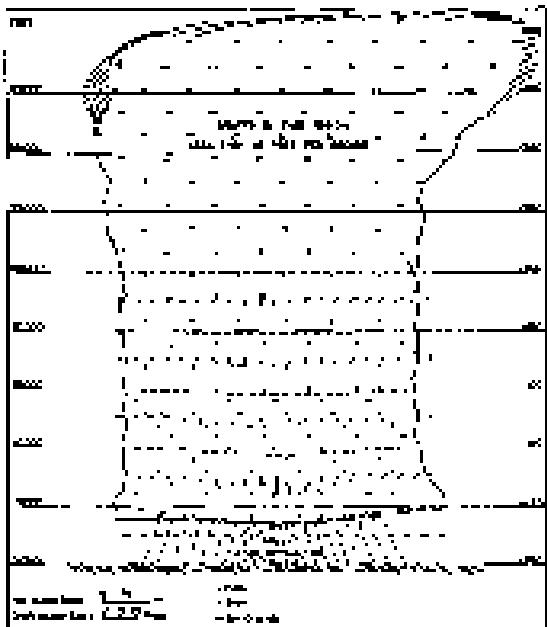

Fig. 9-10. The late phase of a thunderstorm cell. [From U.S. Department of Commerce Weather Bureau Report, June 1949.]

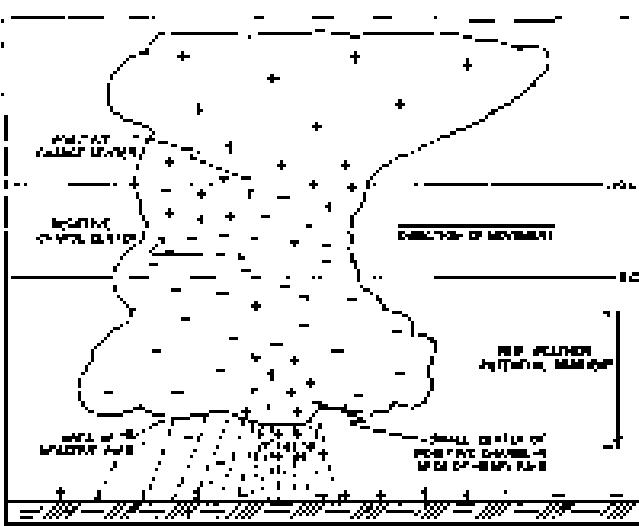

Fig. 9-11. The distribution of electrical charges in a mature thunderstorm cell. [From U.S. Department of Commerce Weather Bureau Report, June 1949.]

9-5 The mechanism of charge separation

We want now to discuss the most important aspect for our purposes—the development of the electrical charges. Experiments of various kinds—including flying airplanes through thunderstorms (the pilots who do this are brave ones!)—tell us that the charge distribution in a thunderstorm cell is something like that shown in Fig. 9-11. The top of the thunderstorm has a positive charge, and the bottom a negative one—except for a small local region of positive charge in the bottom of the cloud, which has caused everybody a lot of worry. No one seems to know why it is there, how important it is—whether it is a secondary effect of the positive rain coming down, or whether it is an essential part of the machinery. Things would be much simpler if it weren't there. Anyway, the predominantly negative charge at the bottom and the positive charge at the top have the correct sign for the battery needed to drive the earth negative. The positive charges are 6 or 7 kilometers up in the air, where the temperature is about -20°C , whereas the negative charges are 3 or 4 kilometers high, where the temperature is between zero and 10°C .

The charge at the bottom of the cloud is large enough to produce potential differences of 30, 000, 000 volts between the cloud and the earth—much bigger than the 0.4 million volts from the "sky" to the ground in a clear

atmosphere. These large voltages break down the air and create giant arc discharges. When the breakdown occurs the negative charges at the bottom of the thunderstorm are carried down to the earth in the lightning strokes.

Now we will describe in some detail the character of the lightning. First of all, there are large voltage differences around, so that the air breaks down. There are lightning strokes between one piece of a cloud and another piece of a cloud, or between one cloud and another cloud, or between a cloud and the earth. In each of the independent discharge flashes—the kind of lightning strokes you see—there are approximately 20 or 30 coulombs of charge brought down. One question is: How long does it take for the cloud to regenerate the 20 or 30 coulombs which are taken away by the lightning bolt? This can be seen by measuring, far from a cloud, the electric field produced by the cloud's dipole moment. In such measurements you see a sudden decrease in the field when the lightning strikes, and then an exponential return to the previous value with a time constant which is slightly different for different cases but which is in the neighborhood of 5 seconds. It takes a thundercloud only 5 seconds after each lightning stroke to build its charge up again. That doesn't necessarily mean that another strike is going to occur in exactly 5 seconds every time, because, otherwise, the geometry is changed, and so on. The strokes occur more or less irregularly, but the important point is that it takes about 5 seconds to recreate the original condition. Thus there are approximately 4 amperes of current in the generating machine of the thunderstorm. This means that any model made to explain how this storm generates its electricity must be one with plenty of juice—it must be a big, rapidly operating device.

Before we go further we shall consider something which is almost certainly completely irrelevant, but nevertheless interesting, because it does show the effect of an electric field on water drops. We say that it may be irrelevant because it relates to an experiment one can do in the laboratory with a stream of water to show the rather striking effects of the electric field on drops of water. In a thunderstorm there is no stream of water; there is a cloud of condensing ice and drops of water. So the question of the mechanisms at work in a thundercloud is probably not at all related to what you can see in the simple experiment we will describe. If you take a small nozzle connected to a water faucet and direct it upward at a steep angle, as in Fig. 9-12, the water will come out in a fine stream that eventually breaks up into a spray of fine drops. If you now put an electric field across the stream at the nozzle (by bringing up a charged rod, for example), the form of the stream will change. With a weak electric field you will find that the stream breaks up into a smaller number of larger-sized drops. But if you apply a stronger field, the stream breaks up into many, many fine drops—smaller than before.* With a weak electric field there is a tendency to inhibit the breaking of the stream into drops. With a stronger field, however, there is an increase in the tendency to separate into drops.

The explanation of these effects is probably the following. If we have the stream of water coming out of the nozzle and we put a small electric field across it one side of the water gets slightly positive and the other side gets slightly negative. Then, when the stream breaks, the drops on one side may be positive, and those on the other side may be negative. They will attract each other and will have a tendency to stick together more than they would have before—the stream doesn't break up as much. On the other hand, if the field is stronger, the charge in each one of the drops gets much larger, and there is a tendency for the charge itself to help break up the drops through their own repulsion. Each drop will break into many smaller ones, each carrying a charge, so that they are all repelled, and spread out so rapidly. So as we increase the field, the stream becomes more finely separated. The only point we wish to make is that in certain circumstances electric fields can have considerable influence on the drops. The exact machinery by which something happens in a thunderstorm is not at all known, and is not at all necessarily related to what we have just described. We have included it just so that

* A handy way to observe the sizes of the drops is to let the spray fall on a large thin metal plate. The larger drops make a bumpy noise.

you will appreciate the complexities that could come into play. In fact, nobody has a theory applicable to clouds based on that idea.

We would like to describe two theories which have been invented to account for the separation of the charges in a thunderstorm. All the theories involve the idea that there should be some charge on the precipitation particles and a different charge in the air. Then by the movement of the precipitation particles—the water or the ice—through the air there is a separation of electric charge. The only question is: How does the charging of the drop begin? One of the older theories is called the "breaking-drop" theory. Somebody discovered that if you have a drop of water that breaks up into two pieces in a windstream, there is positive charge on the water and negative charge in the air. This breaking-drop theory has several disadvantages, among which the most serious is that the sign is wrong. Second, in the large number of temperate-zone thunderstorms which do exhibit lightning, the precipitation effects at high altitudes are in ice, not in water.

From what we have just said, we note that if we could imagine some way for the charge to be different at the top and bottom of a drop and if we could also see some reason why drops in a high-speed airstream would break up into unequal pieces—a large one in the front and a smaller one in the back because of the motion through the air or something—we would have a theory. (Different from any known theory!) Then the small drops would not fall through the air as fast as the big ones, because of the air resistance, and we would get a charge separation. You see, it is possible to conceive all kinds of possibilities.

One of the more ingenious theories, which is more satisfactory in many respects than the breaking-drop theory, is due to C. T. R. Wilson. We will describe it, as Wilson did, with reference to water drops, although the same phenomenon would also work with ice. Suppose we have a water drop that is falling in the electric field of about 100 volts per meter toward the negatively charged earth. The drop will have no induced dipole moment—with the bottom of the drop positive and the top of the drop negative, as drawn in Fig. 9-12. Now there are in the air the "quarks" that we mentioned earlier—the large slow-moving ions. (The fast ions do not have an important effect here.) Suppose that as a drop comes down, it approaches a large ion. If the ion is positive, it is repelled by the positive bottom of the drop and is pushed away. So it does not become attached to the drop. If the ion were to approach from the top, however, it might attach to the negative, top side. But since the drop is falling through the air, there is an air drift relative to it, going upwards, which carries the ion away. If that motion through the air is slow enough, thus the positive ion cannot catch up to the drop either. That would apply, you see, only to the large, slow-moving ions. The positive ions of this type will not attach themselves either to the front or the back of a falling drop. On the other hand, as the large, slow, negative ions are approached by a drop, they will be attracted and will be caught. The drop will acquire negative charge—the sign of the charge having been determined by the original potential difference on the entire earth—and we get the right sign. Negative charge will be brought down to the bottom part of the cloud by the drops, and the positively charged ions which are left behind will be blown to the top of the cloud by the various updraft currents. The theory looks pretty good, and it at least gives the right sign. Also it doesn't depend on having liquid drops. We will see, when we learn about polarized ice in dielectric, that pieces of ice will do the same thing. They also will develop positive and negative charges on their extremities when they are in an electric field.

There are, however, some problems even with this theory. First of all, the total charge involved in a thunderstorm is very high. After a short time, the supply of large ions would get used up. So Wilson and others have had to propose that there are additional sources of the large ions. Once the charge separation starts, very large electric fields are developed, and in these large fields there may be places where the air will become ionized. If there is a highly charged point, or any small object like a drop, it may concentrate the field enough to make a "brush discharge." When there is a strong enough electric field—let us say it is positive electrons will fall into the field and will pick up a lot of speed between collisions. Their speed will be such that in hitting another atom they will tear electrons off of that

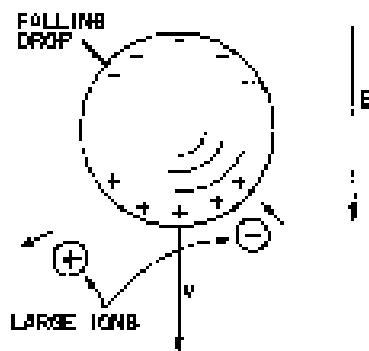

Fig. 9-13. C. T. R. Wilson's theory of charge separation in a thundercloud.

atom, leaving positive charges behind. These new electrons also pick up speed and collide with more electrons. So a kind of chain reaction or avalanche occurs, and there is a rapid accumulation of ions. The positive charges are left near their original positions, so the net effect is to distribute the positive charge so the point into a region around the point. Then, of course, there is no longer a strong field, and the process stops. This is the character of a brush discharge. It is possible that the fields may become strong enough in the cloud to produce a little bit of brush discharge; there may also be other mechanisms. Once the thing is started, to produce a large amount of ionization. But nobody knows exactly how it works. So the fundamental origin of lightning is really not thoroughly understood. We know it comes from the thunderstorms. (And we know, of course, that thunder comes from the lightning—from the thermal energy released by the bolt.)

At least we can understand, in part, the origin of atmospheric electricity. Due to the air currents, ions, and water droplets or particles in a thunderstorm, positive and negative charges are separated. The positive charges are carried upward to the top of the cloud (see Fig. 9-11), and the negative charges are dumped into the ground in lightning strikes. The positive charges leave the top of the cloud, enter the high-altitude layers of more highly conducting air, and spread throughout the earth. In regions of clear weather, the positive charges in this layer are slowly conducted to the earth by the ions in the air—ions formed by cosmic rays, by the sea, and by man's activities. The atmosphere is a busy electrical machine!

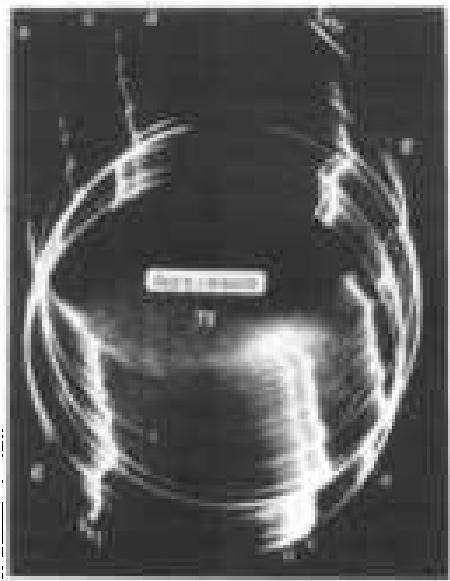

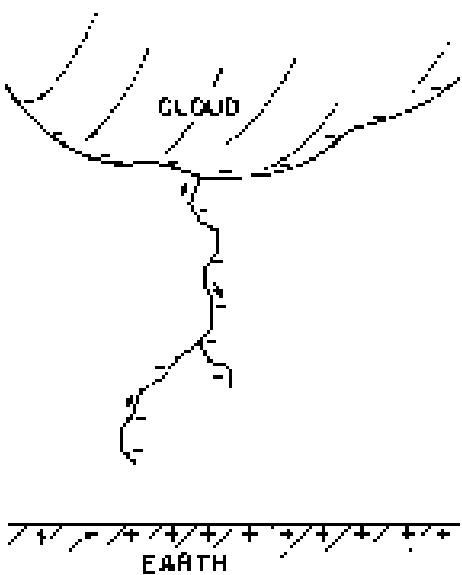

Fig. 9-14. Photograph of a lightning flash taken with a "Boys" camera. [From Schonland, Malan, and Collie, Proc. Roy. Soc. London, Vol. 152 (1935).]

9-6 Lightning

The first evidence of what happens in a lightning stroke was obtained in photographs taken with a camera held by hand and moved back and forth with the shutter open—while pointed toward a place where lightning was expected. The first photographs obtained this way showed clearly that lightning strokes are usually multiple discharges along the same path. Later, the "Boys" camera, which has two lenses mounted 180° apart on a rapidly rotating disc, was developed. The image made by each lens moves across the film—the picture is spread out in time. If, for instance, the stroke repeats, there will be two images side by side. By comparing the images of the two lenses, it is possible to work out the details of the time sequence of the flashes. Figure 9-14 shows a photograph taken with a "Boys" camera.

We will now describe the lightning. Again, we don't understand exactly how it works. We will give a qualitative description of what it looks like, but we won't go into any details of why it does what it appears to do. We will describe only the ordinary case of the cloud with a negative bottom over flat country. Its potential is much more negative than the earth underneath, so negative electrons will be accelerated toward the earth. What happens is the following. It all starts with a thing called a "step leader," which is just as bright as the stroke of lightning. On the photographs one can see a little bright spot at the beginning that starts from the cloud and moves downward very rapidly—at a sixth of the speed of light! It goes only about 50 meters and stops. It pauses for about 50 microseconds, and then takes another step. It pauses again and then goes another step, and so on. It moves in a series of steps toward the ground, along a path like that shown in Fig. 9-15. In the leader there are negative charges from the cloud; the whole column is full of negative charge. Also, the air is becoming ionized by the rapidly moving charges that produce the leader, so the air becomes a conductor along the path traced out. The moment the leader touches the ground, we have a conducting "wye" that runs all the way up to the cloud and is full of negative charge. Now, at last, the negative charge of the cloud can simply escape and run out. The electrons at the bottom of the leader are the first ones to realize this; they dump out, leaving positive charge behind that attracts more negative charge from higher up in the leader, which in its turn pours out, etc. So finally all the negative charge in a part of the cloud runs out along the return in a rapid and energetic way. So the lightning stroke you see runs upwards from the ground, as indicated in Fig. 9-16. In fact, this main stroke—the far the brightest part—is called the return

stroke. It is what produces the very bright light, and the heat, which by causing a rapid expansion of the air makes the thunder clap.

The current in a lightning stroke is about 10,000 amperes at its peak, and it carries down about 20 coulombs.

But we are still not finished. After a time of, perhaps, a few hundredths of a second, when the return stroke has disappeared, another leader comes down. But this time there are no patches. It is called a "dark leader" this time, and it goes all the way down—from top to bottom in one sweep. It goes full stroke on exactly the old track, because there is enough debris there to make it the easiest route. The new leader is again full of negative charge. The moment it touches the ground—bang!—there is a return stroke going straight up along the path. So you see the lightning strike again, and again, and again. Sometimes it strikes only once or twice, sometimes five or ten times—but as many as 42 times on the same track have been—but always in rapid succession.

Sometimes things get even more complicated. For instance, after one of its pauses the leader may develop a branch by sending out sub-steps—which regard the ground but in somewhat different directions, as shown in Fig. 9-15. What happens then depends on whether one branch reaches the ground definitely before the other. If that does happen, the bright return stroke (of negative charge jumping into the ground) works its way up along the branch that touches the ground, and when it reaches and passes the branching point on its way up to the cloud, a bright stroke appears to go down the other branch. Why? Because negative charge is dumping out and that is what lights up the bolt. This charge begins to move at the top of the secondary branch, carrying successive, longer pieces of the branch, so the bright lightning bolt appears to work its way down that branch, at the same time as it works up toward the cloud. If, however, one of these extra leader branches happens to have reached the ground almost simultaneously with the original leader, it can sometimes happen that the dark leader of the second stroke will take the second branch. Then you will see the first main flash in one place and the second flash in another place. It is a variant of the original idea.

Also, our description is oversimplified for the region very near the ground. When the step leader gets to within a hundred meters or so from the ground, there is evidence that a discharge rises from the ground to meet it. Presumably, the field gets big enough for a streamer-type discharge to occur. If, for instance, there is a sharp object, like a building with a point at the top, then as the leader comes down nearby the fields are so large that a discharge starts from the sharp point and reaches up to the leader. The lightning tends to strike such a point.

It has apparently been known for a long time that high objects are struck by lightning. There is a quotation of Artabazis, the advisor to Xerxes, giving his master advice on a contemplated attack on the Greeks during Xerxes' campaign to bring the entire Persian world under the control of the Persians. Artabazis said, "See how God with his lightning always smites the bigger animals and will not suffer them to live long, while these of a lesser bulk escape him not. How likewise his bolts fall ever on the greatest houses and tallest trees." And then he explains the reason: "So, plainly, doth he love to bring down everything that exalt itself."

Do you think—now that you know a true account of lightning striking tall trees—that you have a greater wisdom in advising kings on military matters than did Artabazis 2300 years ago? Do not exalt yourself. You could only do it less poetically.

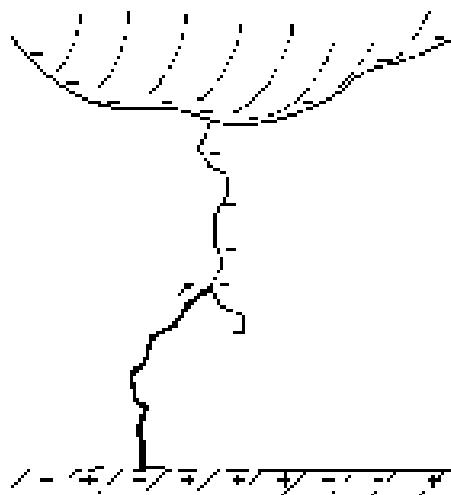

Fig. 9-16. The return lightning stroke runs back up the path made by the leader.

Dielectrics

10-1 The dielectric constant

Here we begin to discuss another of the peculiar properties of matter under the influence of the electric field. In an earlier chapter we considered the behavior of conductors, in which the charges move freely in response to all electric fields to such points that there is no field left inside a conductor. Now we will discuss insulators, materials which do not conduct electricity. One might at first believe that there should be no effect whatsoever. However, using a simple electrostatics and a parallel-plate capacitor, Faraday discovered that this was not so. His experiments showed that the capacitance of such a capacitor is increased when an insulator is put between the plates. If the insulator completely fills the space between the plates, the capacitance is increased by a factor κ which depends only on the nature of the insulating material. Insulating materials are also called dielectrics; the factor κ is then a property of the dielectric, and is called the dielectric constant. The dielectric constant of a vacuum is, of course, unity.

Our problem now is to explain why there is any electrical effect if the insulators are indeed insulators and do not conduct electricity. We begin with the experimental fact that the capacitance is increased and try to reason out what might be going on. Consider a parallel-plate capacitor with some charges on the surfaces of the conductors, let us say negative charge on the top plate and positive charge on the bottom plate. Suppose that the spacing between the plates is d and the area of each plate is A . As we have proved earlier, the capacitance is

$$C = \frac{\epsilon_0 A}{d}, \quad (10.1)$$

and the charge and voltage on the capacitor are related by

$$Q = C V. \quad (10.2)$$

Now the experimental fact is that if we put a piece of insulating material like lucite or glass between the plates, we find that the capacitance is larger. That means, of course, that the voltage is lower for the same charge. But the voltage difference is the integral of the electric field across the capacitor; so we must conclude that inside the capacitor, the electric field is reduced even though the charges on the plates remain unchanged.

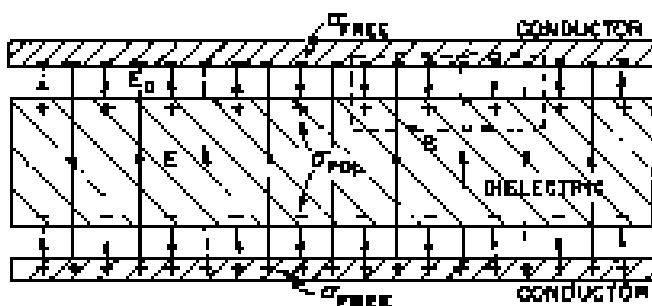

Fig. 10-1. A parallel-plate capacitor with a dielectric. The lines of E are shown.

Now how can that be? We have a law due to Gauss that tells us that the flux of the electric field is directly related to the enclosed charge. Consider the gaussian surface S shown by broken lines in Fig. 10-1. Since the electric field is reduced with the dielectric present, we conclude that the net charge inside the surface must

10-1 The dielectric constant

10-2 The polarization vector P

10-3 Polarization charges

10-4 The electrostatic equations with dielectrics

10-5 Fields and forces with dielectrics

be lower than it would be without the material. There is only one possible conclusion, and that is that there must be positive charge on the surface of the dielectric. Since the field is reduced but is not zero, we would expect this positive charge to be smaller than the negative charge on the conductor. So the phenomena can be explained if we could understand in some way that when a dielectric material is placed in an electric field there is positive charge induced on one surface and negative charge induced on the other.

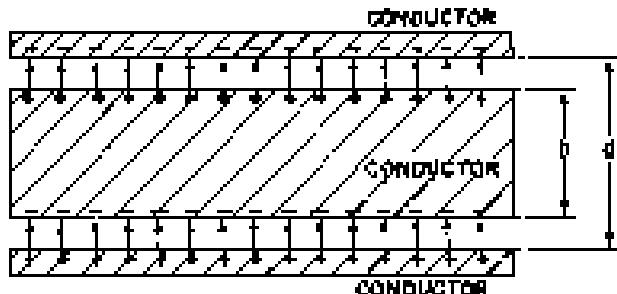

Fig. 10-2. If we put a conducting plate in the gap of a parallel-plate capacitor, the induced charges reduce the field in the conductor to zero.

We would expect that to happen for a conductor. For example, suppose that we had a capacitor with a plate spacing d , and we put between the plates a neutral conductor whose thickness is b , as in Fig. 10-2. The electric field induces a positive charge on the upper surface and a negative charge on the lower surface, so there is no field inside the conductor. The field in the rest of the space is the same as it was without the conductor, because it is the surface density of charge divided by ϵ_0 ; but the distance over which we have to integrate to get the voltage (the potential difference) is reduced. The voltage is

$$V = \frac{\sigma}{\epsilon_0} (d - b).$$

The resulting equation for the capacitance is like Eq. (10.2), with $(d - b)$ substituted for d :

$$C = \frac{\epsilon_0 d}{d - (b/d)} \quad (10.3)$$

The capacitance is increased by a factor which depends upon (b/d) , the proportion of the volume which is occupied by the conductor.

This gives us an obvious model for what happens with dielectrics—that inside the material there are many little sheets of conducting material. The trouble with such a model is that it has a specific axis, the normal to the sheets, whereas most dielectrics have no such axis. However, this difficulty can be eliminated if we assume that all insulating materials contain small conducting spheres separated from each other by insulation, as shown in Fig. 10-3. The phenomenon of the dielectric constant is explained by the effect of the charges which would be induced on each sphere. This is one of the earliest physical models of dielectrics used to explain the phenomenon that Faraday observed. More specifically, it was assumed that each of the atoms of a material was a perfect conductor, but isolated from the others. The dielectric constant κ would depend on the proportion of space which was occupied by the conducting spheres. This is not, however, the model that is used today.

Fig. 10-3. A model of a dielectric as small conducting spheres embedded in an idealized insulator.

10-2 The polarization vector P

If we follow the above analysis further, we discover that the idea of regions of perfect conductivity and insulation is not useful. Each of the small spheres acts like a dipole, the moment of which is induced by the external field. The only thing that is essential to the understanding of dielectrics is that there are many little dipoles induced in the material. Whether the dipoles are induced because there are tiny conducting spheres or for any other reason is irrelevant.

Why should a field induce a dipole moment in an atom if the atom is not a conducting sphere? This subject will be discussed in much greater detail in the next chapter, which will be about the inner workings of dielectric materials. However, we give here one example to illustrate a possible mechanism. An atom has a positive charge on the nucleus, which is surrounded by negative electrons. In an electric field, the nucleus will be attracted in one direction and the electrons in the other. The orbits or wave patterns of the electrons (or whatever picture is used in quantum mechanics) will be distorted to some extent, as shown in Fig. 10-4; the center of gravity of the negative charge will be displaced and will no longer coincide with the positive charge of the nucleus. We have already discussed such distributions of charge. If we look from a distance, such a neutral configuration is equivalent, to a first approximation, to a little dipole.

It seems reasonable that if the field is not too enormous, the amount of induced dipole moment will be proportional to the field. That is, a small field will displace the charges a little bit and a larger field will displace them further-- and in proportion to the field-- unless the displacement gets too large. For the remainder of this chapter, it will be supposed that the dipole moment is exactly proportional to the field.

We will now assume that in each atom there are charges q separated by a distance b , so that qb is the dipole moment per atom. (We use b because we are already using d for the plate separation.) If there are N atoms per unit volume, there will be a dipole moment per unit volume equal to Nqb . This dipole moment per unit volume will be represented by a vector, P . Needless to say, it is in the direction of the *undisturbed* dipole moment, i.e., in the direction of the charge separation b :

$$P = Nqb. \quad (10-4)$$

In general, P will vary from place to place in the dielectric. However, at any point in the material, P is proportional to the electric field E . The constant of proportionality, which depends on the ease with which the electron are displaced, will depend on the kinds of atoms in the material.

What actually determines how this constant of proportionality behaves, how accurately it is constant for very large fields, and what is going on inside different materials, we will discuss at a later time. For the present, we will simply suppose that there exists a mechanism by which a dipole moment is induced which is proportional to the electric field.

10-3 Polarization charges

Now let us see what this model gives for the theory of a condenser with a dielectric. First consider a sheet of material in which there is a certain dipole moment per unit volume. Will there be on the average any charge density produced by this? Not if P is uniform. If the positive and negative charges being displaced relative to each other have the same average density, the fact that they are displaced does not produce any net charge inside the volume. On the other hand, if P were larger at one place and smaller at another, that would mean that more charge would be moved into some region than away from it; we would then expect to get a volume density of charge. For the parallel-plate condenser, we suppose that P is uniform, so we need to look only at what happens at the surfaces. At one surface the negative charges, the electrons, have effectively moved out a distance b ; at the other surface they have moved in, leaving some positive charge effectively out a distance b . As shown in Fig. 10-5, we will have a surface density of charge, which will be called the *surface polarization charge*.

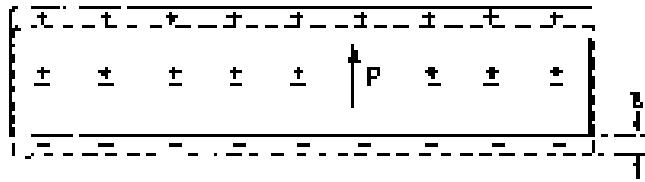

Fig. 10-5. A dielectric slab in a uniform field. The positive charges displaced the distance b with respect to the negatives.

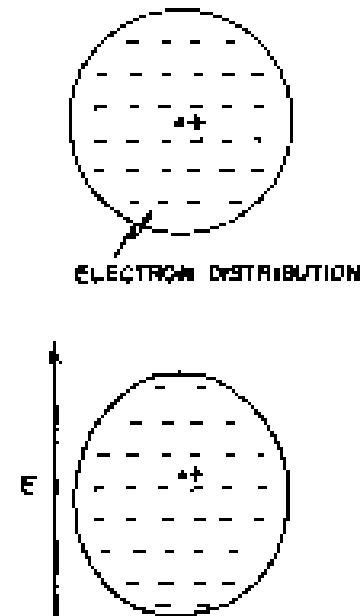

Fig. 10-4. An atom in an electric field has its distribution of electrons displaced with respect to the nucleus.

This charge can be calculated as follows. If A is the area of the plate, the number of electrons that appear at the surface is the product of A and N , the number per unit volume, and the displacement δ , which we assume here is perpendicular to the surface. The total charge is obtained by multiplying by the electronic charge q_e . To get the surface density of the polarization charge induced on the surface, we divide by A . The magnitude of the surface charge density is

$$\sigma_{\text{pol}} = N q_e \delta.$$

But this is just equal to the magnitude P of the polarization vector \mathbf{P} . Eq. (10.4):

$$\sigma_{\text{pol}} = P. \quad (10.5)$$

The surface density of charge is equal to the polarization inside the material. The surface charge is, of course, positive on one surface and negative on the other.

Now let us assume that our slab is the dielectric of a parallel-plate capacitor. The plates of the capacitor also have a surface charge, which we will call σ_{ext} because they can move "freely" anywhere on the conductor. This is, of course, the charge that we put on when we charge the capacitor. It should be emphasized that σ_{ext} exists only because of σ_{int} . If σ_{int} is removed by discharging the capacitor, then σ_{ext} will disappear, not by going out on the discharging wire, but by moving back into the material, by the relaxation of the polarization inside the material.

We can now apply Gauss' law to the Gaussian surface S in Fig. 10-1. The electric field E in the dielectric is equal to the total surface charge density divided by ϵ_0 . It is clear that σ_{ext} and σ_{int} have opposite signs, so

$$E = \frac{\sigma_{\text{ext}} + \sigma_{\text{int}}}{\epsilon_0} \quad (10.6)$$

Note that the field E_0 between the metal plate and the surface of the dielectric is higher than the field E ; it corresponds to σ_{ext} alone. But here we are concerned with the field inside the dielectric which, if the dielectric nearly fills the gap, is the field over nearly the whole volume. Using Eq. (10.5), we can write

$$E = \frac{\sigma_{\text{ext}} - P}{\epsilon_0}. \quad (10.7)$$

This equation doesn't tell us what the electric field is unless we know what P is. Here, however, we are assuming that P depends on E —in fact, that it is proportional to E . This proportionality is usually written as

$$P = \chi \epsilon_0 E. \quad (10.8)$$

The constant χ (Greek "khi") is called the electric susceptibility of the dielectric. Then Eq. (10.7) becomes

$$E = \frac{\sigma_{\text{ext}}}{\epsilon_0} \frac{1}{(1 + \chi)}, \quad (10.9)$$

which gives us the factor $1/(1 + \chi)$ by which the field is reduced.

The voltage between the plates is the integral of the electric field. Since the field is uniform, the integral is just the product of E and the plate separation d . We have that

$$V = Ed = \frac{\sigma_{\text{ext}} d}{\epsilon_0(1 + \chi)}.$$

The total charge on the capacitor is stored, so that the capacitance defined by (10.2) becomes

$$C = \frac{\epsilon_0 d(1 + \chi)}{d} = \frac{\chi \epsilon_0 d}{d}. \quad (10.10)$$

We have explained the observed facts. When a parallel-plate capacitor is filled with a dielectric, the capacitance is increased by the factor

$$\kappa = 1 + \chi. \quad (10.11)$$

which is a property of the material. Our explanation, of course, is not complete until we have explained—as we will do later—how the atomic polarization occurs about.

Let's now consider something a little bit more complicated—the situation in which the polarization \mathbf{P} is not everywhere the same. As mentioned earlier, if the polarization is not constant, we would expect it to look like a charge density in the volume, because more charge might move into one side of a small volume element than leaves it on the other. How can we find out how much charge is gained or lost from a small volume?

First let's compute how much charge moves across any imaginary surface when the material is polarized. The amount of charge that goes across a surface is just \mathbf{P} times the surface area if the polarization is normal to the surface. Of course, if the polarization is tangential to the surface, no charge moves across it.

Following the same arguments we have already used, it is easy to see that the charge moved across any surface element is proportional to the component of \mathbf{P} perpendicular to the surface. Compare Fig. 10-6 with Fig. 10-5. We see that Eq. (10.5) should, in the general case, be written

$$\sigma_{\text{pol}} = \mathbf{P} \cdot \mathbf{n} \quad (10.12)$$

If we are thinking of an imagined surface element inside the dielectric, Eq. (10.12) gives the charge moved across the surface but doesn't result in a net surface charge, because there are equal and opposite contributions from the dielectric on the two sides of the surface.

The displacements of the charges can, however, result in a net charge density. The total charge displaced out of any volume V by the polarization is the integral of the outward normal component of \mathbf{P} over the surface S that bounds the volume (see Fig. 10-7). An equal excess charge of the opposite sign is left behind. Denoting the net charge inside V by ΔQ_{pol} , we write

$$\Delta Q_{\text{pol}} = - \int_S \mathbf{P} \cdot \mathbf{n} d\mathbf{a}. \quad (10.13)$$

We call attribute ΔQ_{pol} to a volume distribution of charge with the density ρ_{pol} , and so

$$\Delta Q_{\text{pol}} = \int_V \rho_{\text{pol}} dV. \quad (10.14)$$

Combining the two equations yields

$$\int_V \rho_{\text{pol}} dV = - \int_S \mathbf{P} \cdot \mathbf{n} d\mathbf{a}. \quad (10.15)$$

We have a kind of Gauss' theorem that relates the charge density from polarized materials to the polarization vector \mathbf{P} . We can see that it agrees with the result we got for the surface polarization charge on the dielectric in a parallel-plate capacitor. Using Eq. (10.15) with the gaussian surface of Fig. 10-1, the surface integral gives \mathbf{P} and, and the charge inside is $\sigma_{\perp\perp}$, so we get again that $\sigma = \mathbf{P}$.

Just as we did for Gauss' law of electrostatics, we can convert Eq. (10.15) to a differential form—using Gauss' mathematical theorem:

$$\int_S \mathbf{P} \cdot \mathbf{n} d\mathbf{a} = \int_V \nabla \cdot \mathbf{P} dV,$$

We get

$$\rho_{\perp\perp} = - \nabla \cdot \mathbf{P}. \quad (10.16)$$

If there is a nonuniform polarization, its divergence gives the net density of charge appearing in the material. We emphasize that this is a perfectly real charge density; we call it "polarization charge" only to remind ourselves how it got there.

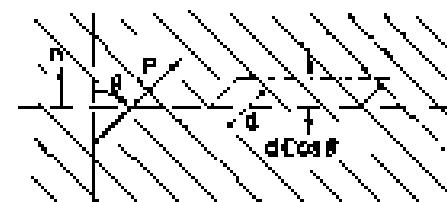

Fig. 10-6. The charge moved across an element of an imaginary surface in a dielectric is proportional to the component of \mathbf{P} normal to the surface.

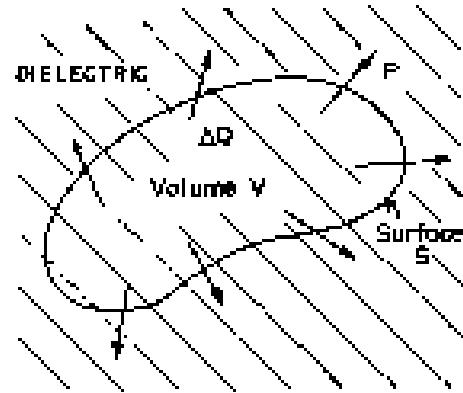

Fig. 10-7. A nonuniform polarization \mathbf{P} can result in a net charge in the body of a dielectric.

10-6 The electrostatic equations with dielectrics

Now let's combine the above result with our theory of electrostatics. The fundamental equation is

$$\nabla \cdot E = \frac{\rho}{\epsilon_0}. \quad (10.17)$$

The ρ here is the density of all electric charges. Since it is not easy to keep track of the polarization charges, it is convenient to separate ρ into two parts. Again we call ρ_{ext} the charge due to nonuniform polarization, and call ρ_{int} all the rest. Usually ρ_{ext} is the charge we put on conductors, or at known places in space. Equation (10.17) then becomes

$$\nabla \cdot E = \frac{\rho_{ext}}{\epsilon_0} + \frac{\rho_{int}}{\epsilon_0} = \frac{\rho_{ext}}{\epsilon_0} - \nabla \cdot P,$$

or

$$\nabla \cdot \left(E + \frac{P}{\epsilon_0} \right) = \frac{\rho_{ext}}{\epsilon_0}. \quad (10.18)$$

If course, the equation for the curl of E is unchanged:

$$\nabla \times E = 0. \quad (10.19)$$

Taking P from Eq. (10.8), we get the simpler equation

$$\nabla \cdot [(1 - \kappa)E] = \nabla \cdot (\kappa E) = \frac{\rho_{ext}}{\epsilon_0}. \quad (10.20)$$

These are the equations of electromatics when there are dielectrics. They don't, of course, say anything new, but they are in a form which is more convenient for computation in cases where ρ_{ext} is known and the polarization P is proportional to E .

Notice that we have not taken the dielectric "constant," κ , out of the divergence. That is because it may not be the same everywhere. If it has everywhere the same value, it can be factored out and the equations are just those of electromatics with the charge density ρ_{ext} divided by κ . In the form we have given, the equations apply to the general case where different dielectrics may be in different places in the field. Then the equations may be quite difficult to solve.

There is a history of some historical importance which should be mentioned here. In the early days of electricity, the atomic mechanism of polarization was not known and the existence of ρ_{int} was not appreciated. The charge ρ_{ext} was considered to be the entire charge density. In order to write Maxwell's equations in a simple form, a new vector D was defined to be equal to a linear combination of E and P :

$$D = \epsilon_0 E + \kappa P. \quad (10.21)$$

As a result, Eqs. (10.18) and (10.19) were written in an apparently very simple form:

$$\nabla \cdot D = \rho_{ext}, \quad \nabla \times E = 0. \quad (10.22)$$

Can one solve these? Only if a third equation is given for the relationship between D and E . When Eq. (10.8) holds, this relationship is

$$D = \epsilon_0 E + \kappa \epsilon_0 E = \kappa \epsilon_0 E. \quad (10.23)$$

This equation was usually written

$$D = \epsilon E, \quad (10.24)$$

where ϵ is still another constant for describing the dielectric property of materials. It is called the "permittivity." (Now you see why we have ϵ_0 in our equations. It is the "permittivity of empty space.") Evidently,

$$\epsilon = \kappa \epsilon_0 = (1 + \kappa) \epsilon_0 \quad (10.25)$$

Today we took up these matters from another point of view, namely, that we have simpler equations in a vacuum, and if we exhibit in every case all the charges, whatever their origin, the equations are always correct. If we separate source of the charges away for convenience, or because we do not want to discuss what is going on in detail, then we can, if we wish, write our equations in any other form that may be convenient.

One more point should be emphasized. An equation like $D \sim \epsilon E$ is an attempt to describe a property of matter. But matter is extremely complicated, and such an equation is at best not correct. For instance, if E gets too large, then D is no longer proportional to E . For small substances, the proportionality breaks down even with relatively small fields. Also, the "constant" of proportionality may depend on how fast E changes with time. Therefore this kind of equation is a kind of approximation, like Hooke's law. It cannot be a deep and fundamental equation. On the other hand, our fundamental equations for E , (10.17) and (10.19), represent our deepest and most complete understanding of electrostatics.

10-5 Fields and forces with dielectrics

We will now prove some rather general theorems for electrostatics in situations where dielectrics are present. We have seen that the capacitance of a parallel-plate capacitor is increased by a definite factor if it is filled with a dielectric. We can show that this is true for a capacitor of any shape, provided the entire region in the neighborhood of the two conductors is filled with a uniform linear dielectric. Without the dielectric, the equations to be solved are

$$\nabla \cdot E_0 = \frac{\rho_{free}}{\epsilon_0} \quad \text{and} \quad \nabla \times E_0 = 0.$$

With the dielectric present, the first of these equations is modified; we have instead the equation:

$$\nabla \cdot (\kappa E) = \frac{\rho_{free}}{\epsilon_0} \quad \text{and} \quad \nabla \times E = 0 \quad (10.26)$$

Now since we are taking κ to be everywhere the same, the last two equations can be written as

$$\nabla \cdot (\kappa E) = \frac{\rho_{free}}{\epsilon_0} \quad \text{and} \quad \nabla \times (\kappa E) = 0. \quad (10.27)$$

We therefore have the same equations for κE as for E_0 , so they have the solution $\kappa E = E_0$. In other words, the field is everywhere reduced, by the factor $1/\kappa$, than in the case without the dielectric. Since the voltage difference is a line integral of the field, the voltage is reduced by this same factor. Since the charge on the electrodes of the capacitor has been taken the same in both cases, Fig. (10.2) tells us that the capacitance, in the case of an everywhere uniform dielectric, is increased by the factor κ .

Let us now ask what the force would be between two charged conductors in a dielectric. We consider a liquid dielectric that is homogeneous everywhere. We have seen earlier that one way to obtain the force is to differentiate the energy with respect to the appropriate distance. If the conductors have equal and opposite charges, the energy $U = Q^2/2C$, where C is their capacitance. Using the principle of virtual work, any component is given by a differentiation; for example,

$$F_x = -\frac{\partial U}{\partial x} = -\frac{Q^2}{2} \frac{1}{x} \left(\frac{1}{C} \right). \quad (10.28)$$

Since the dielectric increases the capacity by a factor κ , all forces will be reduced by this same factor.

One point should be emphasized. What we have said is true only if the dielectric is a liquid. Any mention of conductors that are embedded in solid dielectric changes the mechanical stress conditions of the dielectric and alters its electrical

properties, as well as carrying some mechanical energy change in the dielectric. Moving the conductors in a liquid does not change the liquid. The liquid moves to a new place but its electrical characteristics are not changed.

Much older books on electricity start with the "fundamental" law that the force between two charges is

$$F = \frac{q_1 q_2}{4\pi\epsilon_0 r^2}. \quad (10-29)$$

a point of view which is thoroughly unsatisfactory. For one thing, it is not true in general; it is true only for a world filled with a liquid. Secondly, it depends on the fact that ϵ_0 is a constant, which is only approximately true for most dielectrics. It is much better to start with Coulomb's law for charges in a vacuum, which is always right (for stationary charges).

What does happen in a solid? This is a very difficult problem which has not been solved, because it is, in a strict, indecomposable. If you put charges inside a dielectric solid, there are many kinds of pressures and strains. You cannot deal with virtual work without including also the mechanical energy required to compress the solid, and it is a difficult matter, generally speaking, to make a unique distinction between the electrical forces and the mechanical forces due to the solid material itself. Fortunately, no one ever really needs to know the answer to the question proposed. He may sometimes want to know how much strain there is going to be in a solid, and that can be worked out. But it is much more complicated than the simple result we get for liquids.

A surprisingly complicated problem in the theory of dielectrics is the following: Why does a charged object pick up little pieces of dielectric? If you comb your hair on a dry day, the comb readily picks up small scraps of paper. If you thought carefully about it, you probably assumed the comb had one charge on it and the paper had the opposite charge on it. But the paper is initially electrically neutral. It hasn't any net charge, but it is attracted anyway. It is true that sometimes the paper will come up to the comb and then fly away, repelled immediately after it touches the comb. The reason is, of course, that when the paper touches the comb, it picks up some negative charges and thus the like charges repel. But that doesn't answer the original question. Why did the paper come toward the comb in the first place?

The answer has to do with the polarization of a dielectric when it is placed in an electric field. There are polarization charges of both signs, which are attracted and repelled by the comb. There is a net attraction, however, because the field nearer the comb is stronger than the field farther away—the comb is not an infinite sheet. Its charge is localized. A neutral piece of paper will not be attracted to either plate inside the parallel plates of a capacitor. The variation of the field is an essential part of the attraction mechanism.

As illustrated in Fig. 10-8, a dielectric is always drawn from a region of weak field toward a region of stronger field. In fact, one can prove that for small objects the force is proportional to the gradient of the square of the electric field. Why does it depend on the square of the field? Because the induced polarization charges are proportional to the field, and for given charges the forces are proportional to the field. However, as we have just indicated, there will be a net force only if the square of the field is changing from point to point. So the force is proportional to the gradient of the square of the field. The constant of proportionality involves, among other things, the dielectric constant of the object, and it also depends upon the size and shape of the object.

There is a related problem in which the force on a dielectric can be worked out quite accurately. If we have a parallel-plate capacitor with a dielectric slab only partially inserted, as shown in Fig. 10-9, there will be a force driving the sheet in. A detailed examination of the force is quite complicated; it is related to nonuniformities in the field near the edges of the dielectric and the plates. However, if we do not look at the details, but merely use the principle of conservation of energy, we can easily calculate the force. We can find the force from the formula we de-

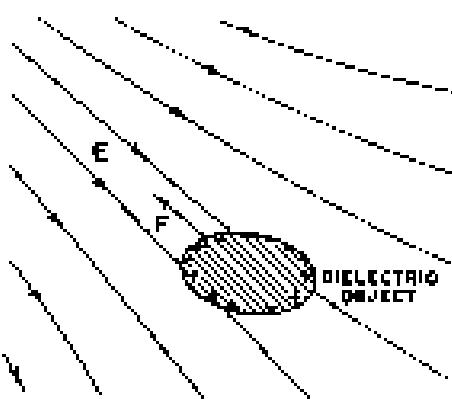

Fig. 10-8. A dielectric object in a nonuniform field feels a force toward regions of higher field strength.

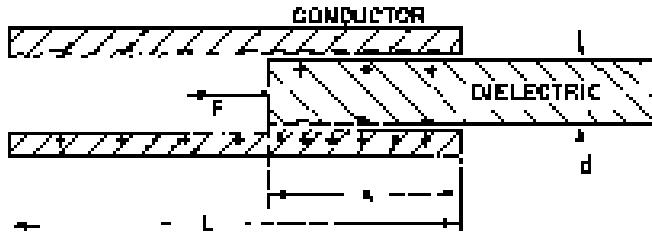

Fig. 10-9. The force on a dielectric sheet in a parallel-plate capacitor can be computed by applying the principle of energy conservation.

rived earlier. Equation (10.28) is equivalent to

$$F_x = -\frac{\partial U}{\partial x} = -\frac{P^2}{2} \frac{\partial C}{\partial x}. \quad (10.30)$$

We need only find out how the capacitance varies with the position of the dielectric slab.

Let's suppose that the total length of the plates is L , that the width of the plates is δY , that the plate separation and dielectric thickness are d , and that the distance x which the dielectric has been inserted is x . The capacitance is the ratio of the total free charge on the plates to the voltage between the plates. We have seen above that for a given voltage V the surface charge density of free charge is σ_0/ϵ_0 . So the total charge on the plates is

$$Q = \frac{\sigma_0 \delta Y}{\epsilon_0} x \Omega + \frac{\sigma_0 \delta Y}{\epsilon_0} (L - x) \Omega,$$

from which we get the capacitance:

$$C = \frac{\epsilon_0 \delta Y}{d} (x + L - x). \quad (10.31)$$

Using (10.30), we have

$$F_x = \frac{P^2}{2} \frac{\epsilon_0 \delta Y}{d} (x - 1). \quad (10.32)$$

Now this equation is not particularly useful for anything unless you happen to need to know the force in such circumstances. We only wished to show that the theory of energy can often be used to avoid enormous complications in determining the forces on dielectric materials—as force would be in the present case.

The discussion of the theory of dielectrics has dealt only with electrical phenomena, accepting the fact that the material has a polarization which is important to the electric field. Why there is such a proportionality is perhaps of greater interest to physics. Once we understand the origin of the dielectric constants from an atomic point of view, we can use electrical measurements of the dielectric constants in varying environments to obtain detailed information about atomic or molecular structures. This aspect will be treated in part in the next chapter.

Inside Dielectrics

11-1 Molecular dipoles

In this chapter we are going to discuss why it is that materials are dielectric. We said in the last chapter that we could understand the properties of electrical systems with dielectrics once we appreciated that when an electric field is applied to a dielectric it induces a dipole moment in the atoms. Specifically, if the electric field E induces an average dipole moment per unit volume P , then κ , the dielectric constant, is given by

$$\kappa = 1 + \frac{P}{\epsilon_0 E} \quad (11.1)$$

We have already discussed how this equation is applied; now we have to discuss the mechanism by which polarization arises when there is an electric field inside a molecule. We begin with the simplest possible example—the polarized air of gases. But even gases already have complications: there are two types. The molecules of atomic gases, like oxygen, which has a symmetrical pair of atoms in each molecule, have no internal dipole moment. But the molecules of others, like water vapor (which has a nonplanar-like arrangement of hydrogen and oxygen atoms) carry a permanent electric dipole moment. As we pointed out in Chapters 6 and 7, there is in the water vapor molecule an average plus charge on the hydrogen atoms and a negative charge on the oxygen. Since the center of gravity of the negative charge and the center of gravity of the positive charge do not coincide, the total charge distribution of the molecule has a dipole moment. Such a molecule is called a polar molecule. In oxygen, because of the symmetry of the molecule, the centers of gravity of the positive and negative charges are the same, so it is a nonpolar molecule. It does, however, become a dipole when placed in an electric field. The factors of the two types of molecule are sketched in Fig. 11-1.

11-2 Electronic polarization

We will first discuss the polarization of nonpolar molecules. We can start with the simplest case of a monoatomic gas (for instance, helium). When an atom of such a gas is in an electric field, the electrons are pulled one way by the field while the nucleus is pulled the other way, as shown in Fig. 10-4. Although the atoms are very stiff with respect to the electrical forces we can apply experimentally, there is a slight net displacement of the centers of charge, and a dipole moment is induced. For small fields, the amount of displacement, and so also the dipole moment, is proportional to the electric field. The displacement of the electron distribution which produces this kind of induced dipole moment is called electronic polarization.

We have already discussed the influence of an electric field on an atom in Chapter 31 of Vol. I, when we were dealing with the theory of the index of refraction. If you think about it for a moment, you will see that what we just discussed is exactly the same as we did there. But now we need worry only about fields that do not vary with time, while the index of refraction depended on time-varying fields.

In Chapter 31 of Vol. I we supposed that when an atom is placed in an oscillating electric field the center of charge of the electrons obey the equation

$$m \frac{d^2x}{dt^2} - m\omega_0^2 x = qE \quad (11.2)$$

Review: Chapter 11, Vol. I, *The Origin of the Refractive Index*.
Chapter 30, Vol. I, *The Principles of Statistical Mechanics*.

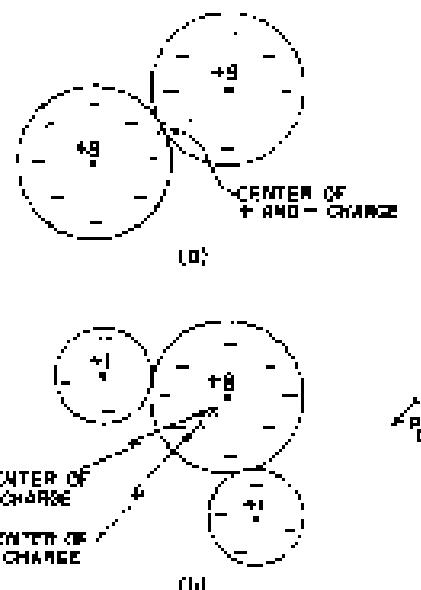

Fig. 11-1. [a] An oxygen molecule with zero dipole moment. [b] The water molecule has a permanent dipole moment P_0 .

The first term is the electron mass times its acceleration and the second is a restoring force, while the right-hand side is the force from the outside electric field. If the electric field varies with the frequency ω , Eq. (11.2) has the solution

$$\epsilon = \frac{ieE}{i\omega(\omega_0^2 - \omega^2)}, \quad (11.3)$$

which has a resonance at $\omega = \omega_0$. When we previously found this solution, we interpreted it as saying that ω_0 was the frequency at which light (in the optical region or in the ultraviolet, depending on the atom) was absorbed. For our purposes, however, we are interested only in the case of constant fields, i.e., for $\omega = 0$, so we can disregard the acceleration term in (11.2), and we find that the displacement is

$$x = \frac{q_0 E}{m\omega_0^2}. \quad (11.4)$$

From this we see that the dipole moment p of a single atom is

$$p = q_0 x = \frac{q_0^2 E}{m\omega_0^2}. \quad (11.5)$$

In this theory the dipole moment p is indeed proportional to the electric field.

People usually write

$$p = \alpha \epsilon_0 E. \quad (11.6)$$

(Again the ϵ_0 is put in for historical reasons.) The constant α is called the polarizability of the atom, and has the dimensions A^3 . It is a measure of how easy it is to induce a moment in an atom with an electric field. Comparing (11.5) with (11.6), one simple theory says that

$$\alpha = \frac{q_0^2}{m\omega_0^2} = \frac{4\pi r^3}{m\omega_0^2}. \quad (11.7)$$

If there are N atoms in a unit volume, the polarization P —the dipole moment per unit volume—is given by

$$P = Np = N\alpha \epsilon_0 E. \quad (11.8)$$

Putting (11.1) and (11.8) together, we get

$$\epsilon - 1 = \frac{P}{\epsilon_0 E} = N\alpha \quad (11.9)$$

or, using (11.7),

$$\epsilon - 1 = \frac{4\pi N r^3}{m\omega_0^2}. \quad (11.10)$$

From Eq. (11.9) we would predict that the dielectric constant ϵ of different gases should depend on the density of the gas and on the frequency ω_0 of its optical absorption.

Our formula is, of course, only a very rough approximation, because in Eq. (11.2) we have taken a model which ignores the complications of quantum mechanics. For example, we have assumed that an atom has only one resonant frequency, when it really has many. To calculate properly the polarizability α of atoms we must use the complete quantum-mechanical theory, but the classical ideas above give us a reasonable estimate.

Let's see if we can get the right order of magnitude for the dielectric constant of some substance. Suppose we try hydrogen. We have once estimated (Chapter 18, Vol. I) that the energy needed to ionize the hydrogen atom should be approximately

$$E \approx \frac{1}{2} \frac{me^4}{h^2 c^2} \quad (11.11)$$

For an estimate of the natural frequency ω_0 , we can set this energy equal to $\hbar\omega_0$, the energy of an atomic oscillator whose natural frequency is ω_0 . We get

$$\omega \approx \frac{1 \text{ cm}^{-1}}{2 \pi N}$$

If we now use this value of ω_0 in Eq. (11.7), we find for the electric susceptibility

$$\chi = \frac{\mu^2 / \epsilon_0}{16 \pi^2 N c^2} \quad (11.12)$$

The quantity $(\mu^2/\epsilon_0 c^2)$ is the radius of the ground-state orbit of a Bohr atom (see Chapter 18, Vol. I) and equals 0.528 nanostrobes. In a gas at standard pressure and temperature (1 atmosphere, 0°C) there are 1.69×10^{27} atoms/cm³, so Eq. (11.9) gives us

$$\chi = 1 + (2.69 \times 10^{19} \text{ Hg} \pi / 0.528 \times 10^{-4})^2 = 1.00020. \quad (11.13)$$

The dielectric constant for hydrogen gas is measured to be

$$\kappa_{\text{exp}} \approx 1.00026.$$

We see that our theory is almost right. We should not expect any better, because the measurements were, of course, made with ordinary hydrogen gas, which has diatomic molecules, not single atoms. We should not be surprised if the polarization of the atoms in a molecule is not quite the same as that of the separate atoms. The molecular effect, however, is not really that large. An exact quantum-mechanical calculation of χ for hydrogen atoms gives a result about 12% higher than (11.12) (the factor changes in (2.69)), and therefore predicts a dielectric constant somewhat closer to the observed one. In any case, it is clear that our model of a dielectric is fairly good.

Another check on our theory is to try Eq. (11.12) on atoms which have a higher frequency of excitation. For instance, it takes about 24.5 volts to pull the electron off helium, compared with the 13.6 volts required to ionize hydrogen. We would, therefore, expect that the absorption frequency ω_0 for helium would be about twice as big as for hydrogen and that χ would be one-quarter as large. We expect that

$$\chi_{\text{He}} \approx 1.000050.$$

Experimentally,

$$\chi_{\text{He}, \text{exp}} = 1.000055,$$

so you see that our simple estimates are coming out on the right track. So we have understood the dielectric constant of nonpolar gases, but only qualitatively, because we have never used a correct quantum theory of the motion of the atomic electrons.

11-3 Polar molecules; orientational polarization

Next we will consider a molecule which carries a permanent dipole moment μ_0 —such as a water molecule. With no electric field, the individual dipoles point in random directions, so the net moment per unit volume is zero. But when an electric field is applied, two things happen: First, there is a surface dipole moment induced because of the forces on the electrons; this part gives just the same kind of electric polarization we found for a nonpolar molecule. For very accurate work, this effect should, of course, be included, but we will neglect it for the moment. (It can always be added in at the end.) Second, the electric field tends to line up the individual dipoles to produce a net induced per unit volume. If all the dipoles in a gas were to line up, there would be a very large polarization, but that does not happen. As ordinary temperature and electric fields break the rotations of the molecules in their thermal motion, keep them from lining up very much. But there is some net alignment, and so some polarization (see Fig. 11-2). The polarization that does occur can be computed by the methods of statistical mechanics we described in Chapter 40 of Vol. I.

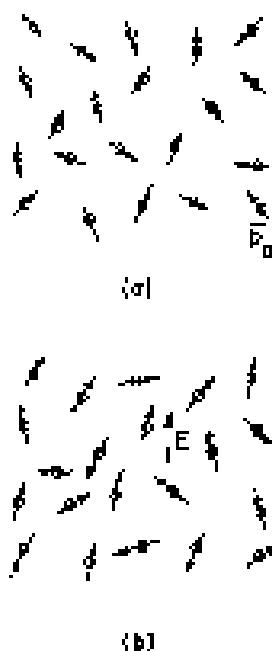

Fig. 11-2. (a) In a gas of polar molecules, the individual moments are oriented at random; the average moment in a small volume is zero. (b) When there is an electric field, there is some average alignment of the molecules.

To use this method we need to know the energy of a dipole in an electric field. Consider a dipole of moment μ_0 in an electric field, as shown in Fig. 11-1. The energy of the positive charge is $q\phi(1)$, and the energy of the negative charge is $-q\phi(2)$. Thus the energy of the dipole is

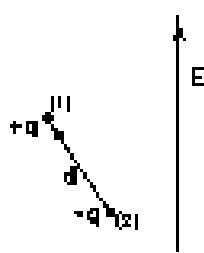

Fig. 11-3. The energy of a dipole μ_0 in the field $E = \rho_0 \cdot \vec{E}$.

$$U = q\phi(1) - q\phi(2) = qd \cdot \nabla\phi,$$

or

$$U = -\rho_0 \cdot E = -\rho_0 E \cos \theta, \quad (11.14)$$

where θ is the angle between μ_0 and E . As we would expect, the energy is lower when the dipoles are lined up with the field.

We now find out how much lining up occurs by using the methods of statistical mechanics. We found in Chapter 40 of Vol. 1 that in a state of thermal equilibrium, the relative number of molecules with the potential energy U is proportional to

$$e^{-U/kT}, \quad (11.15)$$

where $\phi(x, y, z)$ is the potential energy as a function of position. The same arguments would say that, using Eq. (11.14) for the potential energy as a function of angle, the number of molecules at θ per unit solid angle is proportional to $e^{-U/kT}$.

Letting $n(\theta)$ be the number of molecules per unit solid angle at θ , we have

$$n(\theta) = n_0 e^{-U_0/kT}, \quad (11.16)$$

For normal temperatures and fields, the exponent is small, so we can approximate by expanding the exponential:

$$n(\theta) = n_0 \left(1 + \frac{\rho_0 E \cos \theta}{kT} \right). \quad (11.17)$$

We can find n_0 if we integrate (11.17) over all angles; the result should be just N , the total number of molecules per unit volume. The average value of $\cos \theta$ over all angles is zero, so the integral is just n_0 times the total solid angle 4π . We get

$$n_0 = \frac{N}{4\pi}. \quad (11.18)$$

We see from (11.17) that there will be more molecules oriented along the field ($\cos \theta = 1$) than against the field ($\cos \theta = -1$). So in any small volume containing many molecules there will be a net dipole moment per unit volume—that is, a polarization P . To calculate P , we want the vector sum of all the molecular moments in a unit volume. Since we know that the result is going to be in the direction of E , we will just sum the components in that direction (the components at right angles to E will sum to zero);

$$P = \sum_{\text{unit volume}} \rho_0 \cos \theta.$$

We can evaluate the sum by integrating over the angular distribution. The solid angle at θ is $2\pi \sin \theta d\theta$, so

$$P = \int_0^\pi n(\theta) \rho_0 \cos \theta 2\pi \sin \theta d\theta. \quad (11.19)$$

Substituting for $n(\theta)$ from (11.17), we have

$$P = -\frac{N}{2} \int_{-1}^1 \left(1 + \frac{\rho_0 E}{kT} \cos \theta \right) \rho_0 \cos \theta d(\cos \theta),$$

which is easily integrated to give

$$P = \frac{N \rho_0^2 E}{3kT}. \quad (11.20)$$

The polarization is proportional to the field E , so there will be normal dielectric behavior. Also, as we expect, the polarization depends inversely on the temperature, because at higher temperatures there is more disalignment by collisions. This $1/T$ dependence is called Curie's law. The permanent moment p_0 appears squared for the following reason: In a given electric field, the aligning force depends upon σ , and the mean moment lost is produced by the lining up is again proportional to p_0^2 . The average induced moment is proportional to p_0^2 .

We should now try to see how well Eq. (11.20) agrees with experiment. Let's look at the case of steam. Since we don't know what p_0 is, we cannot compute κ directly, but Eq. (11.20) does predict that $\kappa - 1$ should vary inversely as the temperature, and that we should check.

From (11.20) we get

$$\kappa - 1 \approx \frac{F}{\epsilon_0 E} \approx \frac{N p_0^2}{3 \pi k T}. \quad (11.21)$$

So $\kappa - 1$ should vary in direct proportion to the density N , and inversely as the absolute temperature. The dielectric constant has been measured at several different pressures and temperatures, chosen such that the number of molecules in a unit volume remained fixed.⁴ [Notice that if the measurements had all been taken at constant pressure, the number of molecules per unit volume would decrease linearly with increasing temperature and $\kappa - 1$ would vary as T^{-1} instead of as T^{-4} .] In Fig. 11-4 we plot the experimental observations for $\kappa - 1$ as a function of $1/T$. The dependence predicted by (11.21) is followed quite well.

There is another characteristic of the dielectric constant of polar molecules—the variation with the frequency of the applied field. Due to the moment of inertia of the molecules, it takes a certain amount of time for the heavy molecules to turn toward the direction of the field. So if we apply frequencies in the high microwave region or above, the polar contribution to the dielectric constant begins to fall away because the molecules cannot follow. In contrast to this, the electronic polarizability still remains the same up to optical frequencies, because of the smaller inertia is the electrons.

11-4 Electric fields in cavities of a dielectric

We now turn to an interesting (but unapplied) question—the problem of the dielectric constant in dense materials. Suppose that we take liquid helium or liquid argon or some other nonpolar material. We still expect electronic polarization. But in a dense material, P can be large, so the field on an individual atom will be influenced by the polarization of the atoms in its close neighborhood. The question is, what electric field acts on the individual atom?

Imagine that the liquid is put between the plates of a condenser. If the plates are charged, they will produce an electric field in the liquid. But there are also charges in the individual atoms, and the total field E is the sum of both of these effects. This true electric field varies very, very rapidly from point to point in the liquid. It is very high inside the atoms—particularly right next to the nucleus—and relatively small between the atoms. The potential difference between the plates is the line integral of this total field. If we ignore all the fine-grained variations, we can think of an average electric field E , which is just V/d . (This is the field we were using in the last chapter.) We should think of this field as the average over a space containing many atoms.

Now you might think that an "average" atom in an "average" location would feel this average field. But it is not that simple, as we can show by considering what happens if we imagine different-shaped holes in a dielectric. For instance, suppose that we cut a slot in a polarized dielectric, with the slot oriented parallel to the field, as shown in part (a) of Fig. 11-5. Since we know that $\nabla \times E = 0$, the line integral of E around the curve, C , which goes as shown in (b) of the figure, should

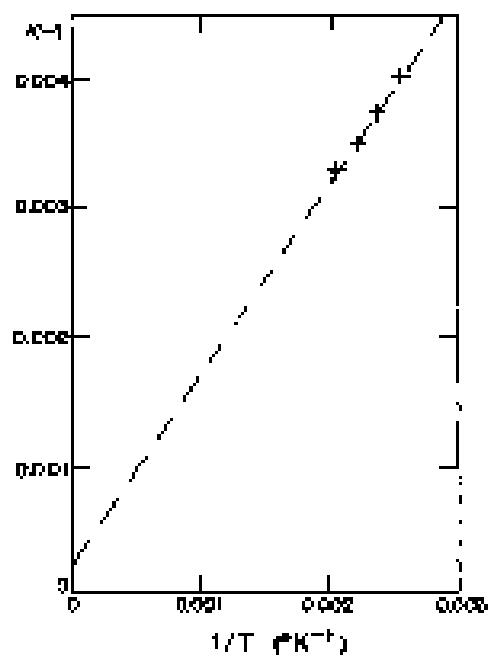

Fig. 11-4. Experimental measurements of the dielectric constant of water vapor at various temperatures.

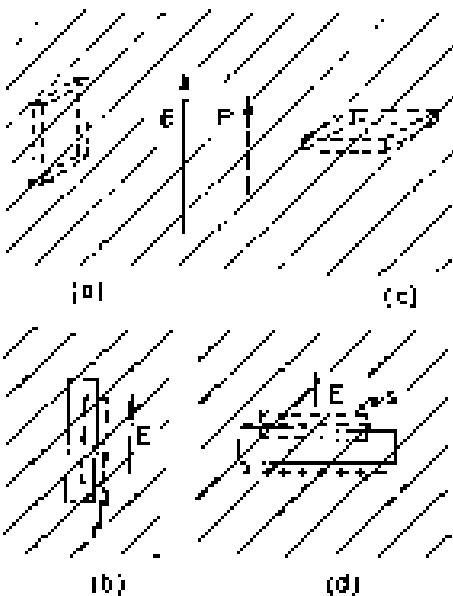

Fig. 11-5. The field in a slot cut in a dielectric depends on the shape and orientation of the slot.

⁴ Singwi, Stenflo, and Göttsche, *Svensk Fysik Revy* 5, 201 (1952).

be zero. The field inside the slot just give a contribution which just cancels the part from the field outside. Therefore the field E_0 actually found in the center of a long thin slot is equal to E , the average electric field found in the dielectric.

Now consider another slot whose boundaries are perpendicular to E , as shown in part (c) of Fig. 11-5. In this case, the field E_0 in the slot is not the same as E because polarization charges appear on the surfaces. If we apply Gauss' law to a surface S drawn as in (d) of the figure, we find that the field E_0 in the slot is given by

$$E_0 = E + \frac{P}{\epsilon_0} \quad (11.22)$$

where E is again the electric field in the dielectric. (The gaussian surface contains the surface polarization charge $\sigma_{\text{surf}} = P$.) We mentioned in Chapter 10 that $\epsilon_0 E + P$ is often called D , so $\epsilon_0 E_0 = D_0$ is equal to D in the dielectric.

Earlier in the history of physics, when it was supposed to be very important to define every quantity by direct experiment, people were delighted to discover that they could define what they meant by E and D in a dielectric without having to crawl around between the atoms. The average field E is numerically equal to the field E_0 that would be measured in a slot cut parallel to the field. And the field D could be measured by finding E_0 in a slot cut normal to the field. But nobody ever measures them that way anyway, so it was just one of those philosophical things.

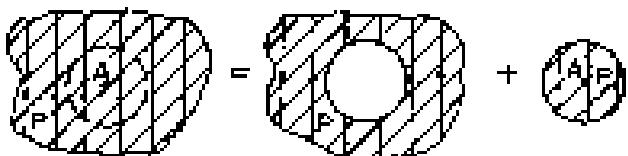

Fig. 11-6. The field at any point A in a dielectric can be considered as the sum of the field in a spherical hole plus the field due to a spherical plug.

For most liquids which are not too complicated in structure, we could expect that an atom finds itself, on the average, surrounded by the other atoms in what would be a good approximation to a spherical hole. And so we should ask: "What would be the field in a spherical hole?" We can find out by noticing that if we imagine carving out a spherical hole in a uniformly polarized material, we are just removing a sphere of polarized material. (We must imagine that the polarization is "frozen in" before we cut out the hole.) By superposition, however, the fields inside the dielectric, before the sphere was removed, is the sum of the fields from all charges outside the spherical volume plus the fields from the charges within the polarized sphere. That is, if we call E the field in the uniform dielectric, we can write

$$E = E_{\text{hole}} + E_{\text{polar}} \quad (11.23)$$

where E_{hole} is the field in the hole and E_{polar} is the field inside a sphere which is uniformly polarized (see Fig. 11-6). The fields due to a uniformly polarized sphere are shown in Fig. 11-7. The electric field inside the sphere is uniform, and its value is

$$E_{\text{polar}} = -\frac{P}{3\epsilon_0} \quad (11.24)$$

Using (11.23), we get

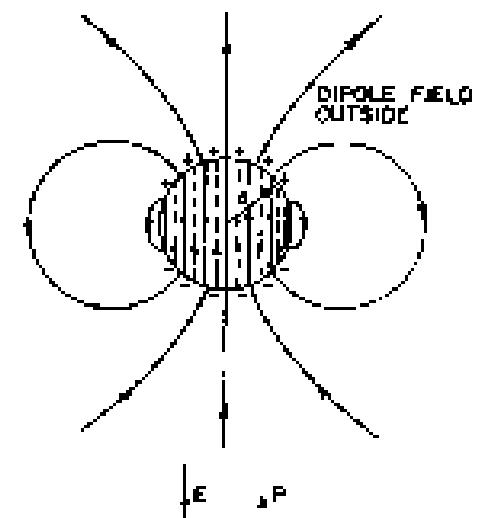

$$E_{\text{hole}} = E + \frac{P}{3\epsilon_0} \quad (11.25)$$

The field in a spherical cavity is greater than the average field by the amount $P/3\epsilon_0$. (The spherical hole gives a field $1/3$ of the way between a slot parallel to the field and a slot perpendicular to the field.)

11-5 The dielectric constant of liquids; the Clausius-Mossotti equation

In a liquid we expect that the field which will polarize an individual atom is more like E_{hole} than just E . If we use the result of (11.25) for the polarizing field in

Fig. 11-7. The electric field of a uniformly polarized sphere.

Eq. (11.6), then Eq. (11.8) becomes

$$P = Nae \left(E + \frac{E}{3\epsilon_0} \right), \quad (11.26)$$

or

$$P = \frac{Nae}{1 - (\epsilon_0/3)} \epsilon_0 E. \quad (11.27)$$

Remembering that $\epsilon - 1$ is just $P/\epsilon_0 E$, we have

$$\epsilon - 1 = \frac{Nae}{1 - (\epsilon_0/3)}, \quad (11.28)$$

which gives us the dielectric constant of a liquid in terms of a , the atomic polarizability. This is called the Gouy-Chapman equation.

Because Nae is very small, as it is for a gas (because the density N is small), then the term $Nae/3$ can be neglected compared with 1, and we get our old result, Eq. (11.9), that

$$\epsilon - 1 \approx Nae. \quad (11.29)$$

Let's compare Eq. (11.28) with some experimental results. It is best necessary to look at gases for which, using the measurement of ϵ , we can find a from Eq. (11.29). For instance, for carbon disulfide at zero degrees centigrade the dielectric constant is 1.0029, so Nae is 0.0029. Now the density of the gas is easily worked out and the density of the liquid can be found in handbooks. At 20°C, the density of liquid CS₂ is 381 times higher than the density of the gas at 0°C. This means that N is 381 times higher in the liquid than it is in the gas so, that—if we make the approximation that the basic atomic polarizability of the carbon disulfide doesn't change when it is condensed into a liquid— Nae in the liquid is equal to 381 times 0.0029, or 1.11. Notice that the $Nae/3$ term amounts to almost 0.4, so it is quite significant. With these numbers we predict a dielectric constant of 2.76, which agrees reasonably well with the observed value of 2.64.

In Table 11-2 we give some experimental data on various materials (taken from the *Handbook of Chemistry and Physics*), together with the dielectric constants calculated from Eq. (11.28) in the way just described. The agreement between observation and theory is even better for argon and oxygen than for CS₂—and not so good for carbon tetrachloride. On the whole, the results show that Eq. (11.28) works very well.

Table 11-1
Computation of the dielectric constants of liquids
from the dielectric constant of the gas.

Substance	Gas			Liquid				
	ϵ (exp)	Nae	Density	Density	Ratio*	Nae	ϵ (predicted)	ϵ (exp)
CS ₂	1.0029	0.0029	0.00039	1.290	381	1.11	2.76	2.64
O ₂	1.000223	0.000223	0.000145	1.19	832	0.435	1.2119	1.2117
CCl ₄	1.00011	0.00011	0.000489	1.59	325	0.907	2.45	2.24
A	1.000545	0.000545	0.00178	1.17	810	0.411	1.517	1.51

* Ratio = Density of liquid/density of gas.

Our derivation of Eq. (11.28) is valid only for *nonpolar* polarization in liquids. It is not right for a polar molecule like H₂O. If we go through the same calculations for water, we get 13.2 for Nae , which means that the dielectric constant for the liquid is negative, while the observed value of ϵ is 80. The problem lies to do with the correct treatment of the permanent dipoles, and Onsager has pointed out the right way to go. We do not have the time to treat the case now, but if you are interested it is discussed in Kittel's book, *Introduction to Solid State Physics*.

11-6 Solid dielectrics

Now we turn to the solids. The first interesting fact about solids is that there can be a permanent polarization built in which exists even without applying an electric field. An example occurs with a material like wax, which contains long molecules having a permanent dipole moment. If you melt some wax and put a strong electric field on it when it is a liquid, so that the dipole moments get partly lined up, they will stay that way when the liquid freezes. The solid material will have a permanent polarization which remains when the field is removed. Such a solid is called an *electret*.

An electret has permanent polarization charges on its surface. It is the electrical analog of a magnet. It is not as useful, though, because free charges from the air are attracted to its surfaces, eventually cancelling the polarization charges. The electret is "discharged" and there are no visible external fields.

A permanent internal polarization P is also found occurring naturally in some crystalline substances. In such crystals, each unit cell of the lattice has an identical permanent dipole moment, as drawn in Fig. 11-8. All the dipoles point in the same direction, even with no applied electric field. Many complicated crystals have, in fact, such a polarization; we do not normally notice it because the external fields are discharged, just as for the electrets.

If these internal dipole moments of a crystal are changed, however, external fields appear because there is not time for stray charges to gather and cancel the polarization charges. If the dielectric is in a condenser, free charges will be induced on the electrodes. For example, the moments can change when a dielectric is heated, because of thermal expansion. The effect is called *pyroelectricity*. Similarly, if we change the stresses in a crystal - for instance, if we bend it - again the moment may change a little bit, and a small electrical effect, called *piezoelectricity*, can be detected.

For crystals that do not have a permanent moment, one can work out a theory of the dielectric constant that involves the electronic polarizability of the atoms. It goes much the same as for liquids. Some crystals also have rotatable dipoles inside, and the rotation of these dipoles will then contribute to ϵ . In ionic crystals such as NaCl there is also ion polarizability. The crystal consists of a checkerboard of positive and negative ions, and in an electric field the positive ions are pulled one way and the negatives the other; there is a net relative motion of the plus and minus charges, and so a volume polarization. We could estimate the magnitude of the ionic polarizability from our knowledge of the stiffness of salt crystals, but we will not go into that subject here.

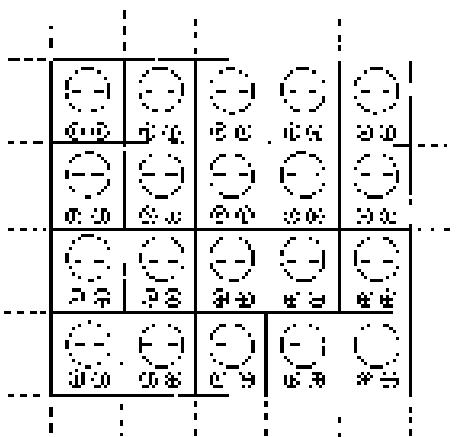

Fig. 11-8. A complex crystal lattice can have a permanent intrinsic polarization P .

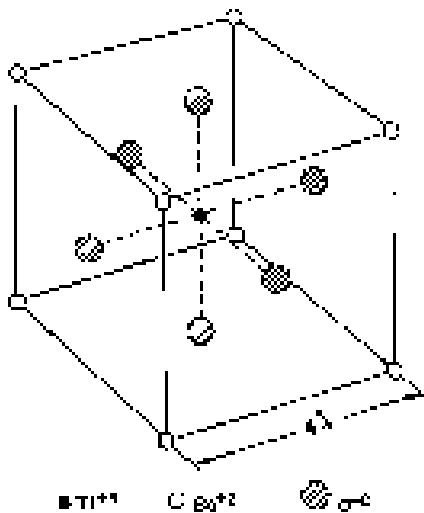

Fig. 11-9. The unit cell of BaTiO_3 . The atomic nuclei fill up most of the space; for clarity, only the positions of their centers are shown.

11-7 Ferroelectricity; BaTiO_3

We want to describe now one special class of crystals which have, just by accident almost, a built-in permanent moment. The situation is so marginal that if we increase the temperature a little bit they lose the permanent moment completely. On the other hand, if they are nearly cubic crystals, so that their moments can be turned in different directions, we can detect a large change in the moment when an applied electric field is changed. All the moments flip over and we get a large effect. Substances which have this kind of permanent moment are called *ferroelectric*, after the corresponding ferromagnetic effects which were first discovered in iron.

We would like to explain how ferroelectricity works by describing a particular example of a ferroelectric material. There are several ways in which the ferroelectric property can originate; but we will take up only one mysterious case - that of barium titanate, BaTiO_3 . This material has a crystal lattice whose basic cell is sketched in Fig. 11-9. It turns out that above a certain temperature, specifically 118°C, barium titanate is an ordinary dielectric with no enormous dielectric constant. Below this temperature, however, it suddenly takes on a permanent polarization.

In working out the polarization of solid material, we must first figure out the local fields in each unit cell. We must include the fields from the polarization

level, just as we did for the case of a liquid. But a crystal is not a homogeneous liquid, so we cannot use for the local field value we would get in a spherical shell. If you work it out for a crystal, you find that the factor $1/3$ in Eq. (11.28) becomes slightly different, but not far from $1/3$. (For a simple cubic crystal, it is just $2/3$.) We will, therefore, assume for our preliminary discussion that the factor is $1/3$ for BaTiO_3 .

Now when we wrote Eq. (11.28) you may have wondered what would happen if N_x became greater than 3 . It appears as though x would become negative. But that surely cannot be right. Let's see what should happen if we were gradually to increase σ in a ferroelectric crystal. As σ gets larger, the polarization gets bigger, making a bigger local field. But a bigger local field will polarize each atom more, raising the local field still more. If the "drive" of the atoms is enough, the process keeps going; there is a kind of feedback that causes the polarization to increase without limit, assuming that the polarization of each atom increases in proportion to the field. The "runaway" condition occurs when $N_x = 3$. The polarization does not become infinite, of course, because the proportionality between the induced moment and the electric field breaks down at high fields, so that our formulas are no longer correct. What happens is that the lattice gets "locked in" with a high, self-generated, internal polarization.

In the case of BaTiO_3 , there is, in addition to an electronic polarization, also a rather large ionic polarization, presumed to be due to titanium ions which will move a little within the cubic lattices. The lattice resists large motions, so after the titanium has gone a little way, it jams up and stops. But the crystal cell is then left with a permanent d-pole moment.

In most crystals, this is really the situation for all temperatures that can be reached. The very interesting thing about barium titanate is that there is such a delicate condition that if N_x is decreased just a little bit it comes back. Since N decreases with increasing temperature "because of thermal expansion" we can vary N_x by varying the temperature. Below the critical temperature it is just barely stuck, so it is easy -by applying an external field- to shift the polarization and have it back in a different direction.

Let's see if we can analyze what happens in more detail. We call T_c the critical temperature at which N_x is exactly 3 . As the temperature increases, N goes down a little bit because of the expansion of the lattice. Since the expansion is small, we can say that near the critical temperature

$$N_x = 3 - \beta(T - T_c), \quad (11.30)$$

where β is a small constant, of the same order of magnitude as the thermal expansion coefficient, or about 20^{-4} to 20^{-5} per degree C. Now if we substitute this relation into Eq. (11.28), we get that

$$x = 1 - \frac{3 - \beta(T - T_c)}{\beta(T - T_c)/3}.$$

Since we have assumed that $\beta(T - T_c)$ is small compared with one, we can approximate this formula by

$$x \approx 1 - \frac{9}{\beta(T - T_c)}. \quad (11.31)$$

This relation is right, of course, only for $T > T_c$. We see that just above the critical temperature x is enormous. Because N_x is so close to 3 , there is a tremendous magnetization effect, and the dielectric constant can easily be as high as 50,000 to 100,000. It is also very sensitive to temperature. For insulators, in temperature, the dielectric constant goes down inversely as the temperature, but, unlike the case of a dipolar gas, for which $x - 1$ goes inversely as the absolute temperature, for ferroelectrics it varies inversely as the difference between the absolute temperature and the critical temperature (this law is called the Curie-Weiss law).

When we lower the temperature to the critical temperature, what happens? If we imagine a lattice of unit cells like that in Fig. 11-9, we see that it is possible

to pick out chains of ions along vertical lines. One of the η 's consists of alternating oxygen and titanium ions. There are other lines made up of either barium or oxygen ions, but the spacing along these lines is greater. We make a simple model to simulate this situation by imagining, as shown in Fig. 11-10(a), a series of chains of ions. Along what we call the main chain, the separation of the ions is a , which is half the lattice constant; the lateral distance between identical chains is $2a$. There are less-dense chains in between which we will ignore for the moment. To make the analysis a little easier, we will also suppose that all the ions on the main chain are identical. (It's not a very simple simplification because all the important effects will still appear. This is one of the tricks of theoretical physics. One does a different problem because it's easier to figure out the first time, then when one understands how the thing works, it's time to put in all the complications.)

Now let's try to find out what would happen with our model. We suppose that the dipole moment of each atom is p and we wish to calculate the field at one of the atoms of the chain. We ignore all the fields from all the other atoms. We will first calculate the field from the dipoles in only one vertical chain; we will talk about the other chains later. The field at the distance r from a dipole in a direction along its axis is given by

$$E = \frac{1}{4\pi\epsilon_0} \frac{2p}{r^3}. \quad (11.32)$$

(a)

At any given atom, the dipoles at equal distances above and below it give fields in the same direction, so for the whole chain we get

$$E_{\text{chain}} = \frac{p}{4\pi\epsilon_0} \frac{2}{a} \cdot \left(1 + \frac{2}{3} + \frac{2}{27} + \frac{2}{64} + \dots \right) = \frac{p}{\epsilon_0} \frac{0.383}{a^2}. \quad (11.33)$$

It is not too hard to show that if our model were like a completely cubic crystal—that is, if the next identical lines were only the distance a away—the number 0.383 would be changed to 1/3. In other words, if the next lines were at the distance a they would contribute only -0.033 unit to our sum. (However, the next main chain we are considering is at the distance $2a$ and, as you remember from Chapter 7, the field from a periodic structure dies off exponentially with distance. Therefore these lines contribute much less than -0.033 and we can just ignore all the other chains.)

It is necessary now to find out what polarizability α is needed to make the runaway process work. Suppose that the induced moment ρ of each atom of the chain is proportional to the field on it, as in Eq. (11.6). We get the polarizing field on the atom from E_{chain} using Eq. (11.32). So we have the two equations

$$\rho = \alpha E_{\text{chain}}$$

and

$$E_{\text{chain}} = \frac{0.383}{a^2} \frac{\rho}{\epsilon_0}.$$

There are two solutions: E and ρ both zero, or

$$\alpha = \frac{a^2}{0.383},$$

with E and ρ both finite. Thus if α is as large as $a^2/0.383$, a permanent polarization established by its own field will set in. This critical equality must be reached for barium titanate at just the temperature T_c . (Notice that if α were larger than the critical value for small fields, it would decrease at larger fields and at equilibrium the same equality we have found would hold.)

For BaTiO_3 , the spacing a is 3×10^{-8} cm, so we never expect that $\alpha = 21.8 \times 10^{-41} \text{ cm}^2$. We can compare this with the known polarizabilities of the individual atoms. The oxygen, $\alpha = 30.2 \times 10^{-41} \text{ cm}^2$; we're on the right track! But barium, $\alpha = 2.4 \times 10^{-41} \text{ cm}^2$; rather small. To use our model we should probably take the average. (We could work out the chain again for alternating

atoms, but the result would be about the same. So $\alpha_{\text{average}} = 16.2 \times 10^{-21}$, which is not high enough to give a permanent polarization.

But wait a moment! We have so far only added up the electronic polarizabilities. There is also some ionic polarization due to the motion of the titanium ion. All we need is an ionic polarizability of $9.1 \times 10^{-24} \text{ cm}^3$. (A more precise computation using alternating atoms shows that actually 11.9×10^{-24} is needed.) To understand the properties of BaTiO₃, we have to assume that such an ionic polarizability exists.

Why the titanium ion in barium titanate should have that much ionic polarizability is not known. Furthermore, why, at a lower temperature, it polarizes along the cube diagonal and the face diagonal equally well is not clear. If we figure out the actual size of the spheres in Fig. 11-9, and ask whether the titanium is a little bit loose in the box formed by its neighboring oxygen atoms—which is what you would hope, so that it could be easily shifted—you find quite the contrary. It fits very tightly. The barium atoms are slightly loose, but if you let them be the ones that move, it doesn't work at all. So you see that the subject is really not one-hundred percent clear; there are still mysteries we would like to understand.

Returning to our simple model of Fig. 11-10(a), we see that the field from one chain would tend to polarize the neighboring chain in the opposite direction, which means that although each chain would be locked, there would be no net permanent moment per unit volume. (Although there would be no external electric effect, there are still certain thermodynamic effects one could observe.) Such systems exist, and are called antiferroelectric. Barium titanate, however, is really like the arrangement in Fig. 11-10(b). The oxygen-titanium chains are all polarized in the same direction because there are intermediate chains of atoms in between. Although the atoms in these chains are not very polarizable, or very dense, they will be somewhat polarized, in the direction parallel to the oxygen-titanium chains. The small dipoles produced at the real oxygen-titanium chains will get it started parallel to the first. So BaTiO₃ is really ferroelectric, and it is because of the atoms in between. You may be wondering: "But what about the direct effect between the two O-Ti chains?" Remember, though, the direct effect dies off exponentially with the separation; the effect of the chain of strong dipoles at $2a$ can be less than the effect of a chain of weak ones at the distance a .

This completes our rather sketchy report on our present understanding of the dielectric constants of gases, of liquids, and of solids.

Electrostatic Analogs

12-1 The same equations have the same solutions

The total amount of information which has been acquired about the physical world since the beginning of scientific progress is enormous, and it seems almost impossible that any one person could know a reasonable fraction of it. But it is actually quite possible for a physicist to retain a broad knowledge of the physical world rather than to become a specialist in some narrow area. The reasons for this are threefold. First, there are great principles which apply to all the different kinds of phenomena—such as the principles of the conservation of energy and of angular momentum. A thorough understanding of such principles gives an understanding of a great deal all at once. Second, there is the fact that many complicated phenomena, such as the behavior of solids under compression, only partially depend on electrical and quantum-mechanical forces, so that if one understands the fundamental laws of electricity and quantum mechanics, there is at least some possibility of understanding many of the phenomena that occur in complex situations. Finally, there is a most remarkable coincidence: The equations for many different physical situations have exactly the same appearance. Of course, the symbols may be different—one letter is substituted for another—but the mathematical form of the equations is the same. This means that having studied one subject, we immediately have a great deal of direct and precise knowledge about the solutions of the equations of another.

We are now finished with the subject of electrostatics, and will soon go on to study magnetism and electrodynamics. But before doing so, we would like to show that while learning electrostatics we have simultaneously learned about a large number of other subjects. We will find that the equations of electrostatics appear in several other places in physics. By a direct translation of the solutions (of course the same mathematical equations must have the same solutions), it is possible to solve problems in other fields with the same ease—or with the same difficulty—as in electrostatics.

The equations of electrostatics, we know, are

$$\nabla \cdot (\epsilon \mathbf{E}) = \frac{\rho_{\text{free}}}{\epsilon_0} . \quad (12.1)$$

$$\nabla \times \mathbf{E} = 0 . \quad (12.2)$$

(We take the equations of electrostatics with dielectrics as to have the most general situation.) The same physics can be expressed in another mathematical form:

$$\mathbf{E} = -\nabla \phi , \quad (12.3)$$

$$\nabla \cdot (\epsilon \nabla \phi) = -\frac{\rho_{\text{free}}}{\epsilon_0} . \quad (12.4)$$

Now the point is that there are many physics problems where mathematical equations have the same form. There is a potential (ϕ) whose gradient multiplied by a scalar function (ϵ) has a divergence equal to another scalar function ($-\rho/\epsilon_0$).

Whatever we know about electrostatics can immediately be carried over into that other subject, and vice versa. (It works both ways, of course—if the other subject has some particular characteristics that are known, then we can apply that knowledge to the corresponding electrostatic problem.) We want to consider a series of examples from different subjects that produce equations of this form.

12-2 The same equations have the same solutions

12-3 The stretched membrane

12-4 The diffusion of neutrinos; a uniform spherical source in a homogeneous medium

12-5 Rotating fluid flow; the flow past a sphere

12-6 Illumination; the uniform lighting of a plane

12-7 The "underlying unity" of nature

12-1 The flow of heat; a point source near an infinite plane boundary

We have discussed one example earlier (Section 5-4)—the flow of heat. Imagine a block of material, which does not be homogeneous but may consist of different materials at different places, in which the temperature varies from point to point. As a consequence of these temperature variations there is a flow of heat, which can be represented by the vector \mathbf{h} . It represents the amount of heat energy which flows per unit time through a unit area perpendicular to the flow. The divergence of \mathbf{h} represents the rate per unit volume at which heat is leaving a region:

$$\nabla \cdot \mathbf{h} = \text{rate of heat out per unit volume.}$$

(We could, of course, write the equation in integral form, just as we did in electrodynamics with Gauss' law—which would say that the flux through a surface is equal to the rate of change of heat energy inside the material. We will not bother to translate the equations back and forth between the differential and the integral forms, because it goes exactly the same as in electrodynamics.)

The rate at which heat is generated or absorbed at various places depends, of course, on the origin. Suppose, for example, that there is a source of heat inside the material (perhaps a hot water source, or a resistor heated by an electric current). Let us call s the heat energy produced per unit volume per second by this source. There may also be losses (or gains) of heat energy in other internal energies in the volume. If ω is the internal energy per unit volume, $d\omega/dt$ will also be a “source” of heat energy. We have, then,

$$\nabla \cdot \mathbf{h} = s - \frac{d\omega}{dt}. \quad (12.5)$$

We are not going to discuss just now the complete equation in which things change with time, because we are making an analogy to electrodynamics, where nothing depends on the time. We will consider only steady heat-flow problems, in which constant sources have produced an equilibrium state. In these cases,

$$\nabla \cdot \mathbf{h} = s. \quad (12.6)$$

It is, of course, necessary to have another equation, which describes how the heat flows at various places. In many materials the heat current is approximately proportional to the rate of change of the temperature with position: the larger the temperature difference, the more the heat current. As we have seen, the vector heat current is proportional to the temperature gradient. The constant of proportionality K , a property of the material, is called the thermal conductivity.

$$h = -K \nabla T. \quad (12.7)$$

If the properties of the material vary from place to place, then $K = K(x, y, z)$, a function of position. [Equation (12.7) is not as fundamental as (12.5), which expresses the conservation of heat energy, since the former depends upon a special property of the substance.] If now we substitute Eq. (12.7) into Eq. (12.6) we have

$$\nabla \cdot (K \nabla T) = -s. \quad (12.8)$$

which has exactly the same form as (12.4). Steady heat-flow problems and electromagnetic problems are the same. The heat flow vector \mathbf{h} corresponds to \mathbf{E} , and the temperature T corresponds to ϕ . We have already decided that a point heat source produces a temperature field which varies as $1/r$ and a heat flow which varies as $1/r^2$. This is nothing more than a translation of the statement from electrodynamics that a point charge generates a potential which varies as $1/r$ and an electric field which varies as $1/r^2$. We can, in general, solve static heat problems as easily as we can solve electrostatic problems.

Consider a simple example. Suppose that we have a cylinder of radius a at the temperature T_1 , maintained by the generation of heat in the cylinder. (It could be, for example, a wire carrying a current, or a pipe with steam condensing inside.)

The cylinder is covered with a concentric sheath of insulating material which has a conductivity K . Say the outside radius of the insulation is b and the outside is kept at temperature T_2 (Fig. 12-1a). We want to find out at what rate heat will be lost by the pipe, or steam pipe, or whatever it is in the ocean. Let the total amount of heat lost from a length L of the pipe be called Q —which is what we are trying to find.

How can we solve this problem? We have two differential equations, but since these are the same as those of electrodynamics, we have really already solved the mathematical problem. The analogous problem is that of a conductor of radius a at the potential ϕ_1 , separated from another conductor of radius b at the potential ϕ_2 , with a conductive layer of dielectric material in between, as drawn in Fig. 12-1(b). Now since the heat flow A corresponds to the electric field E , the quantity Q that we want to find corresponds to the flux of the electric field from a unit length. In other words, to the electric charge per unit length over L . We have solved the electrostatic problem by using Gauss' law. We follow the same procedure for our heat-flow problem.

From the symmetry of the situation, we know that A depends only on the distance from the center. So we enclose the pipe in a gaussian cylinder of length L and radius r . From Gauss' law, we know that the heat flow A multiplied by the area $2\pi rL$ of the surface must be equal to the total amount of heat generated inside, which is what we are calling Q .

$$2\pi r L k = Q \quad \text{or} \quad A = \frac{Q}{2\pi r L}. \quad (12.9)$$

The heat flow is proportional to the temperature gradient:

$$A = -K \nabla T,$$

or, in this case, the magnitude of A is

$$A = -K \frac{dT}{dr}.$$

This, together with (12.9), gives

$$\frac{dT}{dr} = -\frac{Q}{2\pi K L r}. \quad (12.10)$$

Differentiating from $r = a$ to $r = b$, we get

$$T_2 - T_1 = -\frac{Q}{2\pi K L} \ln \frac{b}{a}. \quad (12.11)$$

Solving for Q , we find

$$Q = \frac{2\pi K L (T_2 - T_1)}{\ln(b/a)}. \quad (12.12)$$

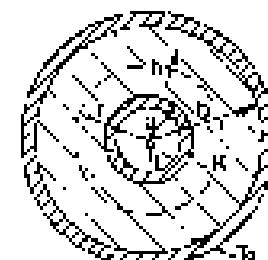

This result corresponds exactly to the result for the charge on a cylindrical condenser:

$$Q = \frac{2\pi e_0 L (\phi_2 - \phi_1)}{\ln(b/a)}.$$

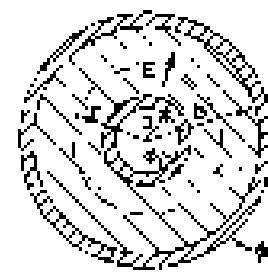

The problems are the same, and they have the same solutions. From our knowledge of electrodynamics, we also know how much heat is lost by an insulated pipe.

Let's consider another example of heat flow. Suppose we wish to know the heat flow in the neighborhood of a point source of heat located a little way beneath the surface of the earth, or near the surface of a large metal block. The idealized heat source might be an atomic bomb that was set off underground, leaving an intense source of heat, or it might correspond to a small radioactive source inside a block of iron—there are numerous possibilities.

We will treat the idealized problem of a point heat source of strength q at the distance a beneath the surface of an infinite block of uniform material whose thermal conductivity is K . And we will neglect the thermal conductivity of the

(a)

(b)

Fig. 12-1. (a) Heat flow in a cylindrical geometry. (b) The corresponding electrical problem.

air outside the material. We want to determine the distribution of the temperature on the surface of the block. How far is it right above the source and at various places on the surface of the block?

How shall we solve it? It is like an electrostatic problem with two materials with different dielectric coefficients ϵ on opposite sides of a plane boundary. And? Perhaps it is the analog of a point charge near the boundary between a dielectric and a conductor, or something similar. Let's see what the situation is near the surface. The physical condition is that the normal component of \mathbf{E} on the surface is zero, since we have assumed there is no heat flow out of the block. We should ask: In what electrostatic problem do we have the condition that the normal component of the electric field \mathbf{E} (which is the analog of \mathbf{h}) is zero at a surface? There is none!

That is one of the things that we have to watch out for. For physical reasons, there may be certain restrictions in the kinds of mathematical conditions which arise in any one subject. So if we have analyzed the differential equation only for certain limited cases, we may have missed some kinds of solutions that can occur in other physical situations. For example, there is no material with a dielectric constant of zero, whereas a vacuum does have zero thermal conductivity. So there is no electrostatic analogy for a perfect heat insulator. We can, however, still use the same method. We can try to imagine what would happen if the dielectric constant were zero. (Of course, the dielectric constant is never zero in any real situation. But we might have a case in which there is a material with a very high dielectric constant, so that we could neglect the dielectric constant of the air outside.)

How shall we find an electric field that has an component perpendicular to the surface? That is, one which is always zero at the surface? You will notice that our problem is opposite to the one of a point charge near a plane conductor. There we wanted the field to be perpendicular to the surface, because the conductor was all at the same potential. In the electrical problem, we invented a solution by imagining a point charge behind the conducting plate. We can use the same idea again. We try to pick an "image source" that will automatically make the normal component of the field zero at the surface. The solution is shown in Fig. 12-2. An image source of the same sign and the same strength placed at the distance a above the surface will cause the field to be always tangential at the surface. The normal components of the two sources cancel out.

Thus our first heat problem is solved. The temperature everywhere is the same, by direct analogy, as the potential due to two equal point charges. The temperature T at the distance r from a single point source G to a infinite medium is

$$T = \frac{G}{4\pi K r} \quad (12.13)$$

(This, of course, is just the analog of $\phi = q/4\pi\epsilon_0 r$.) The temperature for a point source, together with its image source, is

$$T = \frac{G}{4\pi K r_1} + \frac{G}{4\pi K r_2} \quad (12.14)$$

This formula gives us the temperature everywhere in the block. Several isothermal surfaces are shown in Fig. 12-2. Also shown are lines of \mathbf{h} , which can be obtained from $\mathbf{h} = -K \nabla T$.

We originally asked for the temperature distribution on the surface. For a point on the surface at the distance r from the source, $r_1 = r_2 = \sqrt{r^2 - a^2}$, so

$$T(\text{surface}) = \frac{1}{4\pi K} \frac{2G}{\sqrt{r^2 - a^2}} \quad (12.15)$$

This function is also shown in the figure. The temperature is, naturally, higher right above the source than it is farther away. This is the kind of problem that geophysicists often need to solve. We now see that it is the same kind of thing we have already been solving for electricity.

12-3 The stretched membrane

Now let us consider a completely different physical situation which, nevertheless, gives the same equations again. Consider a thin rubber sheet—a membrane—which has been stretched over a large horizontal frame (like a drum-head). Suppose now that the membrane is pushed up in one place and down in another; as shown in Fig. 12-3. Can we describe the shape of the surface? We will show how the problem can be solved when the deflections of the membrane are not too large.

There are forces in the sheet because it is stretched. If we were to make a small cut anywhere, the two sides of the cut would pull apart (see Fig. 12-2). So there is a surface tension in the sheet, analogous to the one-dimensional tension in a stretched string. We define the magnitude of the surface tension τ as the force per unit length which will just hold together the two sides of a cut such as one of those shown in Fig. 12-4.

Suppose now that we look at a vertical cross section of the membrane. It will appear as a curve, like the one in Fig. 12-4. Let u be the vertical displacement of the membrane from its normal position, and x and y the coordinates in the horizontal plane. (The cross section shows a parallel to the x -axis.)

Consider a little piece of the surface of length Δx and width Δy . There will be forces on the piece from the surface tension along each edge. The force along edge 1 (at the figure will be $\tau_1 \Delta y$, directed tangent to the surface—that is, at the angle θ_1 from the horizontal). Along edge 2, the force will be $\tau_2 \Delta y$ at the angle θ_2 . (There will be similar forces on the other two edges of the piece, but we will forget them for the moment.) The net upward force on the piece from edges 1 and 2 is

$$\Delta F = \tau_2 \Delta y \sin \theta_2 - \tau_1 \Delta y \sin \theta_1.$$

We will limit our considerations to small distortions of the membrane, i.e., to small slopes; we can then replace $\sin \theta$ by $\tan \theta$, which can be written as $\partial u / \partial x$. The force is then

$$\Delta F = \left[\tau_2 \left(\frac{\partial u}{\partial x} \right)_2 - \tau_1 \left(\frac{\partial u}{\partial x} \right)_1 \right] \Delta x \Delta y.$$

The quantity in brackets can be equally well written (for small Δx) as

$$\frac{\partial}{\partial x} \left(\tau \frac{\partial u}{\partial x} \right) \Delta x \Delta y,$$

then

$$\Delta F = \frac{\partial}{\partial x} \left(\tau \frac{\partial u}{\partial x} \right) \Delta x \Delta y.$$

There will be another contribution to ΔF from the forces at the other two edges; the total is evidently

$$\Delta F = \left[\frac{\partial}{\partial x} \left(\tau \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left(\tau \frac{\partial u}{\partial y} \right) \right] \Delta x \Delta y. \quad (12.16)$$

The distortions of the diaphragm are caused by external forces. Let's let f represent the upward force per unit area on the sheet (a kind of "pressure") from the external forces. When the membrane is in equilibrium (the static case), this force must be balanced by the internal force we have just computed, Eq. (12.16). That is

$$f = -\frac{\Delta F}{\Delta x \Delta y}.$$

Equation (12.16) can also be written

$$f = -\nabla \cdot (\gamma \nabla u), \quad (12.17)$$

where by ∇ we now mean, of course, the two-dimensional gradient operator ($\partial / \partial x, \partial / \partial y$). We have the differential equation that relates $\partial u / \partial x, y$ to the applied

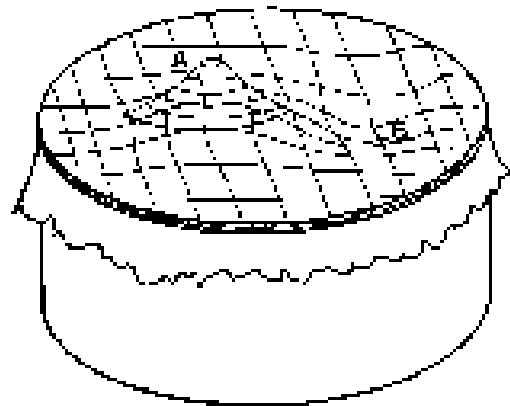

Fig. 12-3. A thin rubber sheet stretched over a cylindrical frame like a drumhead. If the sheet is pulled up at A and down at B, what is the shape of the surface?

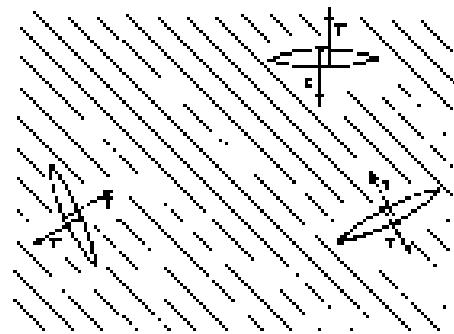

Fig. 12-4. The surface tension τ of a stretched rubber sheet is the force per unit length across a line.

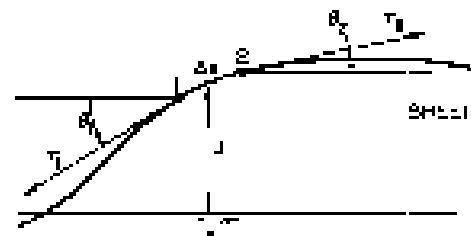

Fig. 12-5. Cross section of the deflected sheet.

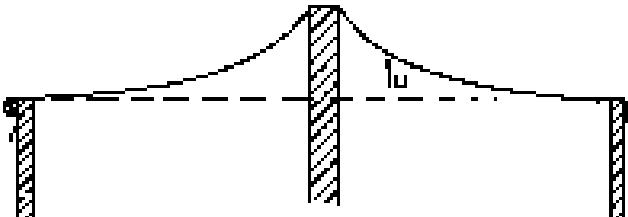

force $f(x, y)$ and the surface tension $\tau(x, y)$, which may, in general, vary from place to place in the sheet. (The distortions of a three-dimensional elastic body are also governed by similar equations, but we will stick to two-dimensions.) We will worry only about the case in which the tension τ is constant throughout the sheet. We can then write for Eq. (12.17a)

$$\nabla^2 u = -\frac{f}{\tau}. \quad (12.18)$$

We have another equation that is the same as for electrostatics!—only this time, limited to two-dimensions. The displacement u corresponds to ϕ , and f/τ corresponds to a/ϵ_0 . So all the work we have done for infinite plane charged sheets, or long parallel wires, or charged cylinders is directly applicable to the stretched membrane.

Suppose we push the membrane at some points up to a definite height—that is, we fix the value of u at some places. That is the analog of having a definite potential at the corresponding places in an electrical situation. So, for instance, we may make a positive "potential" by pushing up on the membrane with an object having the cross-sectional shape of the corresponding cylindrical conductor. For example, if we push the sheet up with a round rod, the surface will take on the shape shown in Fig. 12-6. The height u is the same as the electrostatic potential ϕ of a charged cylindrical rod. It falls off as in (12.1). (The slope, which corresponds to the electric field E , drops off as $1/r$.)

Fig. 12-6. Cross section of a stretched rubber sheet pushed up by a round rod. The function $u(x, y)$ is the same as the electric potential $\phi(x, y)$ near a very long charged rod.

The stretching method has often been used as a way of solving complicated electrical problems experimentally. The analogy is used backwards: various rods and bars are pushed against the sheet so heights that correspond to the potentials of a set of electrodes. Measurements of the height then give the electrical potential for the electrical situation. The analogy has been carried even further. If little balls are placed on the membrane, their motion corresponds approximately to the motion of electrons in the corresponding electric field. One can actually watch the "electrons" move on their trajectories. This method was used to design the complicated geometry of many photomultiplier tubes (such as the ones used for scintillation counters, and the one used for controlling the headlight beams on Cadillacs). The method is still used, but the accuracy is lower. For the most accurate work, it is better to determine the fields by numerical methods, using the large electronic computing machines.

12-4 The diffusion of neutrons; a uniform spherical source in a homogeneous medium

We take another example that gives the same kind of equation, this time having to do with diffusion. In Chapter 49 of Vol. I we considered the diffusion of ions in a single gas, and of one gas through another. This time, let's take a different example—the diffusion of neutrons in a material like graphite. We choose to speak of graphite (a pure form of carbon) because carbon doesn't absorb slow neutrons. In it, the neutrons are free to wander around. They travel in a straight line for several centimeters, on the average, before being scattered by a nucleus and deflected into a new direction. So if we have a large block—many meters on a side—the neutrons initially at one place will diffuse to other places. We want to find a description of their average behavior—that is, their average flux.

Let $N(x, y, z)$ & ΔV be the number of neutrons in the element of volume ΔV at the point (x, y, z) . Because of their motion, some neutrons will be leaving ΔV , and others will be coming in. If there are more neutrons in one region than in a nearby region, more neutrons will go from the first region to the second than come back; there will be a net flow. Following the arguments of Chapter 40 in Vol. I, we describe the flow by a flow vector J . The x -component J_x is the net number of neutrons that pass in unit time a unit area perpendicular to the x -direction. We find that

$$J_x = -D \frac{\partial N}{\partial x}, \quad (12.19)$$

where the diffusion constant D is given in terms of the mean velocity v , and the mean-free-path λ between scatterings is given by

$$D = \frac{1}{3} v \lambda.$$

The vector equation for J is

$$\mathbf{J} = -D \nabla N. \quad (12.20)$$

The rate at which neutrons flow across any surface element $d\mathbf{a}$ is $J \cdot d\mathbf{a}$ (where, as usual, \mathbf{n} is the unit normal). The net flow out of a volume element is then (following the usual gaussian argument) $\mathbf{n} \cdot J dV$. This flow would result in a decrease with time of the number N of ΔV unless neutrons are being created in ΔV (by some nuclear process). If there are sources in the volume that generate S neutrons per unit time in a unit volume, then the net flow out of ΔV will be equal to $(S - \delta N/\delta t) \Delta V$. We have then that

$$\nabla \cdot \mathbf{J} = S - \frac{\delta N}{\delta t}. \quad (12.21)$$

Combining (12.21) with (12.20), we get the neutron diffusion equation

$$\nabla \cdot (-D \nabla N) = S - \frac{\delta N}{\delta t}. \quad (12.22)$$

In the static case—where $\delta N/\delta t = 0$ —we have Eq. (12.4) all over again! We can use our knowledge of electrostatics to solve problems about the diffusion of neutrons. So let's solve a problem. (You may wonder: Why do a problem if we have already done its two problems in electrostatics? We can do it faster this time because we have done the electrostatic problems!)

Suppose we have a block of graphite in which neutrons are being generated, say, by uranium fission—uniformly throughout a spherical region of radius a (Fig. 12-7). We would like to know: What is the density of neutrons everywhere? How uniform is the density of neutrons in the region where they are being generated? What is the ratio of the neutron density at the center to the neutron density at the surface of the source region? Finding the answers is easy. The source density S replaces the charge density ρ , so our problem is the same as the problem of a sphere of uniform charge density. Finding N is just like finding the potential ϕ . We have already worked out the fields inside and outside of a uniformly charged sphere; we can integrate them to get the potential. Outside, the potential is $Q/4\pi r^2$, with the total charge Q given by $4\pi a^3 \rho/3$. So

$$\phi_{\text{outside}} = \frac{\rho a^3}{3 \epsilon_0}, \quad (12.23)$$

For points inside, the field is due only to the charge $Q(r)$ inside the sphere of radius r , $Q(r) = 4\pi r^3 \rho/3$, so

$$\mathbf{E} = \frac{\rho r^2}{3 \epsilon_0}, \quad (12.24)$$

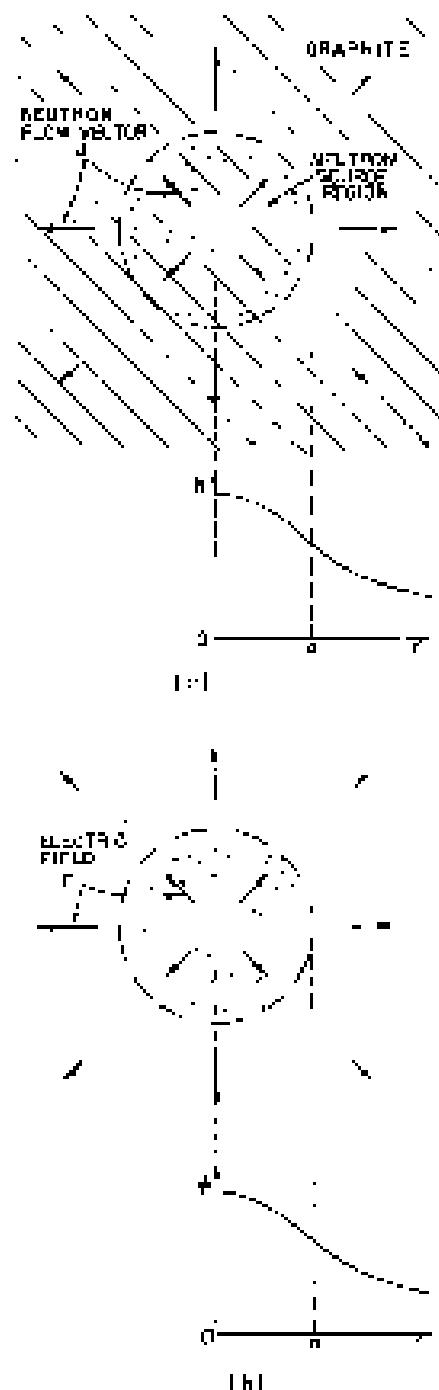

Fig. 12-7. (a) Neutrons are produced uniformly throughout a sphere of radius a in a large graphite block and diffuse outward. The neutron density N is found as a function of r , the distance from the center of the source. (b) The analogous electrostatic situation: a uniform sphere of charge, where N corresponds to ϕ and J corresponds to E .

The field increases linearly with r . Integrating E to get ϕ , we have

$$\phi_{\text{center}} = -\frac{\rho r^2}{6\epsilon_0} + \text{a constant.}$$

At the radius a , ϕ_{center} must be the same as ϕ_{surface} , so the constant must be $\rho a^2/6\epsilon_0$. (We are assuming that ϕ is zero at large distances from the source, which will correspond to N being zero for the densities.) Therefore,

$$\phi_{\text{surface}} = \frac{\rho}{6\epsilon_0} \left(\frac{3a^2}{2} - \frac{r^2}{2} \right). \quad (12.25)$$

We know immediately the neutron density in our other problem. The answer is

$$N_{\text{center}} = \frac{3a^3}{32\pi}, \quad (12.26)$$

and

$$N_{\text{surface}} = \frac{3}{16} \left(\frac{3a^3}{2} - \frac{r^3}{2} \right). \quad (12.27)$$

N is shown as a function of r in Fig. 12-7.

Now what is the ratio of density at the center to that at the edge? At the center ($r = 0$), it is proportional to $3a^3/2$. At the edge ($r = a$) it is proportional to $2a^3/2$, so the ratio of densities is $3/2$. A uniform source doesn't produce a uniform density of neutrons. You see, our knowledge of electrostatics gives us a good start in the physics of nuclear reactors.

There are many physical circumstances in which diffusion plays a big part. The motion of ions through a liquid, or of electrons through a semiconductor, follows the same equation. We find again and again the same equations.

12-5 Irrotational fluid flow; the flow past a sphere

Let's now consider an example which is not really a very good one, because the equations we will use will not really represent the subject with complete generality but only in an artificial idealized situation. We take up the problem of water flow. In the case of the stretched sheet, our arguments were an approximation which we could only for small deflections. For our consideration of water flow, we will not make that kind of an approximation; we must make restrictions that do not apply at all to real water. We treat only the case of the steady flow of an incompressible, nonviscous, circulatory-free liquid. Then we represent the flow by giving the velocity $v(r)$ as a function of position r . If the motion is steady (the only case for which there is an electrostatic analog) v is independent of time. If ρ is the density of the fluid, then ρv is the amount of mass which passes per unit time through a unit area. By the conservation of matter, the divergence of ρv will be, in general, the time rate of change of the mass of the material per unit volume. We will assume that there are no processes for the continuous creation or destruction of matter. The conservation of matter then requires that $\nabla \cdot \rho v = 0$. (It should, in general, be equal to $-\partial \rho / \partial t$, but since our fluid is incompressible, ρ cannot change.) Since v is everywhere the same, we can factor it out, and our equation is simply

$$\nabla \cdot v = 0.$$

Good! We have electrostatics again (with no charges); it's just like $\nabla \cdot E = 0$. Not so! Electrostatics is not simply $\nabla \cdot E = 0$. It is a pair of equations. One equation does not tell us enough; we need still an additional equation. To match electrostatics, we should have also that the curl of v is zero. But that is not generally true for real liquids. Most liquids will ordinarily develop some circulation. So let's not restrict to the situation in which there is no circulation of the fluid. Such flow is often called *irrotational*. Anyway, if we make all our assumptions, we can

imagine a case of fluid flow that is analogous to electrostatics. So we take

$$\nabla \cdot v = 0 \quad (12.28)$$

and

$$\nabla \times v = 0. \quad (12.29)$$

We want to emphasize that the number of circumstances in which liquid flow follows these equations is far from the great majority, but there are a few. They must be cases in which we can neglect surface tension, compressibility, and viscosity, and in which we can assume that the flow is irrotational. These assumptions are valid so rarely for real water that the mathematician Jean von Neumann said that people who analyze Eqs. (12.28) and (12.29) are studying "dry water"! (We take up the problem of fluid flow in more detail in Chapters 19 and 40.)

Because $\nabla \times v = 0$, the velocity of "dry water" can be written as the gradient of some potential:

$$v = -\nabla \phi. \quad (12.30)$$

What is the physical meaning of ϕ ? There isn't any very useful meaning. The velocity can be written as the gradient of a potential simply because the flow is irrotational. And by analogy with electrostatics, ϕ is called the velocity potential, but it is not related to a potential energy in the way that ϕ is. Since the divergence of v is zero, we have

$$\nabla \cdot (\nabla \phi) = \nabla^2 \phi = 0. \quad (12.31)$$

The velocity potential ϕ obeys the same differential equation as the electrostatic potential in free space ($\rho = 0$).

Let's pose a problem in irrotational flow and see whether we can solve it by the methods we have learned. Consider the problem of a spherical ball falling through a liquid. If it is going too slowly, the viscous forces, which we are disregarding, will be important. If it is going too fast, little whirlpools (turbulence) will appear in its wake and there will be some retardation of the water. But if the ball is going neither too fast nor too slow, it is more or less true that the water flow will fit our assumptions, and we can describe the motion of the water by our simple equations.

It is convenient to describe what happens in a frame of reference fixed in the sphere. In this frame we are asking the question: How does water flow past a sphere at rest when the flow at large distances is uniform? That is, when far from the sphere, the flow is everywhere law-like. The flow near the sphere will be as shown by the streamlines drawn in Fig. 12-8. These lines, always parallel to v , correspond to lines of electric field. We want to get a quantitative description for the velocity field, i.e., an expression for the velocity at any point P .

We can find the velocity from the gradient of ϕ , so we first work out the potential. We want a potential that satisfies Eq. (12.31) everywhere, and which also satisfies two restrictions: (1) There is no flow in the spherical region inside the surface of the ball, and (2) the flow is constant at large distances. To satisfy (1), the component of v normal to the surface of the sphere must be zero. That means that $\partial \phi / \partial r$ is zero at $r = a$. To satisfy (2), we must have $\partial \phi / \partial z = v_0$ at all points where $r \gg a$. Strictly speaking, there is no electrostatic case which corresponds exactly to our problem. It really corresponds to putting a sphere of dielectric constant zero in a uniform electric field. If we had worked out the solution to the problem of a sphere of a dielectric constant κ in a uniform field, then by putting $\kappa = 0$ we would immediately have the solution to this problem.

We have not actually worked out this particular electrostatic problem in detail, but let's do it now. (We could work directly on the fluid problem with v and ϕ , but we will use E and ϕ because we are so used to them.)

The problem is: Find a solution of $\nabla^2 \phi = 0$ such that $E = -\nabla \phi$ is a constant, say E_0 for large r , and such that the radial component of E is equal to zero at $r = a$. That is,

$$\frac{\partial}{\partial r} \left(\frac{1}{r^2} \frac{\partial \phi}{\partial r} \right) = 0. \quad (12.32)$$

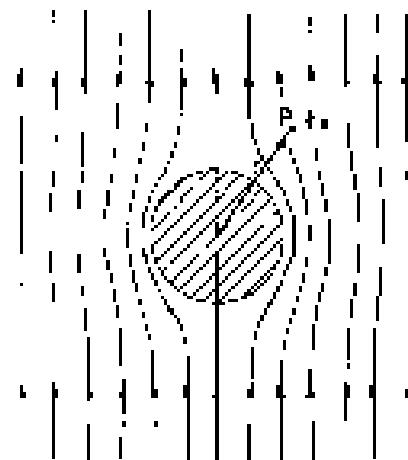

Fig. 12-8. The velocity field of irrotational fluid flow past a sphere.

Our problem involves a new kind of boundary condition, not one for which ϕ is a constant on a surface, but for which $\partial\phi/\partial r$ is a constant. That is a little different. It is not easy to get the answer immediately. First of all, without the sphere, ϕ would be $-E_0 z$. Then E would be in the z -direction and have the constant magnitude E_0 , everywhere. Now we have analyzed the case of a dielectric sphere which has a uniform polarization inside it, and we found that the field inside such a polarized sphere is a uniform field, and that outside it is the same as the field of a point dipole located at the center. So let's guess that the solution we want is a superposition of a uniform field plus the field of a dipole. The potential of a dipole (Chapter 6) is $p_z/4\pi\epsilon_0 r^3$. Thus we assume that

$$\phi = -E_0 z + \frac{p_z}{4\pi\epsilon_0 r^3}. \quad (12.33)$$

Since the dipole field falls off as $1/r^3$, at large distances we have just the field E_0 . Our guess will automatically satisfy condition (2) above. But what do we take for the dipole strength p_z ? To find out, we may use the other boundary condition, Eq. (12.32). We must differentiate ϕ with respect to r , but of course we never do see a constant angle θ , so it is more convenient if we first express ϕ in terms of r and θ , rather than r and θ . Since $z = r \cos \theta$, we get

$$\phi = -E_0 r \cos \theta + \frac{p_z \cos \theta}{4\pi\epsilon_0 r^2}. \quad (12.34)$$

The radial component of E is

$$-\frac{\partial \phi}{\partial r} = E_0 \cos \theta + \frac{p_z \cos \theta}{2\pi\epsilon_0 r^3}. \quad (12.35)$$

This must be zero at $r = a$ for all θ . This will be true if

$$p_z = -2\pi\epsilon_0 a^3 E_0. \quad (12.36)$$

Note carefully that if both terms in Eq. (12.35) had not had the same θ -dependence, it would not have been possible to choose p_z so that (12.35) turned out to be zero at $r = a$ for all angles. The fact that it works out means that we have guessed wisely in writing Eq. (12.33). Of course, when we made the guess we were looking ahead; we knew that we would need another term that (a) satisfied $\nabla^2 \phi = 0$ (any real field would do that), (b) dependent on $\cos \theta$, and (c) fall to zero at large r . The dipole field is the only one that does all three.

Using (12.36), our potential is

$$\phi = E_0 r \cos \theta \left(r + \frac{a^3}{2r^2} \right). \quad (12.37)$$

The solution of the fluid flow problem can be written simply as

$$\psi = -r \cos \theta \left(r - \frac{a^3}{2r^2} \right). \quad (12.38)$$

It is straightforward to find \mathbf{v} from this potential. We will not pursue the matter further.

12-6 Illumination; the uniform lighting of a plane

In this section we turn to a completely different physical problem—we want to illustrate the great variety of possibilities. This time we will do something that leads to the same kind of integral that we found in electrostatics. (If we have a mathematical problem which gives us a certain integral, then we know something about the properties of that integral if it is the same integral that we had to do for another problem.) We take our example from illumination engineering. Suppose there is a light source at the distance a above a plane surface. What is the illumination of the surface? That is, what is the radiant energy per unit time arriving at a unit area of the surface? (See Fig. 12-9.) We suppose that the source is spherically

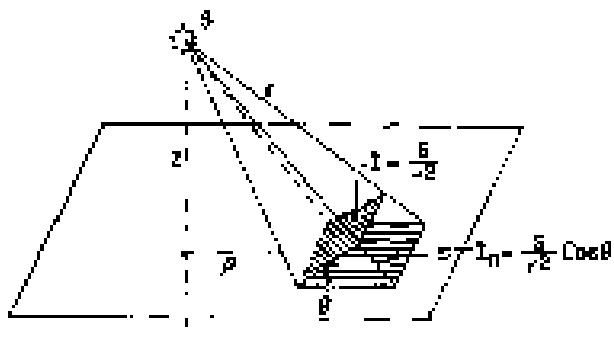

Fig. 12-9. The illumination I_n of a surface is the radiant energy per unit time arriving at a unit area of the surface.

symmetric, so that light is radiated equally in all directions. Then the amount of radiant energy which passes through a unit area at right angles to a light ray varies inversely as the square of the distance. It is evident that the intensity of the light in the direction normal to the flow is given by the same kind of formula as for the electric field from a point source. If the light rays meet the surface at an angle θ to the normal, then I , the energy arriving per unit area of the surface, is only $\cos \theta$ as great, because the same energy goes onto an area larger by $1/\cos \theta$. If we call the strength of our light source S , then I_n , the illumination of a surface, is

$$I_n = \frac{S}{r^2} \cos \theta, \quad (12.39)$$

where r is the unit vector from the source and n is the unit normal to the surface. The illumination I_n corresponds to the normal component of the electric field from a point charge of strength $4\pi r^2 S$. Knowing this, we see that for any distribution of light sources, we can find the answer by solving the corresponding electrostatic problem. We calculate the vertical component of electric field on the plane due to a distribution of charge in the same way as for that of the light sources.*

Consider the following example. We wish for some special experimental situation to arrange that the top surface of a table will have a very uniform illumination. We have available long tubular fluorescent lights which radiate uniformly along their lengths. We can illuminate the table by placing the fluorescent tubes in a regular array on the ceiling, which is at the height a above the table. What is the "ideal" spacing b from tube to tube (but we should use if we want the surface illumination to be uniform to, say, within one part in a thousand)? Answer: (1) Find the electric field from a grid of wires with the spacing b , each charged uniformly; (2) compute the vertical component of the electric field; (3) find out what b must be so that the ripples of the field are not more than one part in a thousand.

In Chapter 7 we saw that the electric field of a grid of charged wires could be represented as a sum of terms, each one of which gave a sinusoidal variation of the field with a period of b/n , where n is an integer. The amplitude of any one of these terms is given by Eq. (7.44):

$$E_1 = 4\pi e^{-2\pi n b/a}.$$

We need consider only $n = 1$, so long as we only want the field at points not too close to the grid. For a complete solution, we would still need to determine the coefficients A_n , which we have not yet done (although it is a straightforward calculation). Since we need only E_z , we can estimate that its magnitude is roughly the same as that of the average field. The exponential factor would then give us directly the relative amplitude of the variations. If we want this factor to be 10^{-3} , we find that b must be $0.91a$. If we make the spacing of the fluorescent tubes $3/4$

* Since we are talking about incoherent sources whose intensities always add linearly, the analogous electric charges will always have the same sign. Also, our analogy applies only to the light energy striking a the top of an opaque surface, so we must include in our integral only the sources which situate on the surface (and, naturally, not sources located below the surface).

of the distance to the ceiling, the exponential factor is then $1/4000$, and we have a safety factor of 4, so we are fairly sure that we will have the illumination constant to one part in a thousand. (An exact calculation shows that A_1 is really twice the average field, so the exact answer is $b = 0.82$.) It is somewhat surprising that for such a uniform illumination the allowed separation of the tubes comes out so large.

12-7 The "underlying unity" of nature

In this chapter, we wished to show that in learning electrodynamics you have learned at the same time how to handle many subjects in physics, and that by keeping this in mind, it is possible to learn almost all of physics in a limited number of years.

However, a question surely suggests itself at the end of such a discussion: Why are the equations from different phenomena so similar? We might say: "It is the underlying unity of nature." But what does that mean? What could such a statement mean? It could mean simply that the equations are similar for different phenomena; but then, of course, we have given no explanation. The "underlying unity" might mean that everything is made out of the same stuff, and therefore obeys the same equations. That sounds like a good explanation, but let us think. The electrostatic potential, the diffusion of neutrons, heat flow—are we really dealing with the same stuff? Can we really imagine that the electrostatic potential is physically identical to the temperature, or to the density of particles? Certainly ϕ is not exactly the same as the thermal energy of particles. The displacement of a membrane is certainly not like a temperature. Why, then, is there "an underlying unity"?

A closer look at the physics of the various subjects shows, in fact, that the equations are not really identical. The equation we found for neutron diffusion is only an approximation that is good when the distance over which we are looking is large compared with the mean free path. If we look more closely, we would see the individual neutrons running around. Certainly the motion of an individual neutron is a completely different thing from the smooth variation we get from solving the differential equation. The differential equation is an approximation, because we assume that the neutrons are smoothly distributed in space.

Is it possible that this is the clue? Thus the thing which is common to all the phenomena is the space, the framework into which the physics is put? As long as things are reasonably smooth in space, then the important things that will be involved will be the rates of change of quantities with position in space. That is why we always get an equation with a gradient. The derivatives must appear in the form of a gradient or a divergence; because the laws of physics are independent of direction, they must be expressible in vector form. The equations of electrodynamics are the simplest vector equations that one can get which involve only the spatial derivatives of quantities. Any other complex problem—or simplification of a complicated problem—must look like electrodynamics. What is common to all our problems is that they involve space and that we have *buried* what is actually a complicated phenomenon by a simple differential equation.

That leads us to another interesting question. Is the same statement perhaps also true for the electrostatic equations? Are they also correct only as a smooth-but-imitation of a really much more complicated microscopic world? Could it be that the real world consists of little X-ons which can be seen only at very tiny distances? And that in our measurements we are always observing on such a large scale that we can't see these little X-ons, and that is why we get the differential equations?

Our currently most complete theory of electrodynamics does indeed have its difficulties at very short distances. So it is possible, in principle, that these equations are smoothed-out versions of something. They appear to be correct at distances down to about 10^{-14} cm, but then they begin to lose weight. It is possible that there is some as yet undiscovered underlying "messiness," and that the details of an underlying complexity are hidden in the smooth-looking equations—as is so

in the "standard" discussion of neutrinos. But no one has yet formulated a successful theory that works that way.

Strangely enough, it turns out (for reasons that we do not at all understand) that the combination of relativity and quantum mechanics as we know them seems to forbid the execution of an operation that is fundamentally different from Eq. (12.4), and which does not at the same time lead to some kind of contradiction. Not simply a disagreement with experiment, but an *internal contradiction*. As, for example, the prediction that the sum of the probabilities of all possible occurrences is not equal to unity, or that energies may sometimes come out as complex numbers, or worse still, negativity. No one has yet made up a theory of electricity for which $\nabla^2\phi = -\rho/e_n$ is understood as a smoothed-out approximation to a mechanism underneath, and which does not lead ultimately to some kind of an absurdity. But, it must be added, it is also true that the assumption that $\nabla^2\phi = -\rho/e_n$ is valid for all distances, no matter how small, leads to absurdities of its own (the electrical energy of an electron is infinite)—absurdities from which we can yet escape.

Magnetostatics

13-1 The magnetic field

The force on an electric charge depends not only on where it is, but also on how fast it is moving. Every point in space is characterized by two vector quantities which determine the force on any charge. First, there is the electric force, which gives a force component independent of the motion of the charge. We describe it by the electric field, E . Second, there is an additional force component, called the magnetic force, which depends on the velocity of the charge. This magnetic force has a strange directional character: At any particular point in space, both the direction of the force and its magnitude depend on the direction of motion of the particle; at every instant the force is always at right angles to the velocity vector; also, at any particular point, the force is always at right angles to a fixed direction in space (see Fig. 13-1); and finally, the magnitude of the force is proportional to the component of the velocity at right angles to this unique direction. It is possible to describe all of this behavior by defining the magnetic field vector B , which specifies both the unique direction in space and the constant of proportionality with the velocity, and to write the magnetic force as $\mathbf{q}v \times \mathbf{B}$. The total electrodynamic force on a charge can, then, be written as

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}). \quad (13.1)$$

This is called the *Lorentz force*.

The magnetic force is easily demonstrated by bringing a bar magnet close to a cathode-ray tube. The deflection of the electron beam shows that the presence of the magnet results in forces on the electrons transverse to their direction of motion, as we described in Chapter 12 of Vol. I.

The unit of magnetic field B is evidently one newton-second per coulomb-meter. The same unit is also one volt-second per meter². It is also called one weber per square meter.

13-2 Electric current; the conservation of charge

We consider first how we can understand the magnetic forces on wires carrying electric currents. In order to do this, we define what is meant by the current density. Electric currents are electric or ionic charges in motion with a net drift or flow. We can represent the charge flow by a vector which gives the amount of charge passing per unit area and per unit time through a surface element at right angles to the flow (just as we did for the case of heat flow). We call this the current density and represent it by the vector j . It is directed along the motion of the charges. If we take a small area ΔS at a given place in the material, the amount of charge flowing across that area in a unit time is

$$j \cdot \mathbf{n} \Delta S, \quad (13.2)$$

where \mathbf{n} is the unit vector normal to ΔS .

The current density is related to the average flow velocity of the charges. Suppose that we have a distribution of charges whose average motion is a drift with the velocity v . As this distribution passes over a surface element ΔS , the charge Δq passing through the surface element in a time Δt is equal to the charge contained in a parallelepiped whose base is ΔS and whose height is $v \Delta t$, as shown in Fig. 13-2. The volume of the parallelepiped is the projection of ΔS at right angles to v times

13-8 Superposition; the right-hand rule

Review: Chapter 13, Vol. I: The Special Theory of Relativity

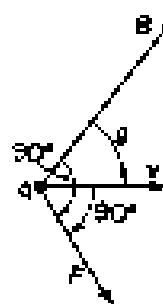

Fig. 13-1. The velocity-dependent component of the force on a moving charge is at right angles to v and to the direction of B . It is also proportional to the component of v at right angles to B , that is, to $v \sin \theta$.

Δt , which when multiplied by the charge density ρ will give Δq . Thus

$$\Delta q = \rho v \cdot n \Delta S \Delta t.$$

The charge per unit time is then $\rho v \cdot n \Delta S$, from which we get

$$j = \rho v \quad (13.3)$$

If the charge distribution consists of individual charges, say electrons, each with the charge q and moving with the mean velocity v , then the current density is

$$j = Nqv, \quad (13.4)$$

where N is the number of charges per unit volume.

The total charge passing per unit time through any surface S is called the electric current, I . It is equal to the integral of the normal component of the flow through all of the elements of the surface:

$$I = \int_S j \cdot n dS \quad (13.5)$$

(see Fig. 13-3).

The current I out of a closed surface S represents the rate at which charge leaves the volume V enclosed by S . One of the basic laws of physics is that electric charge is indestructible; it is never lost or created. Electric charges can move from place to place but never appear from nowhere. We say that charge is conserved. If there is a net current out of a closed surface, the amount of charge inside must decrease by the corresponding amount (Fig. 13-4). We can, therefore, write the law of the conservation of charge as

$$\int_{\text{closed surface}} j \cdot n dS = - \frac{d}{dt} (Q_{\text{inside}}). \quad (13.6)$$

The charge inside can be written as a volume integral of the charge density:

$$Q_{\text{inside}} = \int_V \rho dV. \quad (13.7)$$

If we apply (13.6) to a small volume ΔV , we know that the left-hand integral is $\nabla \cdot j \Delta V$. The charge inside is $\rho \Delta V$, so the conservation of charge can also be written as

$$\nabla \cdot j = - \frac{\partial \rho}{\partial t} \quad (13.8)$$

(Gauss' mathematics once again!).

13-3 The magnetic force on a current

Now we are ready to find the force on a current-carrying wire in a magnetic field. The current consists of charged particles moving with the velocity v along the wire. Each charge feels a transverse force

$$\mathbf{F} = qv \times \mathbf{B}$$

(Fig. 13-5a). If there are N such charges per unit volume, the number in a small volume ΔV of the wire is $N \Delta V$. The total magnetic force ΔF on the volume ΔV is the sum of the forces on the individual charges, that is,

$$\Delta F = (N \Delta V)(qv \times \mathbf{B}).$$

But Nqv is just j , so

$$\Delta F = j \times \mathbf{B} \Delta V \quad (13.9)$$

(Fig. 13-5b). The force per unit volume is $j \times \mathbf{B}$.

If the current is uniform across a wire whose cross-sectional area is A , we may take as the volume element a cylinder with the base area A and the length ΔL . Then

$$\Delta F = j \times B A \Delta L. \quad (13.10)$$

Now we can call jA the vector current I in the wire. (Its magnitude is the electric current in the wire, and its direction is along the wire.) Then

$$\Delta F = I \times B A \Delta L. \quad (13.11)$$

The force per unit length on a wire is $I \times B$.

This equation gives the important result that the magnetic force on a wire, due to the movement of charge in it, depends only on the total current, and not on the amount of charge carried by each particle—or even its sign! The magnetic force on a wire near a magnet is easily shown by observing its deflection when a current is turned on, as was described in Chapter 1 (see Fig. 1-6).

13-4 The magnetic field of steady currents; Ampere's law

We have seen that there is a force on a wire in the presence of a magnetic field, produced, say, by a magnet. From the principle that action equals reaction we might expect that there should be a force on the source of the magnetic field, i.e., on the magnet, when there is a current through the wire.* Thus we indeed find forces, as is seen by the deflection of a compass needle near a current-carrying wire. Now we know that magnets feel forces from other magnets, so that proves that when there is a current in a wire, the wire itself generates a magnetic field. Moving charges, then, produce a magnetic field. We would like now to try to discover the laws that determine how such magnetic fields are created. The question is: Given a current, what magnetic field does it make? The answer to this question was determined experimentally by three critical experiments and a brilliant abooretical argument given by Ampere. We will pass over this interesting historical development and simply say that a large number of experiments have demonstrated the validity of Maxwell's equations. We take them as our starting point. If we drop the terms involving time derivatives in these equations we get the equations of magnetostatics:

$$\nabla \cdot H = 0 \quad (13.12)$$

and

$$\nabla \times B = \frac{j}{\epsilon_0}. \quad (13.13)$$

These equations are valid only if all electric charge densities are constant and all currents are steady, so that the electric and magnetic fields are not changing with time—all of the fields are “static.”

We may remark that it is rather dangerous to think that there is such a thing as a static magnetic situation because there must be currents in order to get a magnetic field at all—and currents can come only from moving charges. “Magnetostatics” is, therefore, an approximation. It refers to a special kind of dynamic situation with large numbers of charges in motion, which we can approximate by a steady flow of charge. Only then can we speak of a current density j which does not change with time. The subject should more accurately be called the study of steady currents. Assuming that all fields are steady, we drop all terms in $\partial E/\partial t$ and $\partial B/\partial t$ from the complete Maxwell equations, Eqs. (2.11), and obtain the two equations (13.12) and (13.13) above. Also notice that since the divergence of the curl of any vector is necessarily zero, Eq. (13.13) requires that $\nabla \cdot j = 0$. This is true, by Eq. (13.8), only if $\partial j/\partial t$ is zero. But that must be so if E is not changing with time, so our assumptions are consistent.

* We will see later, however, that such assumptions are not generally correct for electromagnetic forces!

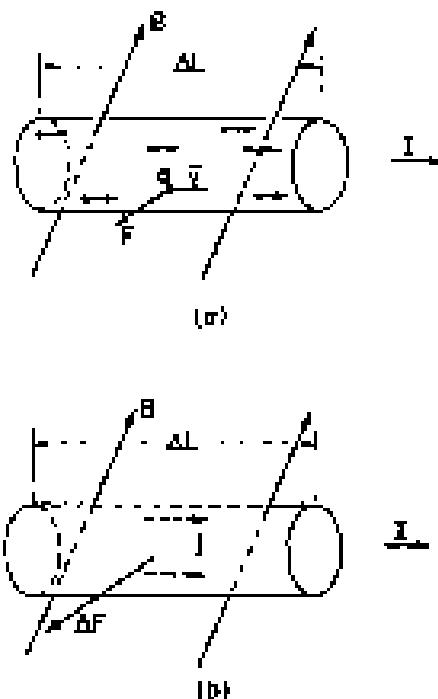

Fig. 13-5. The magnetic force on a current-carrying wire is the sum of the forces on the individual moving charges.

The requirement that $\nabla \cdot \mathbf{B} = 0$ means that we may only have charges which flow in paths that close back on themselves. Only they, for instance, flow in wires that form complete loops—called circuits. The circuits may, of course, contain generators or batteries that keep the charges flowing. But they may not include conductors which are charging or discharging. (We will, of course, extend the theory later to include dynamic fields, but we will first take the simpler case of steady currents.)

Now let us look at Eqs. (13.13) and (13.13) to see what they mean. The first says that the divergence of \mathbf{B} is zero. Comparing it to the analogous equation in electromagnetism, which says that $\nabla \cdot \mathbf{E} = \rho/\epsilon_0$, we can conclude that there is no magnetic analog of an electric charge. There are no magnetic charges from which lines of \mathbf{B} can emerge. If we think in terms of “lines” of the vector field \mathbf{B} , they can never start and they never stop. Then where do they come from? Magnetic fields “appear” in the presence of currents; they have a curl proportional to the current density. Wherever there are currents, there are lines of magnetic field linking loops around the currents. Since lines of \mathbf{B} do not begin or end, they will often close back on themselves, making closed loops. But there can also be complicated situations in which the lines are not simple closed loops. But whatever they do, they never diverge from points. No magnetic charges have ever been discovered, so $\nabla \cdot \mathbf{B} = 0$. This much is true not only for magnetostatics, it is always true even for dynamic fields.

The connection between the \mathbf{B} field and currents is contained in Eq. (13.13). Here we have a new kind of situation which is quite different from electromagnetism, where we had $\nabla \times \mathbf{E} = 0$. That equation meant that the line integral of \mathbf{E} around any closed path is zero:

$$\oint_C \mathbf{E} \cdot d\mathbf{l} = 0.$$

We get this result from Stokes' theorem, which says that the integral around any closed path of any vector field \mathbf{A} is equal to the surface integral of the curl of \mathbf{A} projected at the end of the vector (taken over any surface which has the closed loop as its periphery). Applying the same theorem to the magnetic field vector and using the symbols shown in Fig. 13-6, we get

$$\oint_C \mathbf{B} \cdot d\mathbf{l} = \int_S (\nabla \times \mathbf{B}) \cdot \mathbf{n} dS. \quad (13.14)$$

Taking the curl of \mathbf{B} from Eq. (13.13), we have

$$\oint_C \mathbf{B} \cdot d\mathbf{l} = \frac{1}{\epsilon_0 c^2} \int_S j \cdot \mathbf{n} dS. \quad (13.15)$$

The integral over j , according to (13.5), is the total current I through the surface S . Since for steady currents the current through S is independent of the shape of S , so long as it is bounded by the curve C , one usually speaks of “the current through the ‘loop’.” We have, then, a general law: the circulation of \mathbf{B} around any closed curve is equal to the current I through the loop, divided by $\epsilon_0 c^2$:

$$\oint_C \mathbf{B} \cdot d\mathbf{l} = \frac{I_{\text{through } S}}{\epsilon_0 c^2}. \quad (13.16)$$

This law—called Ampere's law—plays the same role in magnetostatics that Gauss' law played in electromagnetism. Ampere's law alone does not determine \mathbf{B} from currents; we must, in general, also use $\nabla \cdot \mathbf{B} = 0$. But, as we will see in the next section, it can be used to find the field in special circumstances which have certain simple symmetries.

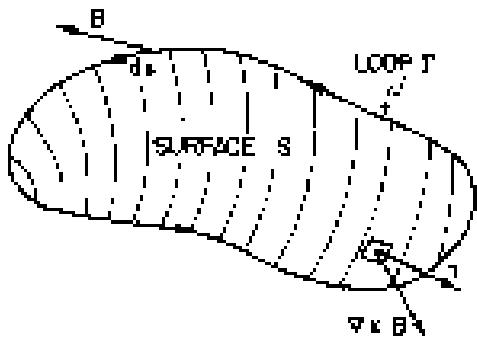

Fig. 13-4. The line integral of the tangential component of \mathbf{B} is equal to the surface integral of the normal component of $\nabla \times \mathbf{B}$.

13-5 The magnetic field of a straight wire and of a solenoid; summing currents

We can illustrate the use of Ampere's law by finding the magnetic field near a wire. We ask: What is the field outside a long, straight wire with a cylindrical cross section? We will assume something which may not be at all evident, but which is nevertheless true: that the field lines of B go around the wire in closed circles. If we make this assumption, then Ampere's law, Eq. (13.16), tells us how strong the field is. From the symmetry of the problem, B has the same magnitude at all points on a circle concentric with the wire (see Fig. 13-7). We can then do the line integral of B at quite easily; it is just the magnitude of B times the circumference. If r is the radius of the circle, then

$$\oint \mathbf{B} \cdot d\mathbf{s} = B \cdot 2\pi r.$$

The total current through the loop is merely the current I in the wire, so

$$B \cdot 2\pi r = \frac{I}{\mu_0 r^2},$$

or

$$B = \frac{1}{4\pi\mu_0 r^2} \frac{2I}{r}. \quad (13.17)$$

The strength of the magnetic field drops off inversely as r , the distance from the axis of the wire. We can, if we wish, write Eq. (13.17) in vector form. Remembering that \mathbf{B} is at right angles both to \mathbf{I} and to \mathbf{r} , we have

$$\mathbf{B} = \frac{1}{4\pi\mu_0 r^2} \frac{2I \times \mathbf{e}_r}{r}. \quad (13.18)$$

We have separated out the factor $1/4\pi\mu_0 r^2$, because it appears often. It is worth remembering that it is exactly 10^{-7} (in the mks system), since an equation like (13.17) is used to define the unit of current, the ampere. At one meter from a current of one ampere the magnetic field is 2×10^{-7} webers per square meter.

Since a current produces a magnetic field, it will exert a force on a nearby wire which is also carrying a current. In Chapter 1 we described a simple demonstration of the forces between two current-carrying wires. If the wires are parallel, each is at right angles to the B field of the other; the wires should then be pushed either toward or away from each other. When currents are in the same direction, the wires attract; when the currents are moving in opposite directions, the wires repel.

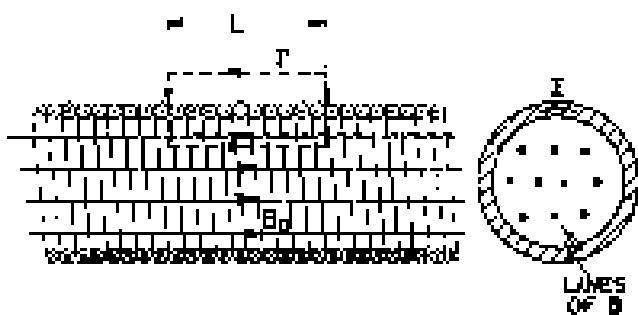

Fig. 13-8. The magnetic field of a long solenoid.

Let's take another example that can be analyzed by Ampere's law if we add some knowledge about the field. Suppose we have a long coil of wire wound in a tight spiral, as shown by the cross sections in Fig. 13-8. Such a coil is called a solenoid. We observe experimentally that when a solenoid is very long compared with its diameter, the field outside is very small compared with the field inside. Using just that fact, together with Ampere's law, we can find the size of the field inside.

Since the field inside must have zero divergence, its lines must go along parallel to the axis, as shown in Fig. 13-8. That being the case, we can use Ampere's law with the rectangular "curve" L shown in the figure. This loop goes the distance

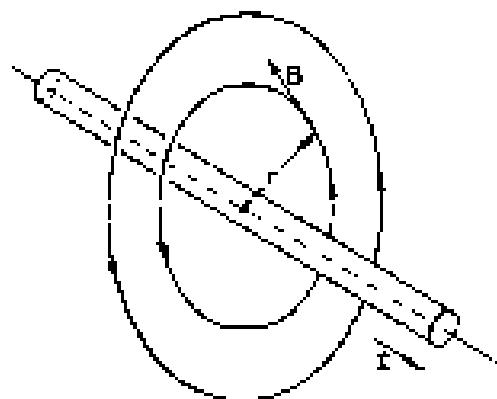

Fig. 13-7. The magnetic field outside of a long wire carrying the current I .

7. inside the solenoid, where the field is, say, B_0 , then goes at right angles to the field, and returns along the outside, where the field is negligible. The line integral of \mathbf{B} for this curve is just B_0L , and it must be $1/\epsilon_0c^2$ times the total current through C , which is NI if there are N turns of the solenoid in the length L . We have

$$B_0L = \frac{NI}{\epsilon_0c^2}.$$

Or, letting n be the number of turns per unit length of the solenoid (that is, $n = N/L$), we get

$$B_0 = \frac{nI}{\epsilon_0c^2}. \quad (13.19)$$

What happens to the lines of \mathbf{B} when they get to the end of the solenoid? Presumably, they spread out in some way and return to enter the solenoid at the other end, as sketched in Fig. 13-9. Such a field is just what is observed outside of a bar magnet. But what is a magnet anyway? Our equations say that \mathbf{B} comes from the presence of currents. Yet we know that ordinary bars of iron (no batteries or generators) also produce magnetic fields. You might expect that there should be some other terms on the right-hand side of (13.12) or (13.13) to represent "the density of magnetization" or some such quantity. But there is no such term. Our theory says that the magnetic effects of iron come from some internal currents which are already taken care of by the j term.

Matter is very complex when looked at from a fundamental point of view—but we saw when we tried to understand Electricity. In order not to interrupt our present discussion, we will wait until later to deal in detail with the interior mechanisms of magnetic materials like iron. You will have to accept, for the moment, that all magnetism is produced from currents, and that in a permanent magnet there are permanent induced currents. In the case of iron, these currents consist of electrons spinning around their own axes. Every electron has such a spin, which corresponds to a tiny circulating current. Of course, one electron doesn't produce much magnetic field, but in an ordinary piece of matter there are billions and billions of electrons. Normally their spin and point every which way, so that there is no net effect. The秘密 is that in a few low substances, like iron & some forms of the electrons spin with their axes in the same direction—for iron, two electrons from each atom take part in this cooperative motion. In a bar magnet there are large numbers of electrons all spinning in the same direction and, as we will see, their total effect is equivalent to a current circulating on the surface of the bar. (This is quite analogous to what we found for dielectrics—that a uniformly polarized dielectric is equivalent to a distribution of charges on its surface.) It is, therefore, no accident that a bar magnet is equivalent to a solenoid.

13-6 The relativity of magnetic and electric fields

When we said that the magnetic force on a charge was proportional to its velocity, you may have wondered: "What velocity? With respect to which reference frame?" It is, in fact, clear from the definition of \mathbf{B} given at the beginning of this chapter that what this vector is will depend on what we choose as a reference frame for specifying the velocity of charges. But we have said nothing about which is the proper frame for specifying the magnetic field.

It turns out that our inertial frame will do. We will also see that magnetism and electricity are not independent things—that they should always be taken together as one complete electromagnetic field. Although in the static case Maxwell's equations separate into two distinct pairs, one pair for electricity and one pair for magnetism, with no apparent connection between the two fields, nevertheless, in nature itself there is a very intimate relationship between them that arises from the principle of relativity. Historically, the principle of relativity was discovered after Maxwell's equations. It was, in fact, the study of electricity and magnetism which led ultimately to Einstein's discovery of his principle of relativity. But let's see

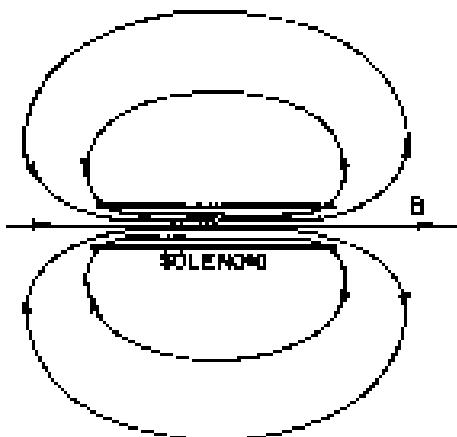

Fig. 13-9. The magnetic field outside of a solenoid.

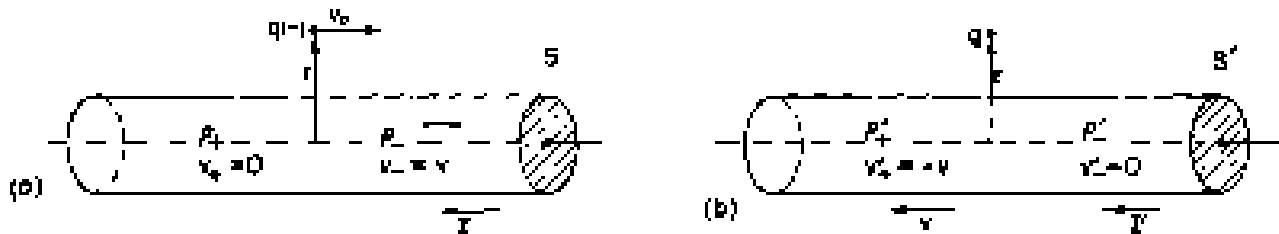

Fig. 13-10. The interaction of a current-carrying wire and a particle with the charge q as seen in two frames. In frame S [part (a)] the wire is at rest; in frame S' [part (b)], the charge is at rest.

what our knowledge of relativity would tell us about magnetic forces if we assume that the relativity principle is applicable—as it is—to electromagnetism.

Suppose we think about what happens when a negative charge moves with velocity v_0 parallel to a current-carrying wire, as in Fig. 13-10. We will try to understand what goes on in two reference frames: one fixed with respect to the wire, as in part (a) of the figure, and one fixed with respect to the particle, as in part (b). We will call the first frame S and the second S' .

In the S -frame, there is clearly a magnetic force on the particle. The force is directed toward the wire, so if the charge is moving freely we would see it curve in toward the wire. But in the S' -frame there will be no magnetic forces on the particle, because its velocity is zero. Does it, therefore, stay where it is? Would we see different things happening in the two systems? The principle of relativity would say that in S' we should also see the particle move closer to the wire. We must try to understand why that would happen.

We return to our atomic description of a wire carrying a current. In a normal conductor, like copper, the electric currents come from the motion of some of the negative electrons—called the conduction electrons—while the positive nuclear charges and the remainder of the electrons stay fixed in the body of the material. We let the density of the conduction electrons be ρ , and their velocity in S be v . The density of the charges at rest in S is ρ_0 , which must be equal to the negative of ρ , since we are considering an uncharged wire. There is thus no electric field outside the wire, and the force on the moving particle is just

$$\mathbf{F} = q\mathbf{v}_0 \times \mathbf{B}.$$

Using the result we found in Eq. (13.18) for the magnetic field at the distance r from the axis of a wire, we conclude that the force on the particle is directed toward the wire and has the magnitude

$$F = \frac{1}{4\pi\epsilon_0 r^2} \cdot \frac{2\mu_0 I^2}{r}.$$

Using Eqs. (13.1) and (13.5), the current I can be written as $\rho \cdot A$, where A is the area of a cross section of the wire. Then,

$$F = \frac{1}{4\pi\epsilon_0 r^2} \cdot \frac{2\mu_0 A \rho v_0}{r}. \quad (13.20)$$

We could continue to treat the general case of arbitrary velocities v_0 and v , but it will be just as good to look at the special case in which the velocity v_0 of the particle is the same as the velocity v of the conduction electrons. So we write $v_0 = v$, and Eq. (13.20) becomes

$$F = \frac{\sigma}{2\pi\epsilon_0} \frac{\mu_0 A \pi^2}{r^2}. \quad (13.21)$$

Now we turn our attention to what happens in S' , in which the particle is at rest and the wire is moving past (toward the left in the figure) with the speed v . The positive charges moving with the wire will make some magnetic field B' at the particle. But the particle is now at rest, so there is no magnetic force on it. If there is any force on the particle, it must come from an electric field. It must

be that the moving wire has produced an electric field. But it can do that only if it appears charged—it must be that a neutral wire with a current appears to be charged while set in motion.

We must look into this. We must try to compute the charge density in the wire in S' from what we know about it in S . One might, at first, think they are the same, but we know that lengths are changed between S and S' (see Chapter 15, Vol. I), so volumes will change also. Since the charge densities depend on the volume occupied by charges, the densities will change, too.

Before we can decide about the charge densities in S' , we must know what happens to the electric charge of a bunch of electrons when the charges are moving. We know that the apparent mass of a particle changes by $(\sqrt{1 - v^2/c^2})$. Does its charge do something similar? No. Charges are always the same, moving or not. Otherwise we would not always observe that the total charge is conserved.

Suppose that we take a block of material, say a conductor, which is initially uncharged. Now we heat it up. Because the electrons have a different mass than the protons, the velocities of the electrons and of the protons will change by different amounts. If the charge of a particle depended on the speed of the particle carrying it, in the heated block the charge of the electrons and protons would no longer balance. A block would become charged when heated. As we have seen earlier, a very small fractional change in the charge of all the electrons in a block would give rise to enormous electric fields. No such effect has ever been observed.

Also, we can point out that the mean speed of the electrons in reality depends on its chemical composition. If the charge on an electron changed with speed, the net charge in a piece of material would be changed in a chemical reaction. Again, a straightforward calculation shows that even a very small dependence of charge on speed would give enormous fields from the simplest chemical reactions. No such effect is observed, and we conclude that the electric charge of a single particle is independent of its state of motion.

So the charge q on a particle is an invariant scalar quantity, independent of the frame of reference. That means that in any frame the charge density of a distribution of electrons is just proportional to the number of electrons per unit volume. We need only worry about the fact that the volume can change because of the relativistic contraction of distances.

We now apply these ideas to our moving wire. If we take a length L_0 of the wire, in which there is a charge density ρ_0 of stationary charges, it will contain the total charge $Q = \rho_0 L_0 A_0$. If the same charges are observed in a different frame to be moving with velocity v , they will all be found in a piece of the material with the shorter length

$$L = L_0 \sqrt{1 - v^2/c^2}. \quad (13.22)$$

but with the same area A_0 (sizes dimensions transverse to the motion are unchanged). See Fig. 13-11.

If we call ρ the density of charges in the frame in which they are moving, the total charge Q will be $\rho L A_0$. This must also be equal to $\rho_0 L_0 A_0$ because charge is the same in any system so that $\rho L = \rho_0 L_0$, or, from (13.22),

$$\rho = \frac{\rho_0}{\sqrt{1 - v^2/c^2}}. \quad (13.23)$$

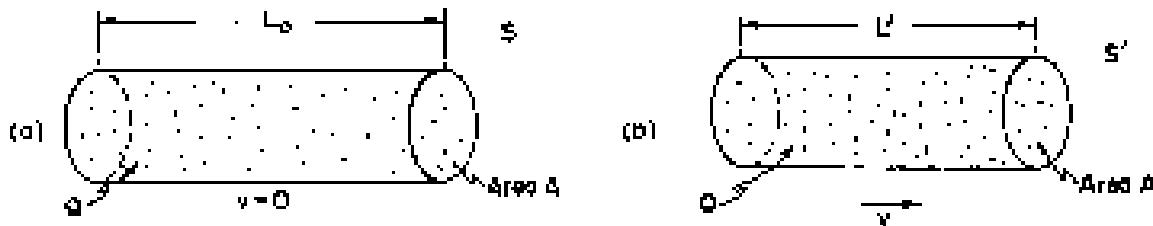

Fig. 13-11. If a distribution of charged particles at rest has the charge density ρ_0 , the same charges will have the density $\rho = \rho_0 / \sqrt{1 - v^2/c^2}$ when seen from a frame with the relative velocity v .

The charge density of a moving distribution of charges varies in the same way as the relativistic mass of a particle.

We now use this general result for the positive charge density ρ_+ of our wire. These charges are at rest in frame S . In S' , however, where the wire moves with the speed v , the positive charge density becomes

$$\rho'_+ = \frac{\rho_+}{\sqrt{1 - v^2/c^2}}. \quad (13.24)$$

The negative charges are at rest in S' . So they have their "rest density" ρ_- in this frame. In Eq. (13.23) $\rho_3 = \rho'_-$, because they have the density ρ'_- when the wire is at rest, i.e., in frame S , where the speed v of the negative charges is 0 . For the conduction electrons, we then have that

$$\rho'_- = \frac{\rho'_-}{\sqrt{1 - v^2/c^2}}. \quad (13.25)$$

or

$$\rho'_- = \rho_- \sqrt{1 - v^2/c^2}. \quad (13.26)$$

Now we can see why there are electric fields in S' —because in this frame the wire has the net charge density ρ' given by

$$\rho' = \rho'_+ + \rho'_-.$$

Using (13.24) and (13.26), we have

$$\rho' = \frac{\rho_+}{\sqrt{1 - v^2/c^2}} + \rho_- \sqrt{1 - v^2/c^2}.$$

Since the stationary wire is neutral, $\rho_+ = -\rho_-$, and we have

$$\rho' = \rho \frac{v^2/c^2}{\sqrt{1 - v^2/c^2}}. \quad (13.27)$$

Our moving wire is positively charged and will produce an electric field E' at the external stationary particle. We have already solved the electrostatic problem of a uniformly charged cylinder. The electric field at the distance r from the axis of the cylinder is

$$E' = \frac{\rho A}{3\pi r^2} = \frac{\rho_- v^2/c^2}{2\pi r^2 c \sqrt{1 - v^2/c^2}}. \quad (13.28)$$

The force on the negatively charged particle is toward the wire. We have, at least, a force in the same direction from the two points of view: the electric force in S' has the same direction as the magnetic force in S .

The magnitude of the force in S' is

$$F' = \frac{q}{2\pi\epsilon_0} \frac{\rho_- A}{r} \frac{v^2/c^2}{\sqrt{1 - v^2/c^2}}. \quad (13.29)$$

Comparing this result for F' with our result for F in Eq. (13.22), we see that the magnitudes of the forces are almost identical from the two points of view. In fact,

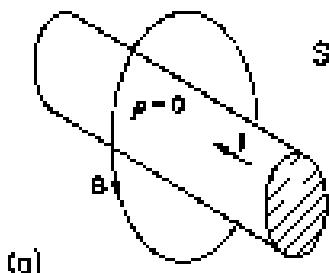

$$F' = \frac{F}{\sqrt{1 - v^2/c^2}}, \quad (13.30)$$

so for the small velocities we have been considering, the two forces are equal. We can say that for low velocities, at least, we understand that magnetism and electricity are just "two ways of looking at the same thing."

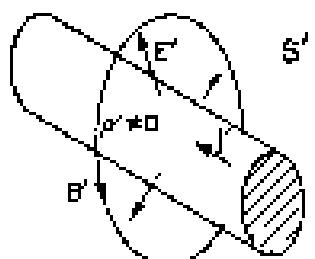

But things are even better than that. If we take into account the fact that forces also transform when we go from one system to the other, we find that the two ways of looking at what happens in motion give the same physical result for any velocity.

One way of seeing this is to ask a question like: What transverse momentum will the particle have after the force has acted for a little while? We know from Chapter 16 of Vol. I that the transverse momentum of a particle should be the same in both the S - and S' -frames. Calling the transverse coordinate p , we want to compare Δp_x and $\Delta p'_x$. Using the relativistically correct equation of motion, $F = dp/dt$, we expect that after the time Δt our particle will have a transverse momentum Δp_x in the S -system given by

$$\Delta p_x = F \Delta t. \quad (13.21)$$

(a)

(b)

Fig. 13-12. In frame S the charge density is zero and the current density is j . There is only a magnetic field. In S' , there is a charge density ρ' , and a different current density j' . The magnetic field B' is different and there is an electric field E' .

In the S' -system, the transverse momentum will be

$$\Delta p'_x = F' \Delta t', \quad (13.22)$$

We must, of course, compare Δp_x and $\Delta p'_x$ for corresponding time intervals Δt and $\Delta t'$. We have seen in Chapter 15 of Vol. I that these intervals referred to a moving particle appear to be longer than those in the rest system of the particle. Since our particle is initially at rest in S' , we expect, for small Δt , that

$$\Delta t = -\frac{\Delta t'}{\sqrt{1-v^2/c^2}}, \quad (13.23)$$

and everything comes out O.K. From (13.21) and (13.22),

$$\frac{\Delta p'_x}{\Delta p_x} = \frac{F' \Delta t'}{F \Delta t},$$

which is just $= 1$ if we combine (13.20) and (13.23).

We have found that we get the same physical result whether we analyze the motion of a particle moving along a wire in a coordinate system at rest with respect to the wire, or in a system at rest with respect to the particle. In the first instance, the force was purely "magnetic;" in the second, it was purely "electric." The two points of view are illustrated in Fig. 13-12 (although there is still a magnetic field B' in the second frame, it produces no forces on the stationary particle).

If we tried to use still another coordinate system, we would have found a different mixture of E and B fields. Electric and magnetic forces are part of one global phenomenon—the electromagnetic interactions of particles. The separation of this interaction into electric and magnetic parts depends very much on the reference frame chosen for the description. But a complete electromagnetic description is invariant; electricity and magnetism taken together are consistent with Lorentz's relativity.

Since electric and magnetic fields appear in different mixtures if we change our frame of reference, we must be careful about how we look at the fields E and B . For instance, if we think of "lines" of E or B , we might get too much reality to them. The lines may disappear if we try to observe them from a different coordinate system. For example, in system S' there are electric field lines, which we do not find "moving past us with velocity v " in system S . In system S there are no electric field lines at all! Therefore it makes no sense to say something like: When I move a magnet, it takes its field with it, so the lines of B are also moved. There is no way to make sense, in general, out of the idea of "the speed of a moving field line." The fields are our way of describing what goes on at a given in space. In particular, E and B tell us about the forces that will act on a moving particle. The question "What is the force on a charge from a moving magnetic field?" doesn't mean anything precise. The force is given by the values of E and B at the charge, and the formula (13.1) is not to be altered if the source of E or B is moving (j is the values of E and B that will be altered by the motion). Our mathematical description deals only with the fields as a function of x , y , z , and t with respect to some inertial frame.

We will take be speaking of "a wave of electric and magnetic fields travelling through space," as, for instance, a light wave. But that is like speaking of a wave travelling on a string. We don't then mean that some part of the string is moving

In the direction of the wave, we mean that the displacement of the string appears first at one point and later at another. Similarly, in an electromagnetic wave, the wave travels, but the magnitude of the fields changes. So in the future when we—or someone else—speak of a “moving” field, you should think of it as just a handy, short way of describing a changing field in some circumstances.

13-7 The transformation of currents and charges

You may have worried about the simplification we made above when we took the same velocity v for the particle and for the conduction electrons in the wire. We could go back and carry through the analysis again for two different velocities, but it is easier to simply notice that charge and current density are the components of a four-vector (see Chapter 17, Vol. I).

We have seen that if ρ_0 is the density of the charges in their rest frame, then in a frame in which they have the velocity v , the density is

$$\rho = \frac{\rho_0}{\sqrt{1 - v^2/c^2}}.$$

In that frame their current density is

$$j = \rho v = \frac{\rho_0 v}{\sqrt{1 - v^2/c^2}}. \quad (13.34)$$

Now we know that the energy U and momentum p of a particle moving with velocity v are given by

$$U = \frac{mc^2}{\sqrt{1 - v^2/c^2}}, \quad p = \frac{mc_0 v}{\sqrt{1 - v^2/c^2}},$$

where m_0 is its rest mass. We also know that U and p form a relativistic four-vector. Since ρ and j depend on the velocity v exactly as do U and p , we can conclude that ρ and j are also the components of a relativistic four-vector. This property is the key to a general analysis of the field of a wire moving with any velocity, which we would need if we want to do the problem again with the velocity v , of the particle different from the velocity of the conduction electrons.

If we wish to transform ρ and j to a coordinate system moving with a velocity w in the x -direction, we know that they transform just like x and (x, y, z) , so that we have (see Chapter 15, Vol. I)

$$\begin{aligned} x' &= \frac{x - wt}{\sqrt{1 - w^2/c^2}}, & j_x' &= \frac{j_x - wp}{\sqrt{1 - w^2/c^2}}, \\ y' &= y, & j_y' &= j_y, \\ z' &= z, & j_z' &= j_z, \\ t' &= \frac{t - px/c^2}{\sqrt{1 - w^2/c^2}}, & p' &= \frac{p - wt/c^2}{\sqrt{1 - w^2/c^2}}. \end{aligned} \quad (13.35)$$

With these equations we can relate charges and currents in one frame to those in another. Taking the charges and currents in either frame, we can solve the electromagnetic problem in that frame by using our Maxwell equations. The result we obtain for the *motion of particles* will be the same no matter which frame we choose. We will return at a later time to the relativistic transformations of the electromagnetic fields.

13-8 Superposition; the right-hand rule

We will conclude this chapter by making two further points regarding the subject of magnetostatics. First, our basic equations for the magnetic field.

$$\nabla \cdot \mathbf{B} = 0, \quad \nabla \times \mathbf{B} = \mu_0 i \epsilon_0 \mathbf{n}$$

are linear in \mathbf{B} and \mathbf{J} . This means that the principle of superposition also applies to magnetic fields. The field produced by two different steady currents is the sum of the individual fields from each current acting alone. Our second remark concerns the right-handed rules which we have encountered (such as the right-hand rule for the magnetic field produced by a current). We have also observed that the magnetization of an iron magnet is to be understood from the spin of the electrons in the material. The direction of the magnetic field of a spinning electron is related to its spin axis by the same right-hand rule. Because \mathbf{B} is determined by a "handed" rule involving either a cross product or a curl—it is called an axial vector. (Vectors whose direction in space does not depend on a reference to a right or left hand are called polar vectors. Displacement, velocity, force, and \mathbf{E} , for example, are polar vectors.)

Physically observable quantities in electromagnetism are not, however, right- (or left-) handed. Electromagnetic interactions are symmetrical under reflection (see Chapter 32, Vol. II). Whenever magnetic forces between two sets of currents are computed, the result is invariant with respect to a change in the hand convention. Our equations lead, independently of the right-hand convention, to the end result that parallel currents attract, and that currents in opposite directions repel. (Try working out the force using "left-hand rules.") An attracted or repulsive is a polar vector. This happens because in describing any excepted interaction, we use the right-hand rule twice—one to find \mathbf{B} from currents, again to find the force this \mathbf{B} produces on a second current. Using the right-hand rule twice is the same as using the left-hand rule twice. If we were to change our convention to a left-handed system all our \mathbf{B} fields would be reversed, but all forces—etc., what is perhaps more relevant, the observed accelerations of objects—would be unchanged.

Although physicists have usually found to their surprise that *not* the laws of nature are not always invariant for mirror reflections, the laws of electromagnetism do have such a basic symmetry.

The Magnetic Field in Various Situations

14-1 The vector potential

In this chapter we continue our discussion of magnetic fields associated with steady currents—the subject of magnetostatics. The magnetic field is related to electric currents by our basic equations:

$$\nabla \cdot \mathbf{B} = 0, \quad (14.1)$$

$$\epsilon_0^2 \nabla \times \mathbf{B} = \frac{\mathbf{j}}{\epsilon_0}. \quad (14.2)$$

We want now to solve these equations, mathematically in a general way, that is, without requiring any special symmetry or intuitive guessing. In electrostatics, we found that there was a straightforward procedure for finding the field when the positions of all electric charges are known: One simply works out the scalar potential ϕ by taking an integral over the charges—as in Eq. (4.23). Then if one wants the electric field, it is obtained from the derivatives of ϕ . We will now show that there is a corresponding procedure for finding the magnetic field \mathbf{B} if we know the current density \mathbf{j} of all moving charges.

In electrostatics we saw that (because the curl of \mathbf{A} was always zero) it was possible to represent \mathbf{E} as the gradient of a scalar field ϕ . Now the curl of \mathbf{B} is not always zero, so it is not possible, in general, to represent it as a gradient. However, the divergence of \mathbf{B} is always zero, and this means that we can always represent \mathbf{B} as the curl of another vector field. For, as we saw in Section 2.8, the divergence of a curl is always zero. Thus we can always relate \mathbf{B} to a field we will call \mathbf{A} by

$$\mathbf{B} = \nabla \times \mathbf{A}. \quad (14.3)$$

Or, by writing out the components,

$$\begin{aligned} B_x &= (\nabla \times \mathbf{A})_x = \frac{\partial A_y}{\partial z} - \frac{\partial A_z}{\partial y}, \\ B_y &= (\nabla \times \mathbf{A})_y = \frac{\partial A_z}{\partial x} - \frac{\partial A_x}{\partial z}, \\ B_z &= (\nabla \times \mathbf{A})_z = \frac{\partial A_x}{\partial y} - \frac{\partial A_y}{\partial x}. \end{aligned} \quad (14.4)$$

Writing $\mathbf{B} = \nabla \times \mathbf{A}$ guarantees that Eq. (14.2) is satisfied, since, necessarily,

$$\nabla \cdot \mathbf{B} = \nabla \cdot (\nabla \times \mathbf{A}) = 0.$$

The field \mathbf{A} is called the *vector potential*.

You will remember that the scalar potential ϕ was not completely specified by its definition. If we have found ϕ for some problem, we can always find another potential ϕ' that is equally good by adding a constant:

$$\phi' = \phi + C.$$

The new potential ϕ' gives the same electric fields, since the gradient ∇C is zero; ϕ' and ϕ represent the same physics.

Similarly, we can take different vector potentials \mathbf{A} , which give the same magnetic fields. Again, because \mathbf{B} is obtained from \mathbf{A} by differentiation, adding a

14-5 The field of a small loop; the magnetic dipole

14-6 The vector potential of a circuit

14-7 The law of Biot and Savart

constant to A cannot change anything physical. But there is even more latitude for A . We can add to A any field which is the gradient of some scalar field, without changing the physics. We can show this as follows. Suppose we have on A that gives correctly the magnetic field B (as above) and suppose, and ask in what circumstances some other new vector potential A' will give the same field B if substituted into (14.3). Then A and A' must have the same curl:

$$\mathbf{B} = \nabla \times A' = \nabla \times A.$$

Therefore

$$\nabla \times A' - \nabla \times A = \nabla \times (A' - A) = 0.$$

But if the curl of a vector is zero it must be the gradient of some scalar field, say ψ , so $A' - A = \nabla\psi$. That means that if A is a satisfactory vector potential for a problem then, for any ψ at all,

$$A' = A + \nabla\psi \quad (14.5)$$

will be an equally satisfactory vector potential, leading to the same field B .

It is usually convenient to take some of the "inside" out of A by arbitrarily placing some other condition on it (in much the same way that we fixed it convenient after to choose to make the potential ϕ zero at large distances). We can, for instance, restrict A by choosing arbitrarily what the divergence of A must be. We can always do that without affecting B . This is because although A' and A have the same curl, and give the same B , they do not need to have the same divergence. In fact, $\nabla \cdot A' = \nabla \cdot A + \nabla^2\psi$, and by a suitable choice of ψ we can make $\nabla \cdot A'$ anything we wish.

What should we choose for $\nabla \cdot A$? The choice should be made to get the greatest mathematical convenience and will depend on the problem we are doing. For magnetostatics, we will make the simple choice

$$\nabla \cdot A = 0. \quad (14.6)$$

(Later, when we take up electrodynamics, we will change our choice.) Our complete definition* of A is then, for the moment, $\nabla \times A = B$ and $\nabla \cdot A = 0$.

To get some experience with the vector potential, let's look first at what it is for a uniform magnetic field B_0 . Taking our z -axis to the direction of B_0 , we must have

$$\begin{aligned} B_x &= \frac{\partial A_z}{\partial y} = \frac{\partial A_z}{\partial z} = 0, \\ B_y &= \frac{\partial A_z}{\partial x} = \frac{\partial A_z}{\partial y} = 0, \\ B_z &= \frac{\partial A_x}{\partial x} = \frac{\partial A_y}{\partial y} = B_0. \end{aligned} \quad (14.7)$$

By inspection, we see that one possible solution of these equations, is

$$A_x = zB_0, \quad A_y = 0, \quad A_z = 0.$$

Or we could equally well take

$$A_x = -yB_0, \quad A_y = 0, \quad A_z = 0.$$

Still another solution is a linear combination of the two:

$$A_x = -yzB_0, \quad A_y = yzB_0, \quad A_z = 0. \quad (14.8)$$

* Our definition still does not uniquely determine A . For a unique specification we would also have to say something about how the field A behaves on some boundary, or at large distances. It is sometimes convenient, for example, to choose a field which goes to zero at large distances.

It is clear that for any particular field B , the vector potential A is not unique; there are many possibilities.

The third solution, Eq. (14.8), has some interesting properties. Since the x -component is proportional to $-y$ and the y -component is proportional to $+x$, A must be at right angles to the vector from the z -axis, which we will call r' (the "prime" is to remind us that it is *not* the vector displacement from the origin). Also, the magnitude of A is proportional to $\sqrt{x^2 + y^2}$ and, hence, to r' . So A can be simply written (for our uniform field) as

$$A = \frac{1}{2}B \times r'. \quad (14.9)$$

The vector potential A has the magnitude $Br'/2$ and rotates about the z -axis as shown in Fig. 14-1. If, for example, the B field is the axial field inside a solenoid, then the vector potential circulates in the same sense as do the currents of the solenoid.

The vector potential for a uniform field can be obtained in another way. The circulation of A on any closed loop C can be related to the surface integral of $\nabla \times A$ by Stokes' theorem, Eq. (3.38):

$$\oint_C A \cdot dr = \int_{\text{Surface } S} (\nabla \times A) \cdot n \, da. \quad (14.10)$$

But the integral on the right is equal to the flux of B through the loop, so

$$\oint_C A \cdot dr = \int_{\text{Surface } S} B \cdot n \, da. \quad (14.11)$$

So the circulation of A around any loop is equal to the flux of B through the loop. If we take a circular loop, of radius r' in a plane perpendicular to a uniform field B , the flux is just

$$\pi r'^2 B.$$

If we choose our origin on an axis of symmetry, so that we can take A as circumferential and a function only of r' , the circulation will be

$$\oint A \cdot dr = 2\pi r' A = \pi r'^2 B.$$

We get, as before,

$$A = \frac{Br'}{2}.$$

In the example we have just given, we have calculated the vector potential from the magnetic field, which is opposite to what one normally does. In complicated problems it is usually easier to solve for the vector potential, and then determine the magnetic field from it. We will now show how this can be done.

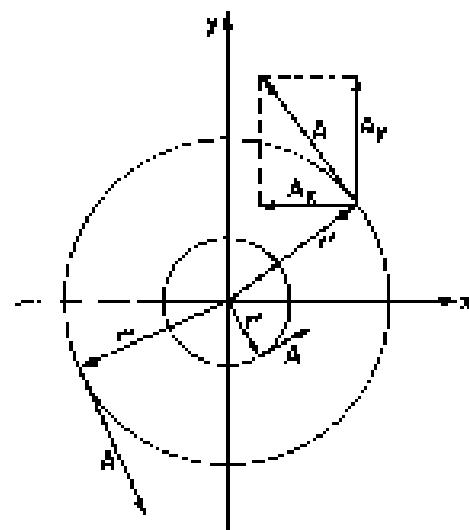

Fig. 14-1. A uniform magnetic field B in the z -direction corresponds to a vector potential A that rotates about the z -axis, with the magnitude $A = Br'/2$ (r' is the displacement from the z -axis).

14-2 The vector potential of known currents

Since B is determined by currents, so also is A . We want now to find A in terms of the currents. We start with our basic equation (14.3):

$$\epsilon^2 \nabla \times B = \frac{j}{\epsilon_0},$$

which becomes, of course, then

$$\epsilon^2 \nabla \times (\nabla \times A) = \frac{j}{\epsilon_0}. \quad (14.12)$$

This equation is for magnetostatics what the equation

$$\nabla \cdot \nabla \phi = -\frac{\rho}{\epsilon_0} \quad (14.13)$$

was for electrostatics.

Our equation (14.12) for the vector potential looks even more like that for ϕ if we rewrite $\nabla \times (\nabla \times A)$ using the vector identity Eq. (2.58):

$$\nabla \times (\nabla \times A) = \nabla(\nabla \cdot A) - \nabla^2 A. \quad (14.14)$$

Since we have chosen to make $\nabla \cdot A = 0$ (and now you see why), Eq. (14.12) becomes

$$\nabla^2 A = - \frac{j}{\epsilon_0 c^2}. \quad (14.15)$$

This vector equation consists, of course, of three equations:

$$\nabla^2 A_x = - \frac{j_x}{\epsilon_0 c^2}, \quad \nabla^2 A_y = - \frac{j_y}{\epsilon_0 c^2}, \quad \nabla^2 A_z = - \frac{j_z}{\epsilon_0 c^2}. \quad (14.16)$$

And each of these equations is *mathematically identical* to

$$\nabla^2 \phi = - \frac{\rho}{\epsilon_0}. \quad (14.17)$$

All we have learned about solving for potentials when ρ is known can be used for solving for each component of A when j is known!

We have seen in Chapter 4 that a general solution for the electrostatic equation (14.17) is

$$\phi(r) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho(2) dV_2}{r_{12}},$$

So we know immediately that a general solution for A_x is

$$A_x(1) = \frac{1}{4\pi\epsilon_0 c^2} \int \frac{j_x(2) dV_2}{r_{12}}, \quad (14.18)$$

and similarly for A_y and A_z . (Figure 14-2 will remind you of our conventions for r_{12} and dV_2 .) We can combine the three solutions in the vector form

$$A(1) = \frac{1}{4\pi\epsilon_0 c^2} \int \frac{\mathbf{j}(2) dV_2}{r_{12}}. \quad (14.19)$$

(You can verify if you wish, by direct differentiation of components, that this integral for A satisfies $\nabla \cdot A = 0$ so long as $\nabla \cdot j = 0$, which, as we saw, must happen for steady currents.)

We have, then, a general method for finding the magnetic field of steady currents. The principle is: the x -component ∇^2 vector potential arising from a current density j is the same as the electric potential ϕ that would be produced by a charge density ρ equal to j_x/c^2 , and similarly for the y - and z -components. (This principle works only with components in fixed directions. The "radial" component of A does not come in the same way from the "radial" component of j , for example.) So from the vector current density j , we can find A using Eq. (14.19), that is, we find each component of A by solving three imaginary electrostatic problems for the charge distributions $\rho_x = j_x/c^2$, $\rho_y = j_y/c^2$, and $\rho_z = j_z/c^2$. Then we get B by taking various derivatives of A to obtain $\nabla \times A$. It's a little more complicated than electrostatics, but the same idea. We will now illustrate the theory by solving for the vector potential in a few special cases.

14-3 A straight wire

For our first example, we will again find the field of a straight wire --which we solved in the last chapter by using Eq. (14.2) and some arguments of symmetry. We take a long straight wire of radius a , carrying the steady current I . (Unlike the charge on a conductor in the electrostatic case, a steady current in a wire is uniformly distributed throughout the cross section of the wire. If we choose our

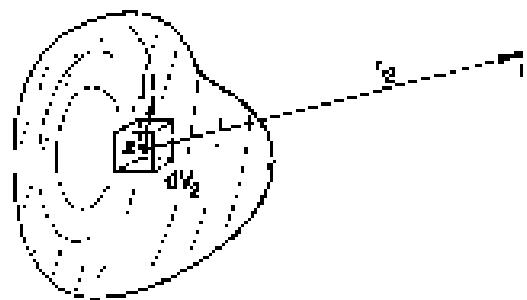

Fig. 14-2. The vector potential A at point 1 is given by an integral over the current elements $j dV$ at all points 2,

coordinates as shown in Fig. 14-3, the current density vector \vec{j} has only a z -component. Its magnitude is

$$j_z = \frac{I}{\pi a^2} z \quad (14.20)$$

inside the wire, and zero outside.

Since j_x and j_y are both zero, we have immediately

$$A_x = 0, \quad A_y = 0.$$

To get A_z we can use our solution for the electrostatic potential ϕ of a wire with a uniform charge density $\rho = j_z/c^2$. For points outside an infinite charged cylinder, the electrostatic potential is

$$\phi = -\frac{\lambda}{2\pi\epsilon_0 c^2} \ln r'$$

where $r' = \sqrt{x^2 + y^2}$ and λ is the charge per unit length, $\pi a^2 \rho$. So A_z must be

$$A_z = -\frac{\pi a^2 j_z}{2\pi\epsilon_0 c^2} \ln r'$$

For points outside a long wire carrying a nonuniform current. Since $\pi a^2 j_z = I$, we can also write

$$A_z = -\frac{I}{2\pi\epsilon_0 c^2} \ln r'. \quad (14.21)$$

Now we can find B from (14.4). There are only two of the six derivatives that are not zero. We get

$$B_x = -\frac{I}{2\pi\epsilon_0 c^2} \frac{\partial}{\partial y} \ln r' = -\frac{I}{2\pi\epsilon_0 c^2} \frac{y}{r'^3}, \quad (14.22)$$

$$B_y = \frac{I}{2\pi\epsilon_0 c^2} \frac{\partial}{\partial x} \ln r' = \frac{I}{2\pi\epsilon_0 c^2} \frac{x}{r'^3}, \quad (14.23)$$

$$B_z = 0.$$

We get the same result as before: B is the same around the wire, and has the magnitude

$$B = \frac{1}{4\pi\epsilon_0 c^2} \frac{2I}{r'}. \quad (14.24)$$

14-4 A long solenoid

Next, we consider again the infinitely long solenoid with a cylindrical differential current of dI per unit length. (We imagine this to be a series of short segments of length dz , carrying the current I , and we neglect the slight pitch of the winding.)

Just as we have defined a "surface charge density" σ , we define here a "surface current density" J equal to the current per unit length on the surface of the solenoid (which is, of course, just the average j times the thickness of the thin winding). The magnitude of J is, here, dz . This surface current (see Fig. 14-4) has the components

$$J_x = -J \sin \phi, \quad J_y = J \cos \phi, \quad J_z = 0.$$

Now we could find A for such a current distribution.

Then, we wish to find A_z for points outside the solenoid. The result is the same as the electrostatic potential outside a cylinder with a similar charge

$$\sigma = \sigma_0 \sin \phi,$$

with $\sigma_0 = J/c^2$. We have not solved such a charge distribution, but we have done something similar. This charge distribution is equivalent to two small cylinders of charge, one positive and one negative, with a slight relative displacement of their

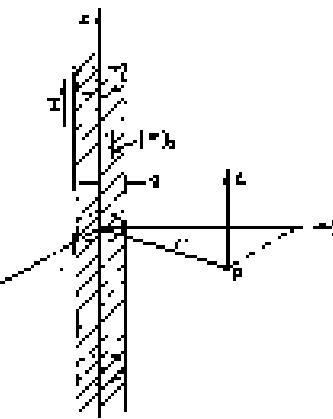

Fig. 14-3. A long cylindrical wire along the z -axis with a uniform current density j .

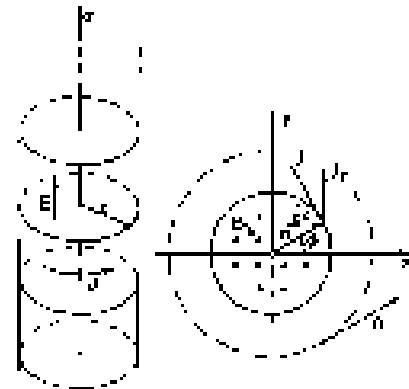

Fig. 14-4. A long solenoid with a surface current density J .

axes in the y -direction. The potential of such a pair of cylinders is proportional to the derivative with respect to y of the potential of a single uniformly charged cylinder. We could work out the constant of proportionality, but let's not worry about it for the moment.

The potential of a cylinder of charge is proportional to $\ln r'$; the potential of the pair is then

$$\psi \propto \frac{\partial \ln r'}{\partial y} = \frac{y}{r'^2}$$

So we know that

$$A_x = -K \frac{y}{r'^2}, \quad (14.25)$$

where K is some constant. Following the same argument, we would find

$$A_y = K \frac{z}{r'^2}. \quad (14.26)$$

Although we said before that there was no magnetic field outside a solenoid, we find now that there is an A -field which circulates around the z -axis, as in Fig. 14-4. The question is: Is it real zero?

Clearly, B_x and B_y are zero, and

$$\begin{aligned} B_z &= \frac{\partial}{\partial z} \left(K \frac{x}{r'^2} \right) - \frac{\partial}{\partial y} \left(-K \frac{y}{r'^2} \right) \\ &= K \left(\frac{1}{r'^4} - \frac{2z^2}{r'^4} + \frac{1}{r'^2} - \frac{2y^2}{r'^4} \right) = 0. \end{aligned}$$

So the magnetic field outside a very long solenoid is indeed zero, even though the vector potential is not.

We can check our result against something else we know: The circulation of the vector potential around the solenoid should be equal to the flux of \mathbf{B} inside the coil (Eq. 14-11). The circulation is $A \cdot 2\pi a$ or, since $A = K/r'$, the circulation is $2\pi K$. Notice that A is independent of r' . That is just as it should be if there is no \mathbf{B} outside, because the flux is just the magnitude of \mathbf{B} inside the solenoid, times πa^2 . It is the same for all circles of radius $r' > a$. We have found in the last chapter that the field inside is $4\pi/\sigma r'^2$, so we can determine the constant K :

$$2\pi K = \pi a^2 \frac{4\pi}{\sigma r'^2},$$

or

$$K = \frac{4\pi^2}{3\sigma a^2}.$$

So the vector potential *outside* has the magnitude

$$A = \frac{4\pi^2}{3\sigma a^2} \frac{1}{r'}, \quad (14.27)$$

and is always perpendicular to the vector \mathbf{r}' .

We have been thinking of a solenoidal coil of wire, but we would get the same fields if we rotated a long cylinder with an electrostatic charge on its surface. If we have a thin cylindrical shell of radius a with a surface charge σ , rotating the cylinder makes a surface current $J = \sigma v$, where $v = \omega a$ is the velocity of the surface charge. There will then be a magnetic field $B = \sigma v a / c r'^2$ inside the cylinder.

Now we can raise an interesting question. Suppose we put a short piece of wire W perpendicular to the axis of the cylinder, extending from the axis out to the surface and fastened to the cylinder so that it rotates with it, as in Fig. 14-5. This wire is moving in a magnetic field, so the $v \times \mathbf{B}$ force will cause the ends of the wire to be charged (they will charge up until the E -field from the charges just balances the $v \times \mathbf{B}$ force). If the cylinder has a positive charge, the end of the wire at the axis will have a negative charge. By measuring the charge on the end of the

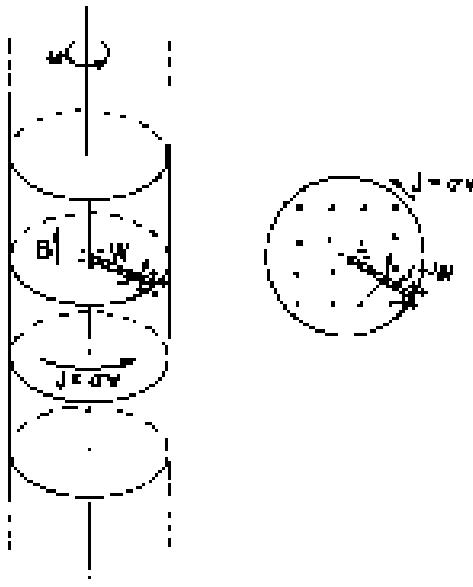

Fig. 14-5. A rotating charged cylinder produces a magnetic field inside. A short radial wire rotating with the cylinder has charges induced on its ends.

wire, we could measure the speed of rotation of the system. We would have an "angular-velocity meter"!

But are you wondering: "What if I put myself in the frame of reference of the rotating cylinder? Then there is just a charged cylinder at rest, and I know that the electrostatic equations say there will be no electric fields inside, so there will be no force pushing charges to the center. So something must be wrong." But there is nothing wrong. There is no "relativity of rotation." A rotating system is not an inertial frame, and the laws of physics are different. We must be sure to use equations of electromagnetism only with respect to inertial coordinate systems.

It would be nice if we could measure the absolute rotation of the earth with such a charged cylinder, but unfortunately the effect is much too small to observe even with the most delicate instruments now available.

14-5 The field of a small loop; the magnetic dipole

Let's use the vector-potential method to find the magnetic field of a small loop of current. As usual, by "small" we mean simply that we are interested in the fields only at distances large compared with the size of the loop. It will turn out that any small loop is a "magnetic dipole." That is, it produces a magnetic field like the electric field from an electric dipole.

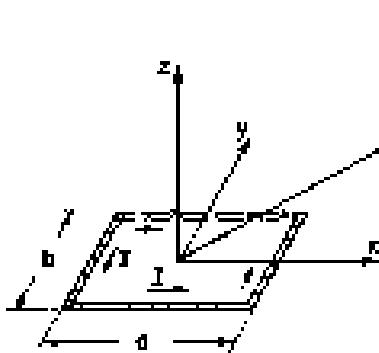

Fig. 14-6. A rectangular loop of wire with side lengths a and b , carrying a current I . What is the magnetic field at P ? ($R \gg a$, or b .)

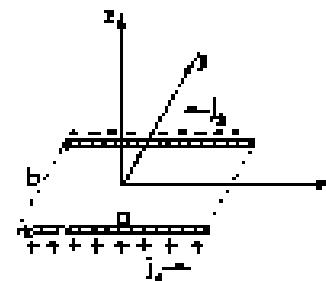

Fig. 14-7. The distribution of J_x in the current loop of Fig. 14-6.

We take first a rectangular loop, and choose our coordinates as shown in Fig. 14-6. There is no current in the z -direction, so A_z is zero. There are currents in the x -direction on the two sides of length a . In each leg, the current density (the current) is uniform. So the situation for A_x is just like the electrostatic potential from two charged rods (see Fig. 14-2). Since the rods have opposite charges, their electric potential at large distances would be just the dipole potential (Section 6-5). At the point P in Fig. 14-6, the potential would be

$$\phi = \frac{L}{4\pi\epsilon_0} \frac{\rho}{R^2}, \quad (14.28)$$

where ρ is the dipole moment of the charge distribution. The dipole moment, in this case, is the total charge on one rod times the separation between them:

$$\rho = qab. \quad (14.29)$$

The dipole moment points in the negative y -direction, so the cosine of the angle between R and ρ is $-y/R$ (where y is the coordinate of P). So we have

$$\phi = -\frac{1}{4\pi\epsilon_0} \frac{\lambda ab}{R^3} \frac{y}{R}.$$

We get A_x simply by replacing λ by I/c^2 :

$$A_x = -\frac{Iab}{4\pi\epsilon_0 c^2} \frac{y}{R^3}. \quad (14.30)$$

By the same reasoning,

$$A_x = \frac{Iab}{4\pi\epsilon_0 c^2} \frac{x}{R^3}. \quad (14.31)$$

Again, A_x , proportional to x and A_z , is proportional to $-y$, so the vector potential (at large distances) goes in circles around the z -axis, circulating in the same sense as I in the loop, as shown in Fig. 14.8.

The strength of A is proportional to Iab , which is the current times the area of the loop. This product is called the *magnetic dipole moment* (or, often, just "magnetic moment") of the loop. We represent it by μ :

$$\mu = Iab. \quad (14.32)$$

The vector potential of a small plane loop of any shape (circle, triangle, etc.) is also given by Eqs. (14.30) and (14.31) provided we replace Iab by

$$\mu = i \cdot (\text{area of loop}). \quad (14.33)$$

We leave the proof of this to you.

We can put our equation in vector form if we define the direction of the vector μ to be the normal to the plane of the loop, with a positive sense given by the right-hand rule (Fig. 14.8). Then we can write

$$A = \frac{1}{4\pi\epsilon_0 c^2} \frac{\mu \times R}{R^3} = \frac{1}{4\pi\epsilon_0 c^2} \frac{\mu \times e_R}{R^3}. \quad (14.34)$$

We have still to find B . Using (14.33) and (14.34), together with (14.4), we get

$$B_x = -\frac{\partial}{\partial z} \frac{\mu}{4\pi\epsilon_0 c^2} \frac{z}{R^3} = -\dots \frac{3xz}{R^5} \quad (14.35)$$

(where by \dots we mean $\mu/(2\pi\epsilon_0 c^2)$).

$$\begin{aligned} B_y &= \frac{\partial}{\partial x} \left(\dots \frac{y}{R^3} \right) = \dots \frac{3yz}{R^5}, \\ B_z &= \frac{\partial}{\partial y} \left(\dots \frac{y}{R^3} \right) - \frac{\partial}{\partial y} \left(\dots \frac{y}{R^3} \right) \\ &= \dots \left(\frac{1}{R^3} - \frac{3x^2}{R^5} \right). \end{aligned} \quad (14.36)$$

The components of the B -field behave exactly like those of the E -field for a dipole oriented along the z -axis. (See Eqs. (6.14) and (6.15); also Fig. 6-5.) That's why we call the loop a magnetic dipole. The word "dipole" is slightly misleading when applied to a magnetic field because there are no magnetic "poles" that correspond to electric charges. The magnetic "dipole field" is not produced by two "charges," but by an elementary current loop.

It is curious, though, that starting with completely different laws, $\nabla \cdot E = \rho/\epsilon_0$ and $\nabla \times B = \mu_0 J$, we can end up with the same kind of a field. Why should that be? It is because the dipole fields appear only when we are far away from all charges or currents. So through most of the relevant space the equations for E and B are identical: both have zero divergence and zero curl. So they give the same solutions. However, the sources whose configuration we summarize by the dipole moments are physically quite different—in one case, it's a circulating current; in the other, a pair of charges, one above and one below the plane of the loop for the corresponding field.

14-6 The vector potential of a closed loop

We are often interested in the magnetic fields produced by circuits of wire in which the diameter of the wire is very small compared with the dimensions of the whole system. In such cases, we can simplify the equations for the magnetic field.

For a thin wire we can write out volume elements as

$$dV = S ds,$$

where S is the cross-sectional area of the wire and ds is the element of distance along the wire. In fact, since the vector ds is in the same direction as j , as shown in Fig. 14-9 (and we can assume that j is constant across any given cross section), we can write a vector equation:

$$j dV = jS ds \quad (14.57)$$

But jS is just what we call the current I in a wire, so our integral for the vector potential (14.29) becomes

$$A(1) = \frac{1}{4\pi\epsilon_0 c^2} \int \frac{I ds}{r_{12}} \quad (14.58)$$

(see Fig. 14-10). (We assume that j is the same throughout the circuit. If there are several branches with different currents, we should, of course, use the appropriate I for each branch.)

Again, we can find the fields from (14.38) either by integrating directly or by solving the corresponding electrostatic problems.

14-7 The Law of Biot and Savart

In studying electrostatics we found that the electric field of a known charge distribution could be obtained directly with the integral (Eq. 4-16):

$$\mathbf{E}(1) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho(Q) \mathbf{e}_{12} dV_2}{r_{12}^2},$$

As we have seen, it is usually much easier to evaluate this integral—there are really three integrals, one for each component—but to do the integral for the potential and take its gradient.

There is a similar integral which relates the magnetic field to the currents. We already have an integral for A , Eq. (14.58), we can get an integral for B by taking the curl of both sides:

$$\mathbf{B}(1) = \nabla \times A(1) = \nabla \times \left[\frac{1}{4\pi\epsilon_0 c^2} \int \frac{j(2) dV_2}{r_{12}} \right]. \quad (14.59)$$

Now we must be careful! The curl operator means taking the derivatives of $A(1)$, that is, it operates only on the coordinates (x_1, y_1, z_1) . We can move the $\nabla \times$ operator inside the integral sign if we remember that it operates only on variables with the subscript 1, which of course appears only in

$$r_{12} = [(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2]^{1/2}. \quad (14.60)$$

We have, for the x -component of B ,

$$\begin{aligned} B_x &= \frac{\partial A_x}{\partial y_1} - \frac{\partial A_y}{\partial z_1} \\ &= \frac{1}{4\pi\epsilon_0 c^2} \int \left[j_x \frac{\partial}{\partial y_1} \left(\frac{1}{r_{12}} \right) - j_y \frac{\partial}{\partial z_1} \left(\frac{1}{r_{12}} \right) \right] dV_2, \quad (14.61) \\ &= \frac{1}{4\pi\epsilon_0 c^2} \int \left[j_x \frac{y_1}{r_{12}^2} - j_y \frac{z_1}{r_{12}^2} \right] dV_2. \end{aligned}$$

The quantity in brackets is just the x -component of

$$\frac{\mathbf{j} \times \mathbf{r}_{12}}{r_{12}^2} \pm \frac{\mathbf{j} \times \mathbf{r}_{12}}{r_{12}^2}.$$

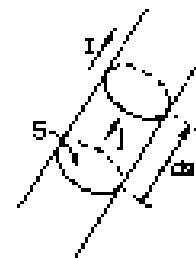

Fig. 14-9. For a fine wire $\int dV$ is the same as $\int ds$.

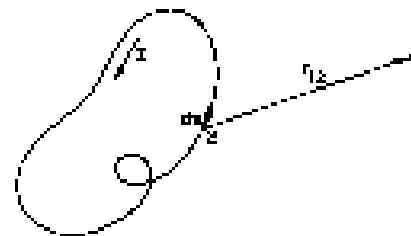

Fig. 14-10. The magnetic field of a wire can be obtained from an integral around the circuit.

Corresponding results will be found for the other components, so we have

$$\mathbf{B}(1) = \frac{1}{4\pi\epsilon_0 c^2} \int \frac{\mathbf{J}(2) \times \mathbf{r}_{12}}{r_{12}^3} dV_2. \quad (14.42)$$

The integral gives \mathbf{B} directly in terms of the known currents. The geometry involved is the same as that shown in Fig. 14-2.

If the currents exist on y in circles of small wires we can, as in the last section, immediately do the integral across the wire, replacing dV by Ids , where ds is an element of length of the wire. Then, using the symbol in Fig. 14-10,

$$\mathbf{B}(1) = -\frac{1}{4\pi\epsilon_0 c^2} \int \frac{I \mathbf{e}_{12} \times ds}{r_{12}^3}. \quad (14.43)$$

(The minus sign appears because we have reversed the order of the cross product.) This equation for \mathbf{B} is called the Biot-Savart law, after its discoverers. It gives a formula for obtaining directly the magnetic field produced by wires carrying currents.

You may wonder: "What is the advantage of the vector potential if we can find \mathbf{B} directly with a vector integral?" After all, A also involves three integrals!" Because of the cross product, the integrals for \mathbf{B} are usually more complicated, as is evident from Eq. (14.41). Also, since the integrals for A are like those of electrostatics, we may already know them. Finally, we will see that in more advanced theoretical matters (in relativity, in advanced foundations of the laws of mechanics, like the principle of least action to be discussed later, and in quantum mechanics) the vector potential plays an important role.

The Vector Potential

15-1 The forces on a current loop; energy of a dipole

In the last chapter we studied the magnetic field produced by a small rectangular current loop. We found that it is a dipole field, with the dipole moment given by

$$\mu = IA, \quad (15.1)$$

where I is the current and A is the area of the loop. The direction of the moment is normal to the plane of the loop, so we can also write

$$\mu = IA\hat{n},$$

where \hat{n} is the unit normal to the area A .

A current loop—in magnetic dipole—not only produces magnetic fields, but will also experience forces when placed in the magnetic field of other currents. We will look first at the forces on a rectangular loop in a uniform magnetic field. Let the x -axis be along the direction of the field and the plane of the loop be placed through the y -axis, making the angle θ with the xy -plane as in Fig. 15-1. Then the magnetic moment of the loop—which is normal to its plane—will make the angle θ with the magnetic field.

Since the currents are opposite on opposite sides of the loop, the forces are also opposite, so there is no net force on the loop (when the field is uniform). Because of forces on the two sides marked 1 and 2 in the figure, however, there is a torque which tends to rotate the loop about the y -axis. The magnitude of these forces F_1 and F_2 is

$$F_1 = F_2 \approx IBa.$$

Their moment arm is

$$a \sin \theta,$$

so the torque is

$$\tau = IabB \sin \theta,$$

or, since IBa is the magnetic moment of the loop,

$$\tau = \mu B \sin \theta.$$

The torque can be written in vector notation:

$$\tau = \mu \times B. \quad (15.2)$$

Although we have only shown that the torque is given by Eq. (15.2) in one rather special case, the result is right for a small loop of any shape, as we will see. You will remember that we found the same kind of relation for the torque on an electric dipole:

$$\tau = p \times E.$$

We now ask about the mechanical energy of our current loop. Since there is a torque, the energy evidently depends on the orientation. The principle of virtual work says that the torque is the rate of change of energy with angle, so we can write

$$dU = -\tau d\theta.$$

15-2 The forces on a current loop; energy of a dipole

15-3 Mechanical and electrical energies

15-4 B times A

15-5 The vector potential and quantum mechanics

15-6 What is true for statics is false for dynamics

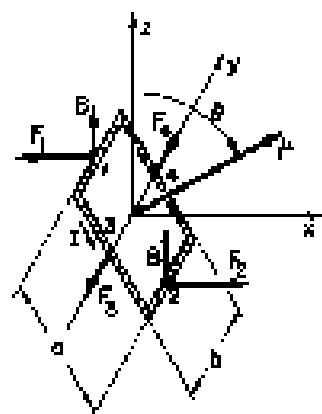

Fig. 15-1. A rectangular loop carrying the current I sits in a uniform field B (in the x -direction). The torque on the loop is $\tau = \mu \times B$, where the magnetic moment $\mu = Ib\hat{n}$.

Setting $\tau = -\mu B \sin \theta$, and integrating, we can write for the energy

$$U = -\mu B \cos \theta + \text{a constant.} \quad (15.3)$$

(The sign is negative because the torque tries to line up the moment with the field; the energy is lowest when μ and B are parallel.)

For reasons which we will discuss later, this energy is not the total energy of a current loop. (We have, for one thing, not taken into account the energy required to maintain the current in the loop.) We will, therefore, call this energy U_{loop} , to remind us that it is only part of the energy. Also, since we are leaving out some of the energy anyway, we can set the constant of integration equal to zero in Eq. (15.3). So we rewrite the equation:

$$U_{\text{loop}} = -\mu \cdot B \quad (15.4)$$

Again, this corresponds to our result for an electric dipole:

$$U = -\mu \cdot E. \quad (15.5)$$

Now the electrostatic energy U in Eq. (15.5) is the *true* energy, but U_{loop} in (15.4) is not the real energy. It can, however, be used in computing forces, by the principle of virtual work, supposing that the current in the loop—or at least μ —is kept constant.

We can show for our rectangular loop that U_{loop} also corresponds to the mechanical work done in bringing the loop into the field. The total force on the loop is zero only in a uniform field; in a non-uniform field there are net forces on a current loop. In putting the loop into a region with a field, we must have gone through places where the field was not uniform, and so work was done. To make the calculation simple, we shall imagine that the loop is brought into the field with its moment pointing along the field. (It can be rotated to its final position after it is in place.)

Imagine that we want to move the loop in the x -direction—toward a region of stronger field—and that the loop is oriented as shown in Fig. 15-2. We start somewhere where the field is zero and integrate the force times the distance as we bring the loop into the field.

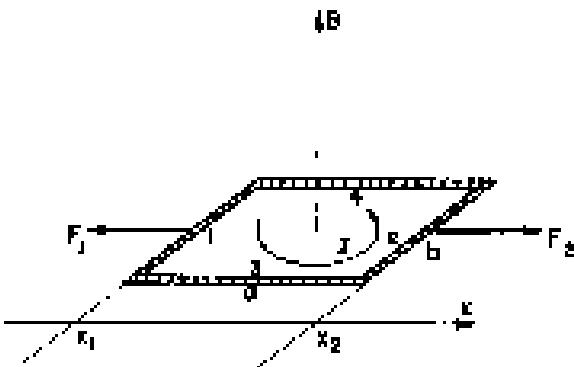

Fig. 15-2. A loop is carried along the x -direction through the field B_x at right angles to x .

First, let's compute the work done on each side separately and then take the sum (rather than adding the forces before integrating). The forces on sides 3 and 4 are at right angles to the direction of motion, so no work is done on them. The force on side 2 is $R B(x)$ in the x -direction, and to get the work done against the magnetic forces we must integrate this from some x where the field is zero, say at $x = -\infty$, to x_2 , its present position:

$$W_2 = - \int_{-\infty}^{x_2} F_2 dx = -ib \int_{-\infty}^{x_2} B(x) dx. \quad (15.6)$$

Similarly, the work done against the forces on side 1 is

$$W_1 = - \int_{-\infty}^{x_1} F_1 dx = ib \int_{-\infty}^{x_1} B(x) dx. \quad (15.7)$$

To find each integral, we need to know how $B(x)$ depends on x . We notice that side 1 follows along right behind side 2, so that its integral includes most of the work done on side 2. In fact, the sum of (15.6) and (15.7) is just

$$W = -\mu \int_{x_1}^{x_2} B(x) dx. \quad (15.8)$$

But if we are in a region where B is nearly the same on both sides 1 and 2, we can write the integral as

$$\int_{x_1}^{x_2} B(x) dx = (x_2 - x_1)B = aB,$$

where B is the field at the center of the loop. The total mechanical energy we have just is

$$U_{\text{mech}} = W = -\mu a B = -\mu B. \quad (15.9)$$

The result agrees with the energy we took for Eq. (15.4).

We would, of course, have gotten the same result if we had added the forces on the loop before integrating to find the work. If we let B_1 be the field at side 1 and B_2 be the field at side 2, then the total force in the \hat{x} -direction is

$$F_x = \mu(B_2 - B_1).$$

If the loop is “vertical,” that is, if B_2 and B_1 are not too different, we can write

$$B_2 \approx B_1 + \frac{\partial B}{\partial x} \Delta x = B_1 + \frac{\partial B}{\partial x} a.$$

So the force is

$$F_x = \mu a \frac{\partial B}{\partial x}. \quad (15.10)$$

The total work done on the loop by external forces is

$$-\int_{x_1}^{x_2} F_x dx = -\mu a \int \frac{\partial B}{\partial x} dx = -\mu a B,$$

which is again just $-\mu B$. Only now we see why it is that the force on a small current loop is proportional to the derivative of the magnetic field, as we would expect from

$$F_x \Delta x = -4C_{\text{max}} = -4(-\mu \cdot B). \quad (15.11)$$

Our result, then, is that even though $C_{\text{max}} = -\mu \cdot B$ may not include all the energy of a system—it is a fake kind of energy—it can still be used with the principle of virtual work to find the forces on steady current loops.

15-2 Mechanical and electrical energies

We want now to show why the energy U_{mech} discussed in the previous section is not the correct energy associated with steady currents—that it does not keep track of the total energy in the world. We have, indeed, emphasized that it can be used like the energy, for calculating forces from the principle of virtual work; we noted that the current in the loop (and all other currents) do not change. Let's see why not this works.

Imagine that the loop in Fig. 15-2 is moving in the $-\hat{x}$ -direction and take the z -axis in the direction of \mathbf{B} . The conduction electrons on side 2 will experience a force along the wire, in the y -direction. But because of their flow as an electric current, there is a component of their motion in the same direction as the force. Each electron is, therefore, doing work done $v_y t$ at the rate $F_y v_y$, where v_y is the component of the electron velocity along the wire. We will call this work done on the electrons’ electrical work. Now it turns out that if the loop is moving in a uniform field, the total electrical work is zero, since positive work is done on some parts of the loop and an equal amount of negative work is done on other parts.

But this is not true if the circuit is moving in a non-uniform field—then there will be a net amount of work done on the electrons. In general, this work would tend to change the flow of the electrons, but if the current is being held constant, energy must be absorbed or delivered by the battery or other source that is keeping the current steady. This energy was not included when we computed $\langle U_{\text{elect}} \rangle$ in Eq. (15.9), because our computations included only the mechanical forces on the body of the wire.

You may be thinking: But the force on the electrons depends on how fast the wire is moved; perhaps if the wire is moved slowly enough this electrical energy can be neglected. It is true that the rate at which the electrical energy is delivered is proportional to the speed of the wire, but the total energy delivered is proportional also to the time that this rate gets on. So the total electrical energy is proportional to the velocity times the time, which is just the distance moved. For a given distance moved in a field the same amount of electrical work is done.

Let's consider a segment of wire of unit length carrying the current I and moving in a direction perpendicular to itself and to a magnetic field B with the speed v_{wire} . Because of the current the electrons will have a drift velocity v_{drift} along the wire. The component of the magnetic force on each electron in the direction of the drift is $qv_{\text{drift}}B$. So the rate at which electrical work is being done is $P_{\text{elect}} = (qv_{\text{drift}}B)v_{\text{wire}}$. If there are N conduction electrons in the unit length of the wire, the total rate at which electrical work is being done is

$$\frac{dU_{\text{elect}}}{dt} = Nqv_{\text{drift}}Bv_{\text{wire}}$$

But $Nqv_{\text{drift}} = I$, the current in the wire, so

$$\frac{dU_{\text{elect}}}{dt} = Iv_{\text{wire}}B.$$

Now since the current is held constant, the forces on the conduction electrons do not cause them to accelerate; the electrical energy is not going into the electrons but from the source that is keeping the current constant.

But notice that the force on the wire is IB , so IBv_{wire} is also the rate of mechanical work done on the wire, $dU_{\text{mech}}/dt = IBv_{\text{wire}}$. We conclude that the mechanical work done on the wire is just equal to the electrical work done by the current source, so the energy of the loop is a *constant*!

This is not a coincidence, but a consequence of the law we already know. The total force on each charge in the wire is

$$F = q(E + v \times B).$$

The rate at which work is done is

$$v \cdot F = q[v \cdot E + v \cdot (v \times B)]. \quad (15.12)$$

If there are no electric fields we have only the second term, which is always zero. We shall see later that changing magnetic fields produce electric fields, so our reasoning applies only to moving wires in steady magnetic fields.

How is it then that the principle of virtual work gives the right answer? Because we still have not taken into account the total energy of the world. We have not included the energy of the currents that are producing the magnetic field we start out with.

Suppose we imagine a complete system such as that drawn in Fig. 15-3(a), in which we are moving our loop with the current I_1 into the magnetic field B_1 produced by the current I_2 in a coil. Now the current I_1 in the loop will also be producing some magnetic field B_2 at the coil. If the loop is moving, the field B_2 will be changing. As we shall see in the next chapter, a changing magnetic field generates an E -field; and this E -field will do work on the charges in the coil. This energy must also be included in our balance sheet of the total energy.

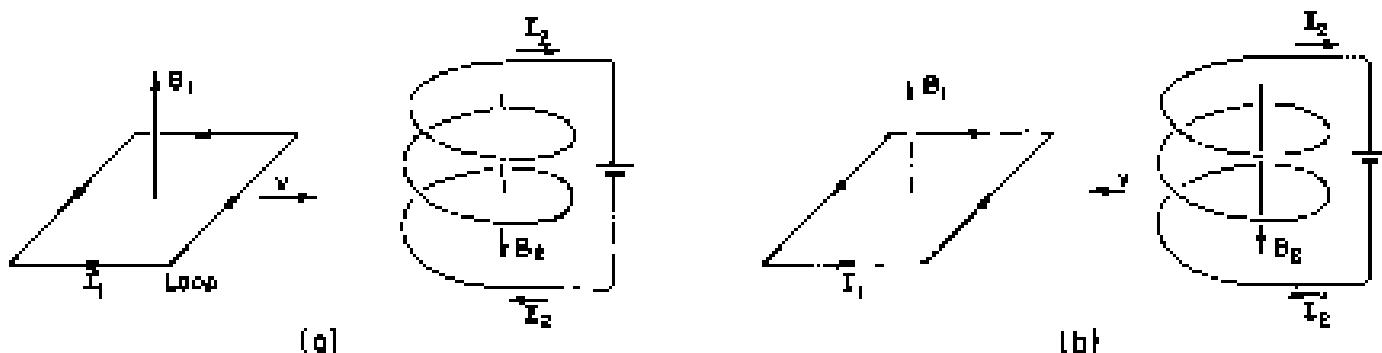

Fig. 15-3. Finding the energy of a small loop in a magnetic field.

We could wait until the next chapter to find out about this new energy term, but we can also see what it will be if we use the principle of relativity in the following way. When we are moving the loop toward the stationary coil we know that its electrical energy is just equal and opposite to the mechanical work done. So

$$U_{\text{mech}} + U_{\text{electr(loop)}} = 0.$$

Suppose now we look at what is happening from a different point of view, in which the loop is at rest, and the coil is moved toward it. The coil is then moving into the field produced by the loop. The same arguments would give that

$$U_{\text{mech}} + U_{\text{electr(coil)}} = 0.$$

The mechanical energy is the same in the two cases because it comes from the force between the two circuits.

The sum of the two equations gives

$$2U_{\text{mech}} + U_{\text{electr(loop)}} + U_{\text{electr(coil)}} = 0.$$

The total energy of the whole system is, of course, the sum of the two electrical energies plus the mechanical energy taken only once. So we have

$$U_{\text{total}} = U_{\text{electr(loop)}} - U_{\text{electr(coil)}} + U_{\text{mech}} = -U_{\text{mech}}. \quad (15.13)$$

The total energy of the world is really the negative of U_{mech} . If we want the true energy of a magnetic dipole, for example, we should write

$$U_{\text{total}} = -g \cdot B.$$

It is only if we make the condition that all currents are constant that we can use only a part of the energy, U_{mech} (which is always the negative of the true energy), to find the mechanical forces. In a more general problem, we must be careful to include all energies.

We saw an analogous situation in electrodynamics. We showed⁴ that the energy of a capacitor is equal to $Q^2/2C$. When we use the principle of virtual work to find the force between the plates of the capacitor, the change in energy is equal to $Q^2/2$ times the change in $1/C$. That is,

$$\Delta E = \frac{Q^2}{2} \Delta \left(\frac{1}{C} \right) = -\frac{Q^2}{2} \frac{\Delta C}{C^2}. \quad (15.14)$$

Now suppose that we were to calculate the work done in moving two conductors subject to the different condition that the voltage between them is held constant. Then we can get the right answers for forces from the principle of virtual work if we do something artificial. Since $(Q = CV)$, the real energy is $\frac{1}{2}CV^2$. But if we define an artificial energy equal to $-\frac{1}{2}CV^2$, then the principle of virtual work can be used to get forces by setting the change in the artificial energy equal to the

mechanical work, provided that we insist that the voltage V be held constant. Then

$$\delta U_{\text{elect}} = \delta \left(-\frac{CV^2}{2} \right) = -\frac{V^2}{2} \delta C, \quad (15.15)$$

which is the same as Eq. (15.14). We get the correct result even though we are neglecting the work done by the electrical system to keep the voltage constant. Again, this electrical energy is just twice as big as the mechanical energy and of the opposite sign.

Thus if we calculate artificially, disregarding the fact that the source of the potential has to do work to maintain the voltage constant, we get the right answer. It is exactly analogous to the situation in magnetostatics.

15-3 The energy of steady currents

We can now use our knowledge that $U_{\text{elect}} = -P_{\text{loss}}$ to find the true energy of steady currents in magnetic fields. We can begin with the true energy of a small current loop. Calling U_{loop} just U , we write

$$U = \mu \cdot B. \quad (15.16)$$

Although we calculated this energy for a plane rectangular loop, the same result holds for a small plane loop of any shape.

We can find the energy of a circuit of any shape by imagining that it is made up of small current loops. Say we have a wire in the shape of the loop Γ of Fig. 15-4. We pull in this curve with the surface S , and on the surface mark out a large number of small loops, each of which can be considered plane. If we set the current I (constant) around each of the little loops, the net result will be the same as a current stream I , since the currents will cancel on all lines intersecting Γ . Physically, the system of little currents is indistinguishable from the original circuit. The energy will also be the same, and so is just the sum of the energies of the little loops.

If the area of each little loop is Δa , its energy is $I^2 B_n \Delta a$, where B_n is the component normal to Δa . The total energy is

$$U = \sum I B_n \Delta a.$$

Going to the limit of infinitesimal loops, the sum becomes an integral, and

$$U = \int B_n da = \int B \cdot n da, \quad (15.17)$$

where n is the unit normal to da .

If we set $B = \nabla \times A$, we can connect the surface integral to a line integral, using Stokes' theorem,

$$\int_S (\nabla \times A) \cdot n da = \oint_C A \cdot ds, \quad (15.18)$$

where ds is the line element along Γ . So we have the energy for a circuit of any shape:

$$U = \int_{\text{circuit}} A \cdot ds. \quad (15.19)$$

In this expression A refers, of course, to the vector potential due to those currents (other than the I in the wire) which produce the field B at the wire.

Now any distribution of steady currents can be imagined to be made up of filaments that run parallel to the lines of current flow. For each pair of such circuits, the energy is given by (15.19), where the integral is taken around one circuit, using the vector potential A from the other circuit. For the total energy we want the sum of all such pairs. If instead of keeping track of the pairs, we take the complete sum over all the filaments, we would be enumerating the energy twice (we saw a similar effect in electrodynamics), so the total energy can be written

$$U = \frac{1}{2} \int B \cdot A dV. \quad (15.20)$$

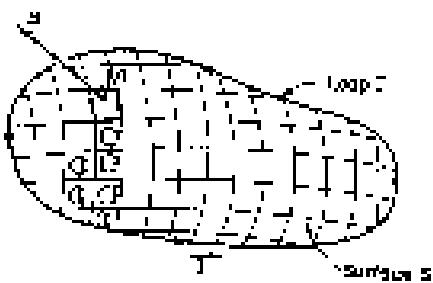

Fig. 15-4. The energy of a large loop in a magnetic field can be considered as the sum of energies of smaller loops.

This formula corresponds to the result we found for the electrostatic energy:

$$U = \frac{1}{2} \int \rho \phi dV. \quad (15.21)$$

So we may if we wish think of A as a kind of potential energy for currents in magnetostatics. Unfortunately, this idea is not too useful because it is true only for static fields. In fact, neither of the equations (15.20) and (15.21) gives the correct energy when the fields change with time.

15-4 \mathbf{A} versus \mathbf{A}

In this section we would like to discuss the following questions: Is the vector potential merely a device which is useful in making calculations—as the scalar potential is useful in electrostatics—or is the vector potential a “real” field? Isn’t the magnetic field the “real” field, because it is responsible for the force on a moving particle? First we should say that the phrase “a real field” is not very meaningful. For one thing, you probably don’t feel that the magnetic field is very “real” anyway, because even the whole idea of a field is a rather abstract thing. You cannot put out your hand and feel the magnetic field. Furthermore, the value of the magnetic field is not very definite; by choosing a suitable moving coordinate system, for instance, you can make a magnetic field at a given point disappear.

What we mean here by a “real” field is this: a real field is a mathematical function we use for avoiding the idea of action at a distance. If we have a charged particle at the position P , it is affected by other charges located at some distance from P . Our way to describe the interaction is to say that the other charges make some “condition”—whatever it may be—in the environment at P . If we know that condition, which we describe by giving the electric and magnetic fields, then we can determine completely the behavior of the particle—with no further reference to how those conditions come about.

In other words, if those other charges were altered in some way, but the conditions at P that are described by the electric and magnetic field at P remain the same, then the motion of the charge will also be the same. A “real” field is then a set of numbers we specify in such a way that what happens at P depends only on the numbers at that point. We do not need to know any more about what’s going on at other places. It is in this sense that we will discuss whether the vector potential is a “real” field.

You may be wondering about the fact that the vector potential is not unique: that it can be changed by adding the gradient of any scalar with no change at all in the forces on particles. That has got, however, nothing to do with the question of reality in the sense that we are talking about. For instance, the magnetic field is in a sense altered by a relativity change (as are also E and A). But we are not worried about what happens if the field was changed in this way. That doesn’t really make any difference; that has nothing to do with the question of whether the vector potential is a proper “real” field for describing magnetic effects, or whether it is just a useful mathematical tool.

We should also make some remarks on the usefulness of the vector potential A . We have seen that it can be used in a formal procedure for calculating the magnetic fields of known currents, just as ϕ can be used to find electric fields. In electrostatics we saw that ϕ was given by the scalar integral

$$\phi(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho(2)}{r_{12}} dV_2. \quad (15.22)$$

From this ϕ , we get the three components of E by three differential operations. This procedure is usually easier to handle than evaluating the three integrals in the vector formula

$$\mathbf{E}(\mathbf{r}) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho(2)\mathbf{e}_{12}}{r_{12}^2} dV_2. \quad (15.23)$$

First, there are three integrals; and second, each integral is in general somewhat more difficult.

The advantages are much less clear for magnetostatics. The integral for A is already a vector integral:

$$A(\mathbf{r}) = \frac{1}{4\pi\mu_0 c^2} \int \frac{\mathbf{j}(\mathbf{r}') dV_s}{r_{12}}, \quad (15.24)$$

which is, of course, three integrals. Also, when we take the curl of A to get \mathbf{B} , we have six derivatives to do and combine by pairs. It is not immediately obvious whether in most problems this procedure is really any easier than computing \mathbf{B} directly from

$$\mathbf{B}(\mathbf{r}) = \frac{1}{4\pi\mu_0 c^2} \int \frac{\mathbf{j}(\mathbf{r}') \times \mathbf{r}_{12}}{r_{12}^3} dV_s. \quad (15.25)$$

Using the vector potential is often more difficult for simple problems for the following reason. Suppose we are interested only in the magnetic field \mathbf{B} at one point, and that the problem has some axis symmetry—say we want the field at a point on the axis of a ring of current. Because of the symmetry, we can easily get \mathbf{B} by doing the integral of Eq. (15.25). If, however, we hope to find A first, we would have to compute \mathbf{B} from derivatives of A , so we must know what A is at all points in the neighborhood of the point of interest. At most c^2 of these points are off the axis of symmetry, so the integral for A gets complicated. In the ring problem, for example, we would need to use elliptic integrals. In such problems, A is clearly not very useful. It is true that in many complex problems it is easier to work with A , but it would be hard to argue that this use of technique would justify making you learn about one more vector field.

We have introduced A because it does have an important physical significance. Not only is it related to the energies of currents, as we saw in the last section, but it is also a "real" physical field in the sense that we described above. In classical mechanics it is clear that we can write the force on a particle as

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B}), \quad (15.26)$$

so that, given the forces, everything about the motion is determined. In any region where $\mathbf{B} = 0$ even if A is not zero, such as outside a solenoid, there is no discernible effect of A . Therefore for a long time it was believed that A was not a "real" field. It turns out, however, that there are phenomena involving quantum mechanics which show that the field A is in fact a "real" field in the sense we have defined it. In the next section we will show you how that works.

15-5 The vector potential and quantum mechanics

There are many changes in what concepts are important when we go from classical to quantum mechanics. We have already discussed some of them in Vol. 1. In particular, the force concept gradually fades away, while the concepts of energy and momentum become of paramount importance. You remember that instead of particle motions, one deals with probability amplitudes which vary in space and time. In these amplitudes there are strengths related to momenta, and quantities related to energies. The momenta and energies, which determine the phases of wave functions, are therefore the important quantities in quantum mechanics. Instead of forces, we deal with the way interactions change the wavelength(s) of the waves. The idea of a force becomes quite secondary—if it is there at all. When people talk about nuclear forces, for example, what they usually analyze and work with are the energies of interaction of two nucleons, and not the force between them. Nobody ever calculates the energy to find out what the force looks like. In this section we want to describe how the vector and scalar potentials enter into quantum mechanics. It is, in fact, just because momentum and energy play a central role in quantum mechanics that A and ϕ provide the most direct way of introducing electrodynamic effects into quantum descriptions.

We must review a little how quantum mechanics works. We will consider again the imaginary experiment described in Chapter 17 of Vol. 1, in which elec-

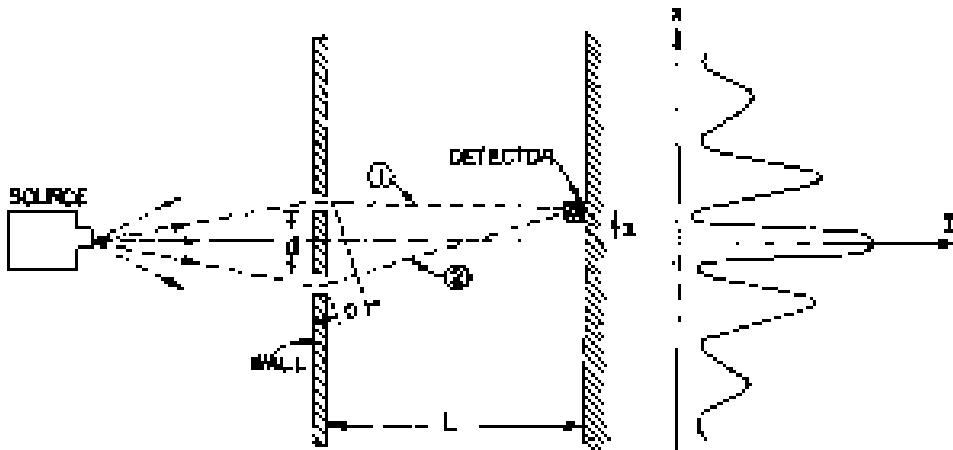

Fig. 15-5. An interference experiment with electrons
(see also Chapter 37 of Vol. II).

itrons are diffracted by two slits. The arrangement is shown again in Fig. 15-5. Electrons, all of nearly the same energy, leave the source and travel toward a wall with two narrow slits. Beyond the wall is a "backstop" with a movable detector. The detector measures the rate, which we call I , at which electrons arrive at a small region of the backstop at the distance x from the axis of symmetry. The rate is proportional to the probability that an individual electron that leaves the source will reach that region of the backstop. This probability has the complicated-looking distribution shown in the figure, which we understand as due to the interference of two amplitudes, one from each slit. The interference of the two amplitudes depends on their phase difference. That is, if the amplitudes are $C_1 e^{i\Phi_1}$ and $C_2 e^{i\Phi_2}$, the phase difference $\delta = \Phi_1 - \Phi_2$ determines their interference pattern [see Eq. 429.12 in Vol. II]. If the distance between the screen and the slits is L , and if the difference in the path lengths for electrons going through the two slits is a , as shown in the figure, then the phase difference of the two waves is given by

$$\delta = \frac{a}{\lambda}. \quad (15.27)$$

As usual, we let $\delta = \lambda/2\pi$, where λ is the wavelength of the space variation of the probability amplitude. For simplicity, we will consider only values of x much less than L ; then we can set

$$a = \frac{x}{L} d$$

and

$$\delta = \frac{x}{L} \frac{d}{\lambda}. \quad (15.28)$$

When x is zero, δ is zero: the waves are in phase, and the probability has a maximum. When x is λ , the waves are out of phase, they interfere destructively, and the probability is a minimum. So we get the wavy function for the electron intensity.

Now we would like to state the law that for quantum mechanics replaces the force law $F = -q\mathbf{E} \times \mathbf{B}$. It will be the law that determines the behavior of quantum-mechanical particles in an electromagnetic field. Since what happens is determined by amplitudes, the law must tell us how the magnetic influences affect the amplitudes; we are no longer dealing with the acceleration of a particle. The law is the following: the phase of the amplitude to arrive via any trajectory is changed by the presence of a magnetic field by an amount equal to the integral of the vector potential along the whole trajectory times the charge of the particle over Planck's constant. That is,

$$\text{Magnetic change in phase} = \frac{q}{h} \int_{\text{trajectory}} \mathbf{A} \cdot d\mathbf{s}. \quad (15.29)$$

If there were no magnetic field there would be a certain phase of arrival. If there is a magnetic field \mathbf{B} , then the phase of the arriving wave is increased by the integral in Eq. (15.29).

Although we will not need to use it for our present discussion, we note that the effect of an electrostatic field is to produce a phase change given by the negative of the time integral of the scalar potential ϕ :

$$\text{Electric charge in phase} = -\frac{q}{\hbar} \int \phi \, dt.$$

These two expressions are correct for only for static fields, but together give the correct result for any alternating field, static or dynamic. This is the law that replaces $P = g(\mathbf{E} + \mathbf{v} \times \mathbf{B})$. We want now, however, to consider only a static magnetic field.

Suppose that there is a magnetic field present in the two-slit experiment. We want to ask for the phase of arrival at the screen of the two waves whose paths pass through the two slits. Their interference determines where the maxima in the probability will be. We may call Φ_1 the phase of the wave along trajectory (1). If $\Phi_1(B=0)$ is the phase without the magnetic field, then when the field is turned on the phase will be

$$\Phi_1 = \Phi_1(B=0) + \frac{q}{\hbar} \int_{(1)} A \cdot d\mathbf{s}. \quad (15.30)$$

Similarly, the phase for trajectory (2) is

$$\Phi_2 = \Phi_2(B=0) + \frac{q}{\hbar} \int_{(2)} A \cdot d\mathbf{s}. \quad (15.31)$$

The interference of the waves at the detector depends on the phase difference

$$\delta = \Phi_2(B=0) - \Phi_1(B=0) + \frac{q}{\hbar} \int_{(2)-1} A \cdot d\mathbf{s} - \frac{q}{\hbar} \int_{(1)} A \cdot d\mathbf{s}. \quad (15.32)$$

The no field difference we will call $\delta(B=0)$, it is just the phase difference we have calculated above in Eq. (15.28). Also, we notice that the two integrals can be written as one integral that goes forward along (1) and back along (2); we call this the closed path (1-2). As we have

$$\delta = \delta(B=0) - \frac{q}{\hbar} \oint_{(1-2)} A \cdot d\mathbf{s}. \quad (15.33)$$

This equation tells us how the electron motion is changed by the magnetic field; with it we can find the new positions of the intensity maxima and minima at the backstop.

Before we do that, however, we want to raise the following interesting and important point. You remember that the vector potential function has some arbitrariness. Two different vector potential functions A and A' whose difference is the gradient of some scalar function ψ , both represent the same magnetic field, since the curl of a gradient is zero. They give, therefore, the same classical forces $q\mathbf{v} \times \mathbf{B}$. In quantum mechanics the effects depend on the vector potential, which of the many possible A -functions is correct?

The answer is that the same arbitrariness in A continues to exist for quantum mechanics. If in Eq. (15.33) we change A to $A' = A + \nabla\psi$, the integral on A becomes

$$\oint_{(1-2)} A \cdot d\mathbf{s} = \oint_{(1-2)} A' \cdot d\mathbf{s} + \oint_{(1-2)} \nabla\psi \cdot d\mathbf{s}.$$

The integral of $\nabla\psi$ is around the closed path (1-2), but the integral of the tangential component of a gradient on a closed path is always zero, by Stokes' theorem. Therefore both A and A' give the same phase differences and the same quantum-mechanical interference effects. In both classical and quantum theory it is only the curl of A that matters; any choice of the function of A which has the correct curl gives the correct physics.

The same conclusion is evident if we use the results of Section 14-1. There we found that the line integral of A around a closed path is the flux of B through the path, which here is the flux between points (1) and (2). Equation (15.33) can, if we wish, be written as

$$i = \mu(B - 0) + \frac{q}{\pi} [\text{Flux of } B \text{ between (1) and (2)}], \quad (15.34)$$

where by the flux of B we mean, as usual, the surface integral of the normal component of B . The result depends only on B , and therefore only on the curl of A .

Now because we can write the result in terms of B as well as in terms of A , you might be inclined to think that the B holds its own as a "real" field and that the A can still be thought of as an artificial construction. But the definition of "real" field that we originally proposed was based on the idea that a "real" field would not act on a particle from a distance. We can, however, give an example in which B is zero—or at least arbitrarily small—at any place where there is some chance to find the particle, so that it is not possible to think of it acting directly on them.

You remember that for a long solenoid carrying an electric current there is a B -field inside but none outside, while there is lots of A circulating around outside, as shown in Fig. 15-6. If we assume a situation in which electrons are to be found only outside of the solenoid—only where there is A —there will still be an influence on the motion, according to Eq. (15.33). Classically, that is impossible. Classically, the force depends only on B ; in order to know that the solenoid is carrying current, the particle must go through it. But quantum-mechanically you could find out that there is a magnetic field inside the solenoid by going around it—without ever going close to it!

Suppose that we put a very long solenoid of small diameter just behind the wall and between the two slits, as shown in Fig. 15-7. The diameter of the solenoid is to be much smaller than the distance d between the two slits. In these circumstances, the deflection of the electrons at the slit gives no appreciable probability that the electrons will get near the solenoid. What will be the effect on our interference experiment?

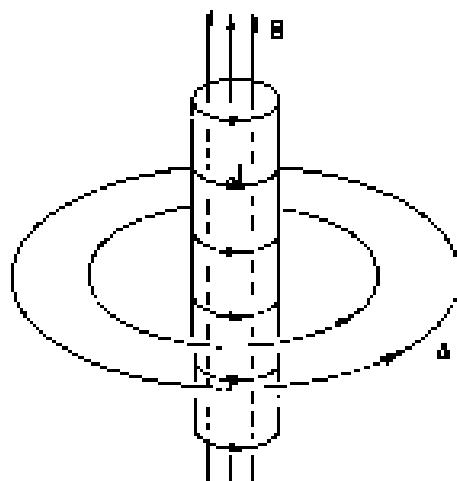

Fig. 15-6. The magnetic field and vector potential of a long solenoid.

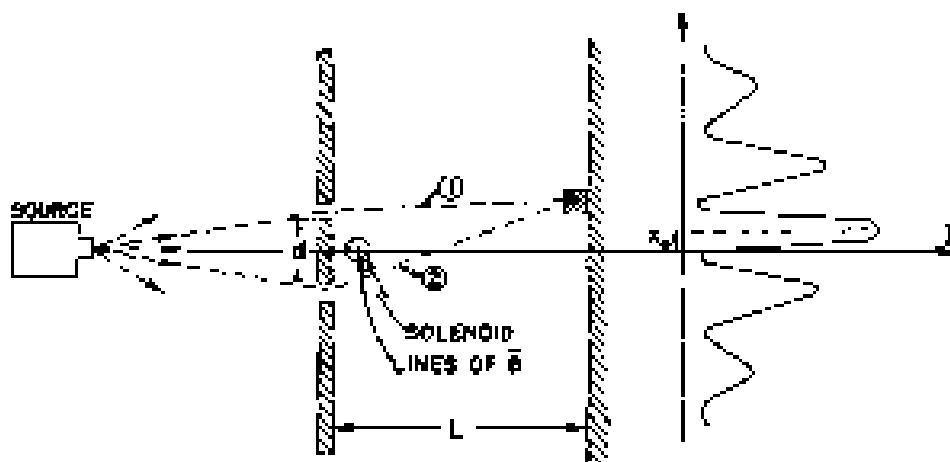

Fig. 15-7. A magnetic field can influence the motion of electrons even though it exists only in regions where there is an arbitrarily small probability of finding the electrons.

We compare the situation with and without a current through the solenoid. If we have no current, we have no B or A and we get the original pattern of electron intensity at the backstop. If we turn the current on in the solenoid and build up a magnetic field B inside, then there is an A outside. There is a shift in the phase difference proportional to the circulation of A outside the solenoid, which will mean that the pattern of maxima and minima is shifted to a new position. In fact, since the flux of B inside is a constant for any pair of paths, so also is the circulation of A . For every arrival point there is the same phase change! This corresponds

to shifting the entire pattern in x by a congruent amount, say x_0 , that we can easily calculate. The maximum intensity will occur where the phase difference between the two waves is zero. Using Eq. (15.32) or Eq. (15.33) for δ and Eq. (15.28) for $\delta(\theta = 0)$, we have

$$x_0 = -\frac{L}{\lambda} \lambda \frac{q}{k} \int_{n=2}^{\infty} A \cdot d\mathbf{r}, \quad (15.35)$$

or

$$x_0 = -\frac{I}{q} \lambda \frac{q}{k} [\text{flux of } \mathbf{B} \text{ between (1) and (2)}]. \quad (15.36)$$

The pattern with the solenoid in place should appear* as shown in Fig. 15-7. At least, that is the prediction of quantum mechanics.

Precisely this experiment has recently been done. It is a very, very difficult experiment. Because the wavelength of the electrons is so small, the apparatus must be on a tiny scale to observe the interference. The slits must be very close together, and that means that one needs an exceedingly small solenoid. It turns out that in certain circumstances, iron crystals will grow in the form of very long, microscopically thin filaments called whiskers. When these iron whiskers are magnetized they are like a tiny solenoid, and there is no field outside except near the ends. The electron interference experiment was done with such a whisker between two slits, and the predicted displacement in the pattern of electrons was observed.

In our sense then, the A -field is "real." You may say: "But there was a magnetic field." There was, but remember our original idea—that a field is "real" if it is what must be specified at the position of the particle in order to get the motion. The B -field in the whisker acts at a distance. If we want to describe its influence not as action-at-a-distance, we must use the vector potential.

This subject has an interesting history. The theory we have described was known from the beginning of quantum mechanics in 1926. The fact that the vector potential appears in the wave equation of quantum mechanics (called the Schrödinger equation) was obvious from the day it was written. That it cannot be replaced by the magnetic field in any easy way was observed by one soon after the other who tried to do so. This is also clear from our example of electrons moving in a region where there is no field and being affected nevertheless. But because in classical mechanics A did not appear to have any direct importance and, furthermore, because it could be changed by adding a gradient, people repeatedly said that the vector potential had no direct physical significance—that only the magnetic and electric fields are "right" over in quantum mechanics. It seems strange in retrospect that no one thought of discussing this experiment until 1956, when Bohm and Aharonov first suggested it and made the whole question crystal clear. The implication was there all the time, but no one paid attention to it. Thus many people were rather shocked when the matter was brought up. That's why someone thought it would be worth while to do the experiment to see that it really was right, even though quantum mechanics, which had been believed for so many years, gave an unequivocal answer. It is interesting that something like this can be around for thirty years but, because of certain prejudices of what is real and is not significant, continues to be ignored.

Now we wish to continue in our analysis a little further. We will show the connection between the quantum-mechanical formula and the classical formula to show why it turns out that if we look at things on a large enough scale it will look as though the particles are acted on by a force equal to $qv \times \mathbf{B}$ or the curl of A . To get classical mechanics from quantum mechanics, we need to consider cases in which all the wavelengths are very small compared with distances over which external conditions, like L and a , vary appreciably. We shall not prove the result in great generality, but only in a very simple example, to show how it works. Again we consider the same slit experiment. But instead of putting all the magnetic field in a very tiny region between the slits, we imagine a magnetic field that extends

* If the field \mathbf{B} curves out of the plane of the figure, the flux as we have defined it is negative and x_0 is positive.

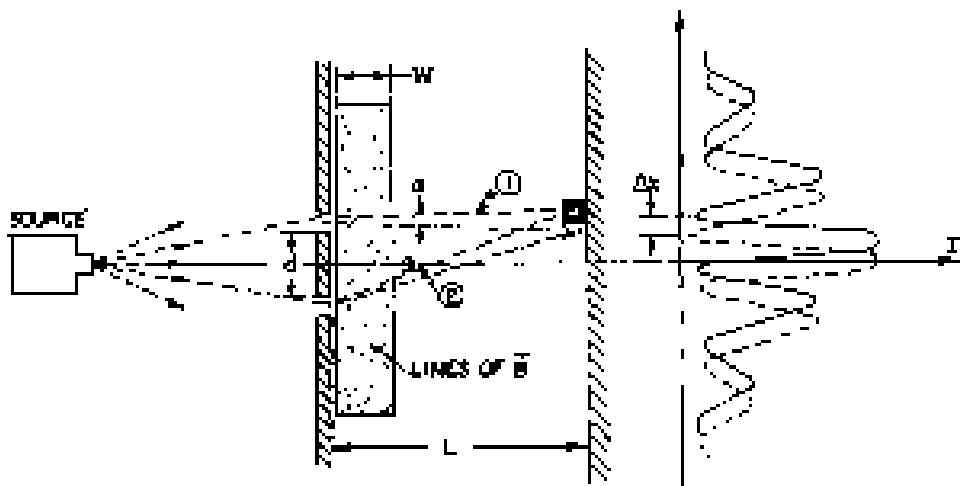

Fig. 15-8. The shift of the interference pattern due to a strip of magnetic field.

over a larger region behind the slits, as shown in Fig. 15-8. We will take the idealized case where we have a magnetic field which is uniform in a narrow strip of width w , considered small, as compared with L . (This can easily be arranged; the magnet can be put as far out as we want.) In order to calculate the shift in phase, we must take the two integrals of A along the two trajectories (1) and (2). They differ, as we have seen, merely by the flux of B between the paths. To our approximation, the flux is fixed. The phase difference for the two paths is then

$$\delta = \delta(B=0) + \frac{q}{h} B w d. \quad (15.37)$$

We note that, to our approximation, the phase shift is independent of the angle. So again, the effect will be to shift the whole pattern upward by an amount Δx . Using Eq. (15.28),

$$\Delta x = \frac{L\lambda}{\theta} \Delta\phi = \frac{L\lambda}{d} [\delta - \delta(B=0)].$$

Using (15.37) for $\delta - \delta(B=0)$,

$$\Delta x = L\lambda \frac{q}{h} B w. \quad (15.38)$$

Such a shift is equivalent to deflecting all the trajectories by the small angle α (see Fig. 15-8), where

$$\alpha = \frac{\Delta x}{L} = \frac{\lambda}{\theta} q B w. \quad (15.39)$$

Now classically we would also expect a thin strip of magnetic field to deflect all trajectories through some small angle, say α' , as shown in Fig. 15-9(a). As the electrons go through the magnetic field, they feel a transverse force $qv \times B$ which leads to a finite v/v . The change in their transverse momentum is just equal to this impulse, so

$$\Delta p_x = qvB. \quad (15.40)$$

The angular deflection [Fig. 15-9(b)] is equal to the ratio of this transverse momentum to the total momentum p . We get that

$$\alpha' = \frac{\Delta p_x}{p} = \frac{qvB}{p}. \quad (15.41)$$

We can compare this result with Eq. (15.39), which gives the same quantity computed quantum-mechanically. But the connection between classical mechanics and quantum mechanics is this: A particle of momentum p corresponds to a quan-

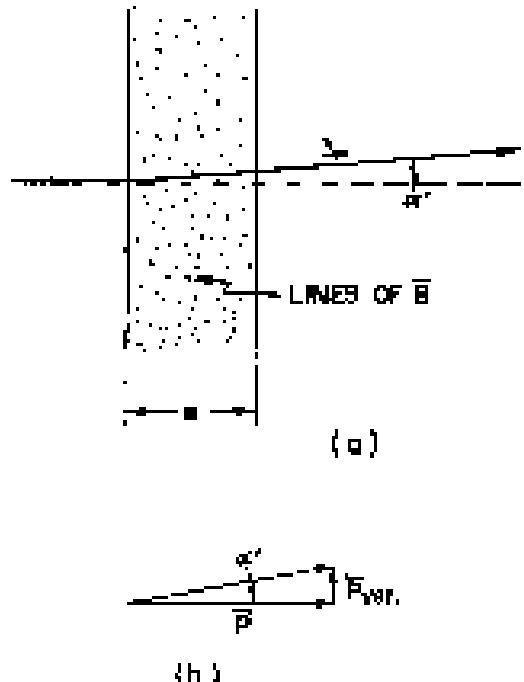

Fig. 15-9. Deflection of a particle due to passage through a strip of magnetic field.

term amplitude varying with the wavelength $\lambda = \hbar/\omega$. With this equality, ϕ and ψ are identical; the electrical and quantum calculations give the same result.

From the analysis we see how it is that the vector potential which appears in quantum mechanics in an explicit form produces a classical force which depends only on its derivatives. In quantum mechanics what matters is the interference between nearby paths; it always turns out that the effects depend only on how much the field A changes from point to point, and therefore only on the derivatives of A and not on the value itself. Nevertheless, the vector potential A together with the scalar potential ϕ that goes with it happens to give the most direct description of the physics. This becomes more and more apparent the more deeply we go into the quantum theory. In the general theory of quantum electrodynamics, one takes the vector and scalar potentials as the fundamental quantities in a set of equations that replace the Maxwell equations; E and B are slowly disappearing from the modern expression of physical laws; they are being replaced by A and ϕ .

15-6 What is true for statics is false for dynamics

We are now at the end of our exploration of the subject of static fields. Already in this chapter we have come perilously close to having to worry about what happens when fields change with time. We were barely able to avoid it in our treatment of magnetic energy by taking refuge in a relativistic argument. Even so, our treatment of the energy problem was somewhat artificial and perhaps even misleading, because we ignored the fact that moving coils must, in fact, produce changing fields. It is now time to take up the treatment of time-varying fields—the subject of electrodynamics. We will do so in the next chapter. First, however, we would like to emphasize a few points.

Although we began this course with a presentation of the complete and correct equations of electromagnetism, we immediately began to study some incomplete pieces—because that was easier. There is a great advantage in starting with the simpler theory of static fields, and proceeding only later to the more complicated theory which includes dynamic fields. There is less new material to learn all at once, and there is time for you to develop your intellectual muscles in preparation for the bigger task.

But there is one danger in this process that before we get to see the complete story, the incomplete truths learned en route may become ingrained and taken as the whole truth—that what is true and what is only sometimes true will become confused. So we give in Table 15-1 a summary of the important formulas we have covered, separating those which are true in general from those which are true for statics, but false for dynamics. This summary also shows, in part, where we are going, since as we treat dynamics we will be developing in detail what we must just state here without proof.

It may be useful to make a few remarks about the table. First, you should notice that the equations we started with are the *true* equations; we have not misled you there. The electromagnetic force law, called the *Ampère law*, $F = q(E + v \times B)$ is true. It is only Coulomb's law that is false, in as much only for statics. The four Maxwell equations for E and B are also true. The equations we took for statics are false, of course, because we left off all terms with time derivatives.

Gauss' law, $\nabla \cdot E = \rho/\epsilon_0$, continues, but the curl of E is not zero in general. So E cannot always be equivalent to the gradient of a scalar—the electrostatic potential. We will see that a scalar potential will remain, but it is a time-varying quantity that must be used together with vector potentials for a complete description of the electric field. The equations governing this new scalar potential are, necessarily, also new.

We must also give up the idea that E is zero in conductors. When the fields are changing, the charges in conductors do not, in general, have time to rearrange themselves to make the field zero. They are set in motion, but never reach equilibrium. The only general statement is: electric fields in conductors produce currents.

Table 15-1

ELECTRICITY IN GENERAL (true only for statics)		TRUE ALWAYS	
$E = \frac{1}{4\pi\epsilon_0} \frac{q\phi}{r^2}$	(Coulomb's law)	$E = q(E + v \times B)$	(Lorentz force)
		$\rightarrow \nabla \cdot E = \frac{\rho}{\epsilon_0}$	(Gauss' law)
$\nabla \times E = 0$		$\rightarrow \nabla \times E = -\frac{\partial B}{\partial t}$	(Faraday's law)
$E = -\nabla\phi$		$E = -\nabla\phi = \frac{\partial A}{\partial r}$	
$B(t) = \frac{1}{4\pi\epsilon_0} \frac{\rho(2)\phi_{ext}}{r_{ext}^2} dV_2$			
For conductors, $E = 0$, $\phi = \text{constant}$, $Q = CV$		In a conductor, E makes current j	
$c^2 \nabla \times B = \frac{j}{\epsilon_0}$	(Ampere's law)	$\rightarrow \nabla \cdot B = 0$	(No magnetic charges)
$B(t) = \frac{1}{4\pi\epsilon_0 c^2} \int \frac{\rho(2)}{r_{ext}^2} \frac{\phi_{ext}}{r_{ext}^2} dV_2$		$B = \nabla \times A$	
$\nabla^2 \phi = -\frac{\rho}{\epsilon_0}$	(Poisson's equation)	$\rightarrow c^2 \nabla \times B = \frac{1}{\epsilon_0} j + \frac{\partial A}{\partial t}$	
$\left. \begin{array}{l} \nabla^2 A = -\frac{j}{\epsilon_0 c^2} \\ \text{with} \\ \nabla \cdot A = 0 \end{array} \right\}$		$\left. \begin{array}{l} \nabla^2 \phi = \frac{1}{\epsilon_0} \frac{\partial^2 \phi}{\partial t^2} = -\frac{\rho}{\epsilon_0} \\ \text{and} \\ \nabla^2 A = \frac{1}{\epsilon_0} \frac{\partial^2 A}{\partial t^2} = -\frac{j}{\epsilon_0 c^2} \\ \text{with} \\ c^2 \nabla \cdot A + \frac{\partial \phi}{\partial t} = 0 \end{array} \right\}$	
$\phi(t) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho(2)}{r_{ext}} dV_2$		$\left. \begin{array}{l} \phi(t) = \frac{1}{4\pi\epsilon_0} \int \frac{\rho(2, t')}{r_{ext}} dV_2 \\ \text{and} \\ A(t, t) = \frac{1}{4\pi\epsilon_0 c^2} \int \frac{j(2, t')}{r_{ext}} dV_2 \\ \text{with} \\ t' = t - \frac{r_{ext}}{c} \end{array} \right\}$	
$A(t) = \frac{1}{4\pi\epsilon_0 c^2} \int \frac{j(2)}{r_{ext}} dV_2$			
$V = \frac{1}{2} \int \rho\phi dV + \frac{1}{2} \int j \cdot A dV$		$W = \int \left(\frac{\epsilon_0}{2} E \cdot E + \frac{\mu_0}{2} B \cdot B \right) dV$	

The equations marked by an arrow (\rightarrow) are Maxwell's equations.

tents. So in varying fields a conductor is not an equipotential. It also follows that the idea of a capacitor is no longer precise.

Since there are no magnetic charges, the divergence of \mathbf{B} is always zero. So \mathbf{B} can always be equated to $\nabla \times \mathbf{A}$. (Everything doesn't change!) But the generation of \mathbf{B} is not only from currents: $\nabla \times \mathbf{B}$ is proportional to the current density plus a new term $\partial \mathbf{A} / \partial t$. This means that \mathbf{A} is related to currents by a new equation. It is also related to ϕ . If we make use of our freedom to choose $\nabla \cdot \mathbf{A}$ for our own convenience, the equations for \mathbf{A} and ϕ can be arranged to take on a simple and elegant form. We therefore make the condition that $\nabla^2 \nabla \cdot \mathbf{A} = -\partial \mathbf{A} / \partial t$, and the differential equations for \mathbf{A} and ϕ appear as shown in the table.

The potentials A and ϕ can still be found by integrals over the currents and charges, but not the same integrals as for statics. Most wonderfully, though, the true integrals are like the static ones, with only a small and physically appealing modification. When we do the integrals to find the potentials at some point, say point (1) in Fig. 15-10, we must use the values of J and ρ at the point (2) at an earlier time $t' = t - r_{12}/c$. As you would expect, the influences propagate from point (2) to point (1) at the speed c . With this small change, one can solve for the fields of varying currents and charges, because once we have A and ϕ , we get \mathbf{E} from $\nabla \times \mathbf{A}$, as before, and \mathbf{B} from $\nabla \phi - A_t / c$.

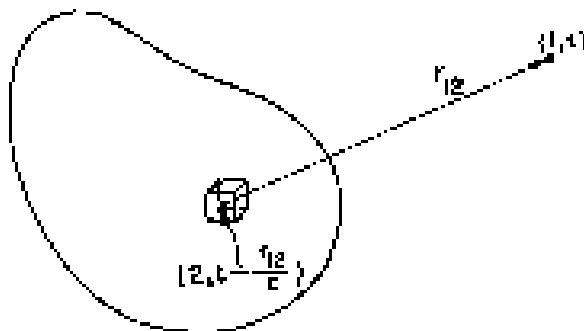

Fig. 15-10. The potentials at point (1) and at the time t are given by summing the contributions from each element of the source at the moving point (2), using the currents and charges which were present at the earlier time $t - r_{12}/c$.

Finally, you will notice that some results—for example, that the energy density in an electric field is $\epsilon_0 E^2/2$ —are true for electrodynamics as well as for statics. You should not be misled into thinking that this is at all “natural.” The validity of any formula derived in the static case must be demonstrated over again for the dynamic case. A concrete example is the expression for the electrostatic energy, in terms of a volume integral of ρu . This result is true only for statics.

We will consider all these matters in more detail in due time, but it will perhaps be useful to keep in mind this summary, so you will know what you can forget, and what you should remember as always true.

Induced Currents

16-1 Motors and generators

The discovery in 1820 that there was a close connection between electricity and magnetism was very exciting—until then, the two subjects had been considered to quite independent. The first discovery was that currents in wires make magnetic fields; then, in the same year, it was found that wires carrying current in a magnetic field have forces on them.

One of the immediate questions whenever there is a new electrical force is the possibility of using it in an engine to do work. Almost immediately after their discovery, people started to design electric motors using the forces on current-carrying wires. The principle of the electrodynamic motor is shown in bare outline in Fig. 16-1. A rectangular magnet—usually with some pieces of soft iron—is used to produce a magnetic field in two slots. Across each slot there is a north and south pole, as shown. A rectangular coil of copper is placed with one side in each slot. When a current passes through the coil, it flows in opposite directions in the two slots, so the forces are also opposite, producing a torque on the coil about the axis shown. If the coil is mounted so as to turn it can turn, it can be coupled to pulleys or gears and can do work.

The same idea can be used for making a sensitive instrument for electrical measurements. That the moment the force law was discovered the precision of electrical measurements was greatly increased. First, the torque of such a motor can be made much greater for a given current by making the current go around many turns instead of just one. Then the coil can be mounted so that it turns with very little torque either by supporting its shaft on very delicate jewel bearings or by hanging the coil on a very fine wire or a quartz fiber. Then an exceedingly small current will move the coil, and for small angles the amount of rotation will be proportional to the current. The rotation can be measured by gluing a pointer to the coil or, for the most delicate instruments, by attaching a small mirror to the coil and looking at the shift of the image of a scale. Such instruments are called galvanometers. Voltmeters and ammeters work on the same principle.

The same ideas can be applied on a large scale to make large motors for providing mechanical power. The coil can be made to go around and around by arranging that the connections to the coil are reversed each half-turn by contacts mounted on the shaft. Then the torque is always in the same direction. Small dc motors are made just this way. Larger motors, dc or ac, are often made by replacing the permanent magnet by an electromagnet energized from the electrical power source.

With the realization that electric currents make magnetic fields, people immediately suggested that somehow or other, magnetic fields also make electric fields. Various experiments were tried. For example, two wires were placed parallel to each other and a current was passed through one of them in the hope of inducing a current in the other. The thought was that the magnetic field might in some way drag the electrons along in the second wire, giving some sort of law of "like prefers to move alike." With the largest available current and the most sensitive galvanometer to detect any current, the result was negative. Large magnets next to wires also produced no observed effects. Finally, Faraday discovered in 1831 the essential feature that had been missed—that electric effects exist only when there is something changing. If one of a pair of wires has a changing current, a current is induced in the other. Or if a magnet is moved near an electric circuit, there is a current. Why this occurs is not known. This was the induction effect rediscovered

16-4 Electrical technology

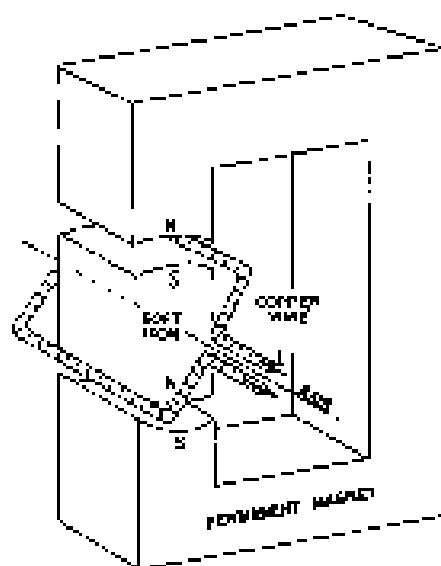

Fig. 16-1. Schematic outline of a simple electromagnetic motor.

by Faraday. It transformed the rather dull subject of static fields into a very exciting dynamic subject with an enormous range of wonderful phenomena. This chapter is devoted to a qualitative description of some of them. As we will see, one can quickly get into fairly complicated situations that are hard to analyze quantitatively in all their details. But never mind, our main purpose in this chapter is just to acquaint you with the phenomena involved. We will take up the detailed analysis later.

We can easily understand one feature of magnetic induction from what we already know, although it was not known in Faraday's time. It comes from the $v \times B$ force on a moving charge that is proportional to its velocity in a magnetic field. Suppose that we have a wire which passes near a magnet, as shown in Fig. 16-2, and that we connect the ends of the wire to a galvanometer. If we move the wire across the end of the magnet the galvanometer pointer moves.

The magnet produces some vertical magnetic field, and when we push the wire across the field, the electrons in the wire feel a sideways force—not right angles to the field and to the wire. The field pushes the electrons along the wire. But why does this move the galvanometer, which is so far from the force? Because when the electrons which feel the magnetic force try to move, they pull—by electric repulsion—the electrons a little farther down the wire; these, in turn, repel the electrons a little further on, and so on for a long distance. An amazing thing.

It was so interesting to Gauss and Weber—who first built a galvanometer—that they tried to see how far the forces in the wire would go. They strung a wire all the way across their city. Mr. Gauss, at one end, connected the wires to a battery (batteries were known before generators) and Mr. Weber watched the galvanometer move. They had a way of signaling long distances—it was the beginning of the telegraph! Of course, this has nothing directly to do with induction—it has to do with the very wires carrying currents, whether the currents are pushed by induction or not.

Now suppose in the setup of Fig. 16-2 we leave the wire alone and move the magnet. We still see no effect on the galvanometer. As Faraday discovered, moving the magnet under the wire—one way—has the same effect as moving the wire over the magnet—the other way. But when the magnet is moved, we no longer have any $v \times B$ force on the electrons in the wire. This is the new effect that Faraday found. Today, we might hope to understand it from a relativistic argument.

We already understand that the magnetic field of a magnet comes from its internal currents. So we expect to observe the same effect if instead of a magnet in Fig. 16-2 we use a coil of wire in which there is a current. If we move the wire past the coil there will be a current through the galvanometer, or also if we move the coil past the wire. But there is now a more exciting thing: If we change the magnetic field of the coil not by moving it, but by changing its current, there is again an effect in the galvanometer. For example, if we have a loop of wire near a coil, as shown in Fig. 16-3, and if we keep both of them stationary but switch off the current, there is a pulse of current through the galvanometer. When we switch the coil on again, the galvanometer kicks in the other direction.

Whenever the galvanometer in a situation such as the one shown in Fig. 16-2, or in Fig. 16-3, has a current, there is a net push on the electrons in the wire in one direction along the wire. There may be pushes in different directions at different places, but there is more push in one direction than another. What counts is the push integrated around the complete circuit. We call this net integrated push the electromotive force (abbreviated emf) in the circuit. More precisely, the emf is defined as the tangential force per unit charge in the wire integrated over length, once around the complete circuit. Faraday's complete discovery was that emf's can be generated in a wire in three different ways: by moving the wire, by moving a magnet near the wire, or by changing a current in a nearby wire.

Let's consider the simple machine of Fig. 16-1 again, only now, instead of putting a current through the wire to make it turn, let's turn the loop by an external force, for example by hand or by a waterwheel. When the coil rotates, its wires are moving in the magnetic field and we will find an emf in the circuit of the coil. The motor becomes a generator.

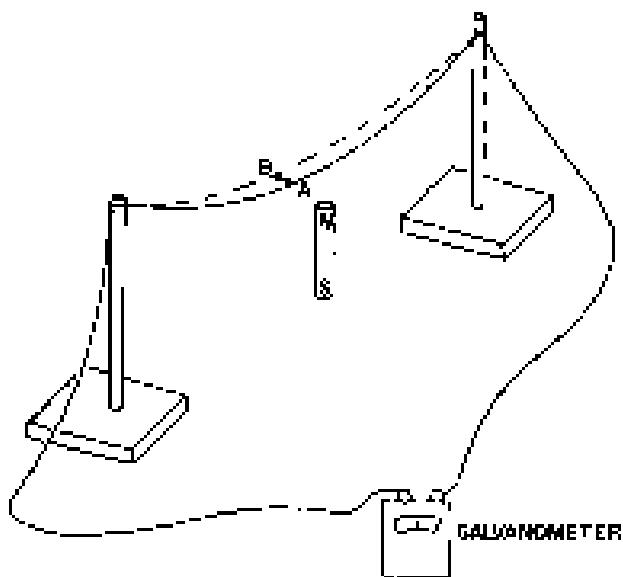

Fig. 16-2. Moving a wire through a magnetic field produces a current, as shown by the galvanometer.

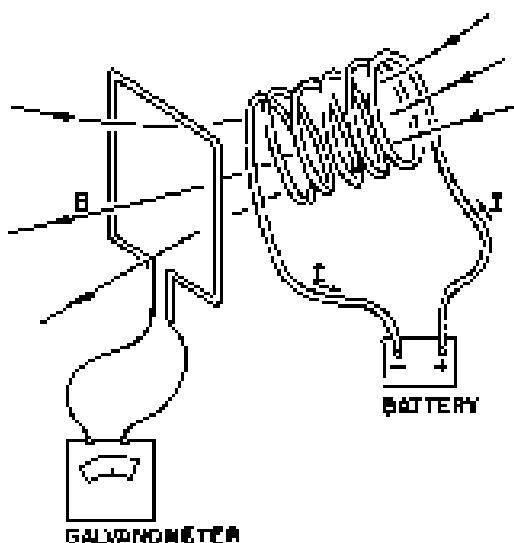

Fig. 16-3. A coil with current produces a current in a second coil if the first coil is moved or if its current is changed.

The coil of the generator has an induced emf from its motion. The amount of the emf is given by a simple rule discovered by Faraday. (We will just state the rule now and wait until later to examine it in detail.) The rule is that when the magnetic flux that passes through the loop that is the normal component of \mathbf{B} integrated over the area of the loop is changing with time, the emf is equal to the rate of change of the flux. We will refer to this as "the DRS rule." You see that when the coil of Fig. 16-1 is rotated, the flux through it changes. At the start some flux goes through one way; then when the coil has rotated 180° the same flux goes through the other way. If we continuously rotate the coil the flux is first positive, then negative, then positive, and so on. The rate of change of the flux must alternate also. So there is an alternating emf in the coil. If we connect the two ends of the coil to outside wires through some sliding contacts called slip-slugs (just so the wires won't get twisted) we have an alternating-current generator.

Or we can also manage, by means of some sliding contacts, that after every one-half rotation, the connection between the coil ends and the outside wires is reversed, so that when the emf reverses, so do the connections. Then the pulses of emf will always push currents in the same direction through the external circuit. We have what is called a direct-current generator.

The machine of Fig. 16-1 is either a motor or a generator. The reciprocity between motors and generators is nicely shown by using two identical dc "motors" of the permanent magnet kind, with their coils connected by two copper wires. When the shaft of one is turned mechanically, it becomes a generator and drives the other as a motor. If the shaft of the second is turned, it becomes the generator and drives the first as a motor. So here is an interesting example of a new kind of equivalence of nature; motor and generator are equivalent. The quantitative equivalence is, in fact, not completely accidental. It is related to the law of conservation of energy.

Another example of a device that can operate either to generate emf's or to respond to emf's is the receiver of a standard telephone—that is, ac "earphone." The original telephone of Bell consisted of two such "earphones," connected by two long wires. The basic principle is shown in Fig. 16-4. A permanent magnet produces a magnetic field in two "yokes" of soft iron, and in a thin diaphragm that is moved by sound pressure. When the diaphragm moves, it changes the amount of magnetic field in the yokes. Therefore a coil of wire wound around one of the yokes will have the flux through it changed when a sound wave hits the diaphragm.

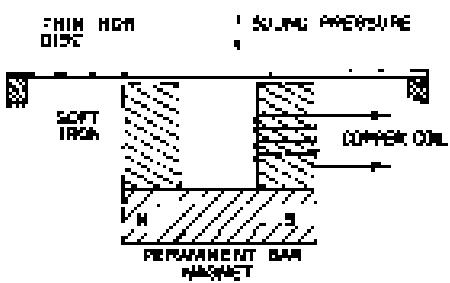

Fig. 16-4. A telephone transducer or receiver.

So there is an emf in the coil. If the ends of the coil are connected to a circuit, a current, which is an electrical representation of the sound is set up.

If the ends of the coil of Fig. 16-4 are connected by two wires to another identical gauge, varying currents will flow in the second coil. These currents will produce a varying magnetic field and will make a varying attraction on the iron diaphragm. The diaphragm will wiggle and make sound waves approximately similar to the ones that moved the original diaphragm. With a few bits of iron and copper the human voice is transmitted over wires!

(The modern home telephone uses a receiver like the one described but uses an improved invention to get a more powerful transmitter. It is the "carbon-bubble microphone," that uses sound pressure to vary the electric current from a battery.)

16-2 Transformers and inductances

One of the most interesting features of Faraday's discovery is just that an coil *causes* a driving coil—which we can understand in terms of the magnetic force $\mu_0 H \times B$ —but that a changing current in one coil makes an emf in a second coil. And quite surprisingly the amount of emf induced in the second coil is given by the same “flux rule”: that the emf is equal to the rate of change of the flux through the coil. Suppose that we take two coils, each wound around separate bundles of iron sheets (these help to make stronger magnetic fields), as shown at Fig. 16-5. Now we connect one of the coils—coil (a)—to an alternating-current generator. The continually changing current produces a continually varying magnetic field. This varying field generates an alternating emf in the second coil—coil (b). It is an emf, for example, produced enough power to light an electric bulb.

The emf alternates in coil (b) at a frequency which is of course, the same as the frequency of the original generator. But the current in coil (a) can be larger or smaller than the current in coil (b). The current in coil (b) depends on the emf induced in it and on the resistance and inductance of the rest of its circuit. The emf can be less than that of the generator if, say, there is little flux change. Or the emf in coil (b) can be much much larger than that in the generator by winding coil (b) with many turns. Even in a given magnetic field the flux through the coil is then greater. (Or if you prefer to look at it another way, the emf is the same in each turn, and since the total emf is the sum of the emfs of the separate turns, many turns in series produce a large emf.)

Such a combination of two coils—usually with an arrangement of iron sheets to guide the magnetic fields—is called a “transformer.” It can “transform” one emf (also called a “voltage”) to another.

There are also induction effects in a single coil. For instance, in the setup in Fig. 16-3 there is a changing flux not only through coil (b), which lights the bulb, but also through coil (a). The varying current in coil (a) produces a varying magnetic field inside铁心 and the flux of this field is continually changing, so there is a self-induced emf in coil (a). There is an emf acting on any current when it is building up a magnetic field—or, in general, when the field is changing in any way. The effect is called *self-inductance*.

When we gave “the flux rule” that the emf is equal to the rate of change of the flux linkage, we didn't specify the direction of the emf. There is a simple rule, called Lenz's rule, for figuring out which way the emf goes: the emf tries to oppose any flux change. That is, the direction of an induced emf is always such that if a current were to flow in the direction of the emf, it would produce a flux of *B* that opposes the change in *B* that produces the emf. Lenz's rule can be used to find the direction of the emf in the generator of Fig. 16-1, or in the transformer windings of Fig. 16-5.

In particular, if there is a changing current in a single coil (or in any wire) there is a “back” emf in the circuit. This emf acts on the charges flowing in coil (a) of Fig. 16-5 to oppose the change in magnetic field, and so in the direction to oppose the change in current. It tries to keep the current constant; it is opposite in the current when the current is increasing, and it is in the direction of the current

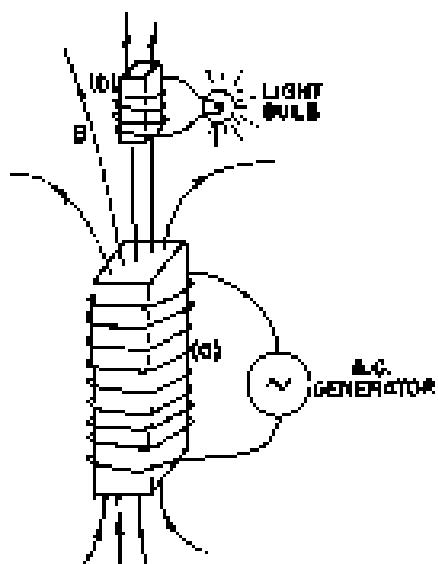

Fig. 16-5. Two coils, wrapped around bundles of iron sheets, allow a generator to light a bulb with no direct connection.

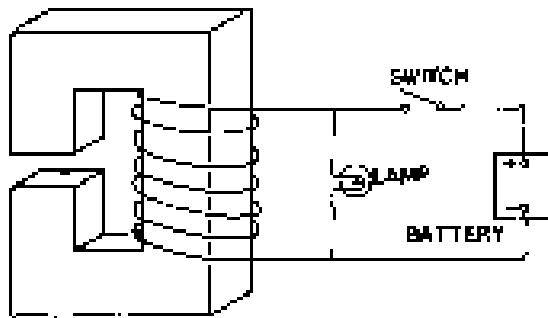

Fig. 16-6. Circuit connections for an electromagnet. The lamp shows the passage of current when the switch is opened, preventing the appearance of excessive emfs.

when it is decreasing. A current in a self-inductance has "inertia," because the inductive effects try to keep the flow constant, just as mechanical inertia tries to keep the velocity of an object constant.

Any large electromagnet will have a large self-inductance. Suppose that a battery is connected to the coil of a large electromagnet, as in Fig. 16-6, and that a strong magnetic field has been built up. (The current reaches a steady value determined by the battery voltage and the resistance of the wire in the coil.) But now suppose that we try to disconnect the battery by opening the switch. If we really opened the circuit, the current would go to zero rapidly, and in doing so it would generate an enormous emf. In most cases this emf would be large enough to develop an arc across the opening contacts of the switch. The high voltage that appears might also damage the insulation of the coil—or you, if you are the person who opens the switch! For these reasons, electromagnets are usually connected in a circuit like the one shown in Fig. 16-6. When the switch is opened, the current does not change rapidly but remains steady, flowing instead through the lamp, being driven by the coil due to the self-inductance of the coil.

16-3 Forces on induced currents

You have probably seen the dramatic demonstration of Lenz's rule made with the paddle shown in Fig. 16-7. It is an electromagnet, just like coil (a) of Fig. 16-5. An aluminum ring is placed on the end of the magnet. When the rod is connected to an alternating-current generator by closing the switch, the ring flies into the air. The force results, of course, from the induced currents in the ring. The fact that the ring flies away shows that the currents in it oppose the change of the field through it. When the magnet is reaching a double-poled stage, the induced current in the ring is making a downward-point north pole. The ring and the coil are repelled over the two magnets with like poles opposite. If a thin radial cut is made in the ring the force disappears, showing that it does indeed come from the currents in the ring.

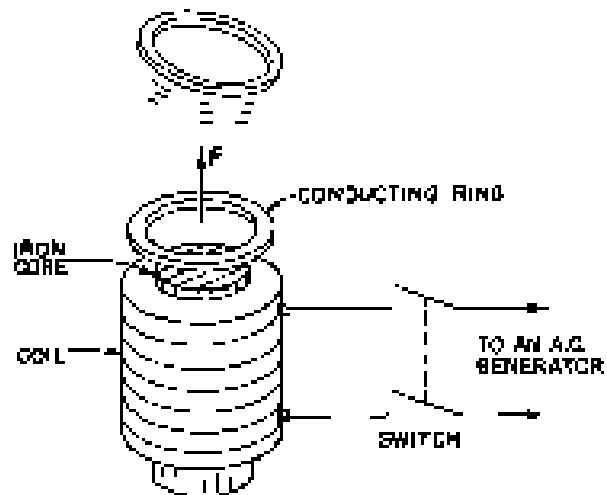

Fig. 16-7. A conducting ring is strongly repelled by an electromagnet with a varying current.

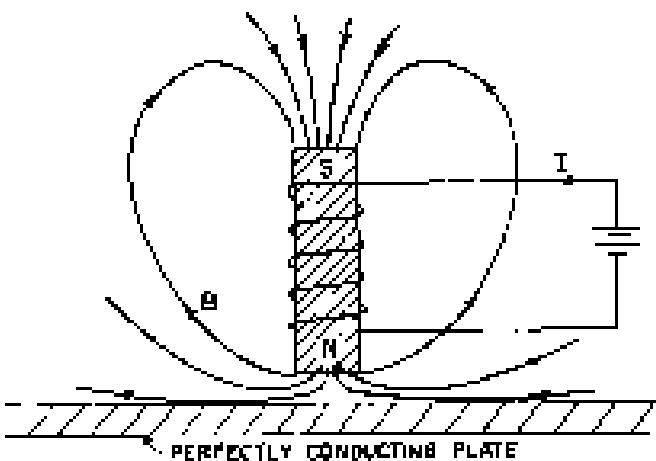

Fig. 16-8. An electromagnet near a perfectly conducting plate.

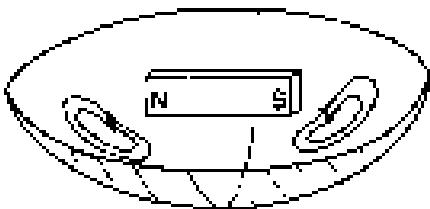

Fig. 16-9. A bar magnet is suspended above a superconducting bowl, by the repulsion of eddy currents.

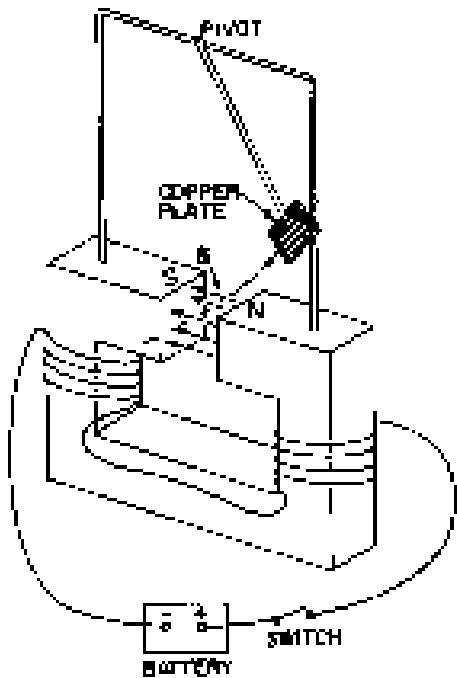

Fig. 16-10. The breaking of the pendulum shows the forces due to eddy currents.

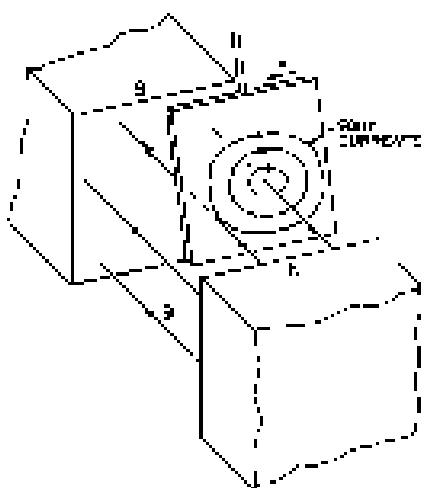

Fig. 16-11. The eddy currents in the copper pendulum.

If, instead of the ring, we place a disc of aluminum or copper across the end of the electromagnet of Fig. 16-7, it is also repelled; induced currents circulate in the material of the disc, and again produce a repulsion.

An interesting effect, similar in origin, occurs with a sheet of a perfect conductor. In a "perfect conductor" there is no resistance whatever to the current. So if currents are generated in it, they can keep going forever. In fact, the slight emf would generate an arbitrarily large current which really means that there can be no emfs at all. Any attempt to make a magnetic flux go through such a sheet generates currents that create opposite B fields—all with infinitesimal emfs, so with no flux entering.

If we have a sheet of a perfect conductor and put an electromagnet next to it, when we turn on the current in the magnet, currents called eddy currents appear in the sheet, so that no magnetic flux enters. The field lines would look as shown in Fig. 16-8. The same thing happens, of course, if we bring a bar magnet near a perfect conductor. Since the eddy currents are creating opposing fields, the magnets are repelled from the conductor. This makes it possible to suspend a bar magnet in air above a sheet of perfect conductor shaped like a dish, as shown in Fig. 16-9. The magnet is suspended by the repulsion of the induced eddy currents in the perfect conductor. These are no perfect conductors at ordinary temperatures, but some materials become perfect conductors at low enough temperatures. For instance, below 1.3°K tin conducts perfectly. It is called a superconductor.

If the conductor in Fig. 16-8 is not quite perfect there will be some resistance to flow of the eddy currents. The currents will tend to die out and the magnet will slowly settle down. The eddy currents in an imperfect conductor need not stop being going, and to have an emf the flux must keep changing. The loss of the magnetic field gradually punishes the conductor.

In a normal conductor, there are not only repulsive forces from eddy currents, but there can also be sideways forces. For instance, if we move a magnet sideways along a conducting surface the eddy currents produce a force of drag, because the induced currents are opposing the change in the location of flux. Such forces are proportional to the velocity and are like a kind of viscous force.

These effects show up nicely in the apparatus shown in Fig. 16-10. A square sheet of copper is suspended on the end of a rod to make a pendulum. The copper swings back and forth between the poles of an electromagnet. When the magnet is turned on, the pendulum motion is suddenly arrested. As the metal plate cuts the flux of the magnet, there is a current induced in the plate which acts to oppose the change in flux through the plate. If the sheet were a perfect conductor, the currents would be so great that they would push the plate out again—it would bounce back. With a copper plate there is some resistance in the plate, so the currents start by bringing the plate almost to a dead stop as it starts to enter the field. Then, as the currents die down, the plate slowly settles to rest in the magnetic field.

The nature of the eddy currents in the copper pendulum is shown in Fig. 16-11. The strength and geometry of the currents are quite sensitive to the shape of the plate. If, for instance, the copper plate is replaced by one which has several narrow slits cut in it, as shown in Fig. 16-12, the eddy-current effects are drastically reduced. The pendulum swings through the magnetic field with only a small retarding force. The reason is that the currents in each section of the copper have less flux to drive them, so the effects of the resistance of each loop are greater. The currents are smaller and the drag is less. The viscous character of the force is seen even more clearly if a sheet of copper is placed between the poles of the magnet of Fig. 16-10 and then released. It doesn't fall; it just sinks slowly downward. The eddy currents exert a strong resistance to the motion—just like the viscous drag in water.

If, instead of dragging a conductor past a magnet, we try to rotate it in a magnetic field, there will be a resistive torque from the same effects. Alternatively, if we rotate a magnet—and over and over—a conducting plate or ring, the ring is dragged around; currents in the ring will create a torque that tends to relax the ring with the magnet.

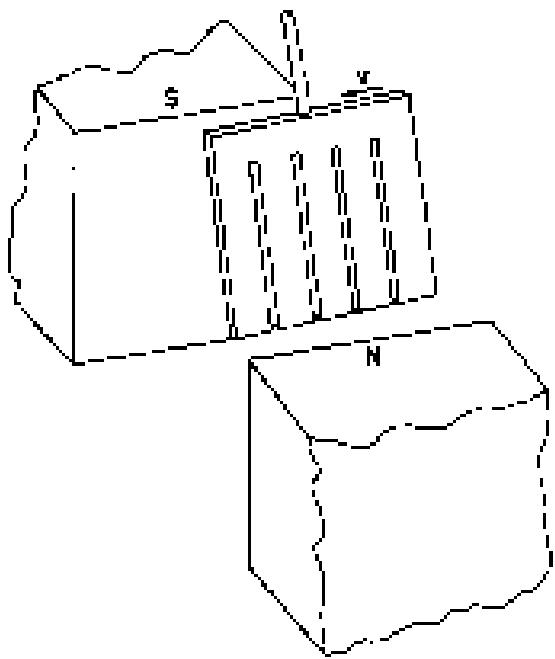

Fig. 16-12. Eddy-current effects are drastically reduced by cutting slots in the plate.

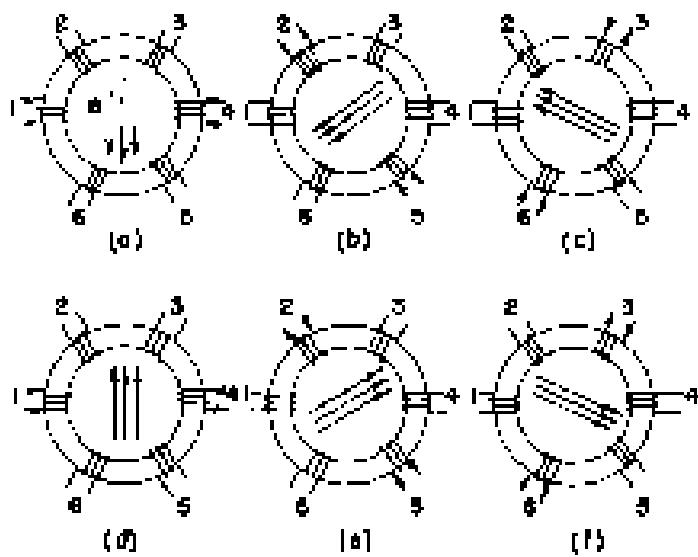

Fig. 16-13. Making a rotating magnetic field.

A field just like that of a rotating magnet can be made with an arrangement of coils such as is shown in Fig. 16-13. We take a torus of iron (that is, a ring of iron like a doughnut) and wind six coils on it. If we put a current, as shown in part (a), through windings (1) and (4), there will be a magnetic field in the direction shown in the figure. If we now switch the current to windings (2) and (5), the magnetic field will be in a new direction, as shown in part (b) of the figure. Continuing the process, we get the sequence of fields shown in the rest of the figure. If the process is done smoothly, we have a "rotating" magnetic field. We can easily get the required sequence of currents by connecting the ends to a three-phase power line, which provides just such a sequence of currents. "Three-phase power" is made in a generator using the principle of Fig. 16-1, except that there are three loops fastened together on the same shaft in a symmetrical way—that is, with an angle of 120° from one loop to the next. When the coils are rotated as a unit, the emf is a maximum in one, then in the next, and so on in a regular sequence. There are many practical advantages of three-phase power. One of them is the possibility of making a rotating magnetic field. The torque produced on a conductor by such a rotating field is easily shown by standing a metal ring on an insulating table just above the torus, as shown in Fig. 16-14. The rotating field causes the ring to spin about a vertical axis. The basic elements seen here are quite the same as those at play in a large commercial three-phase induction motor.

Another form of induction motor is shown in Fig. 16-15. The arrangement shown is not suitable for a practical high-efficiency motor but will illustrate the principle. The electromagnet M , consisting of a bundle of laminated iron sheets wound with a solenoidal coil, is powered with alternating current from a generator. The magnet produces a varying flux of Φ through the aluminum disc. If we have just these two components, as shown in part (a) of the figure, we do not yet have a motor. There are eddy currents in the disc, but they are symmetric and there is no torque. (There will be some heating of the disc due to the induced currents.) If we now cover only one-half of the magnet pole with an aluminum plate, as shown in part (b) of the figure, the disc begins to rotate, and we have a motor. The operation depends on two eddy-current effects. First, the eddy currents in the aluminum plate oppose the changes of flux through it, so the magnetic field above the plate always lags the field above last half of the pole, which is not covered. This so-called "shaded-pole" effect produces a field which is the "skewed" region versus

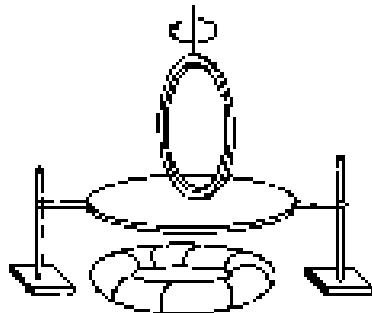

Fig. 16-14. The rotating field of Fig. 16-13 can be used to provide torque on a conducting ring.

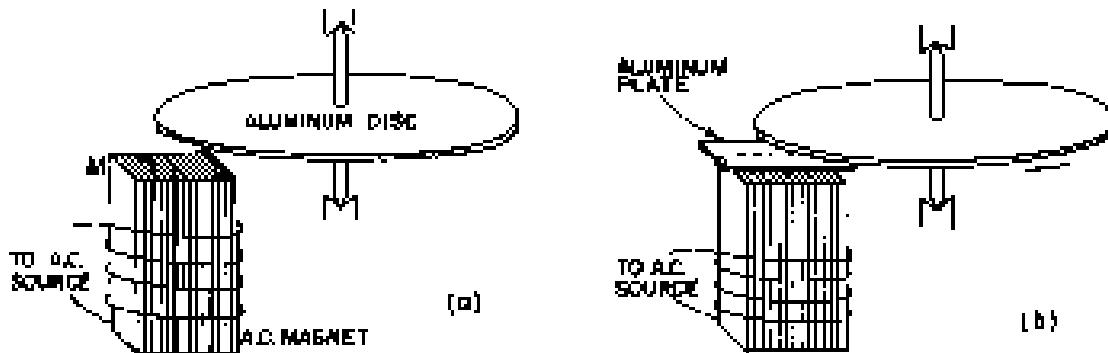

Fig. 16-15. A simple example of a shaded-pole induction motor.

much like that in the "unshaded" region except that it is delayed a constant amount in time. The result is as if there were a magnet only half as wide which is continually being moved from the unshaded region toward the shaded one. Then the varying fields interact with the eddy currents in the disc to produce the torque on it.

16-4 Electrical technology

When Faraday first made public his remarkable discovery that a changing magnetic flux produces an emf, he was asked (as anyone is asked when he discovers a new fact of nature), "What is the use of it?" All he had found was the oddity that a tiny current was produced when he moved a wire near a magnet. Of what possible "use" could that be? His answer was: "What is the use of a newborn baby?"

Yet think of the tremendous practical applications his discovery has led to. What we have been describing are not just rays but complex changes in great cases to represent the principle of some practical machine. For instance, the rotating ring in the turning field is an induction motor. There are, of course, some differences between it and a practical induction motor. The ring has a very small torque; it can be stopped with your hand. For a good motor, things have to be put together more intimately: there shouldn't be so much "wasted" magnetic field out in the air. First, the field is concentrated by using iron. We have not discussed how iron does that, but iron can make the magnetic field tens of thousands of times stronger than copper coils alone could do. Second, the gaps between the pieces of iron are made small; to do that, some iron is even built into the rotating ring. Everything is arranged so as to get the greatest forces and the greatest efficiency—that is, conversion of electrical power to mechanical power until the "ring" can no longer be held still by your hand.

This problem of closing the gaps and making the thing work in the most practical way is engineering. It requires serious study of design problems, although there are no new basic principles from which the forces are obtained. But there is a long way to go from the basic principles to a practical and economic design. Yet it is just such careful engineering design that has made possible such a tremendous thing as Boulder Dam and all that goes with it.

What is Boulder Dam? A huge river is stopped by a concrete wall. But what a wall it is! Shaped with a perfect curve that is very carefully worked out so that the least possible amount of concrete will hold back a whole river. It thickens at the bottom in that wonderful shape that the artists like but that the engineers can appreciate because they know that such thickening is related to the increase of pressure with the depth of the water. But we are getting away from electricity.

Then the water of the river is diverted into a huge pipe. That's a nice engineering accomplishment in itself. The pipe feeds the water into a "waterwheel"—a huge turbine—and makes wheels turn. (Another engineering feat.) But why turn wheels? They are coupled to an exquisitely intricate mess of copper and iron, all

twisted and intertwined. With two parts—one that has and one that doesn't. All a complex intermixture of a few iron and copper but also some paper and shellac for insulation. A revolving magnet thing. A generator. Somewhere out of the mass of copper and iron comes a few special pieces of copper. The dam, the turbine, the iron, the copper, all put there to make something special happen to a few bars of copper—an emf. Then the copper bars go a little way and circle for several times around another piece of iron in a transformer; then their job is done.

But around that same piece of iron coils another cable of copper which has no direct connection whatsoever to the bars from the generator; they have just been influenced because they passed near it to get their emf. The transformer converts the power from the relatively low voltages required for the efficient design of the generator to the very high voltages that are best for efficient transmission of electrical energy over long cables.

And everything must be enormously efficient—there can be no waste, no loss. Why? The power for a metropolis is going through. If a small fraction were lost—one or two percent—think of the energy left behind! If one percent of the power were lost in the transformer, that energy would need to be taken out somewhere. If it appeared as heat, it would quickly melt the whole thing. There is, of course, some small inefficiency, but all that is required are a few pumps which circulate some oil through a radiator to keep the transformer from heating up.

Out of the Boulder Dam come a few dozen rods of copper—long, long, long rods of copper perhaps the thickness of your wrist that go for hundreds of miles in all directions. Small rods of copper carrying the power of a giant river. Then the rods are split to make more rods . . . then to more transformers . . . sometimes to great generators which receive the current in another form . . . sufficient to generate running for big industrial purposes . . . in more transformers . . . then more splitting and spreading . . . until finally the river is spread throughout the whole city—running motors, making heat, making light, working industry. The cascade of hot little jets cold water over 600 miles away—all done with specially arranged pieces of copper and iron. Large motors for rolling steel, or tiny motors for a dentist's drill. Thousands of little wheels, turning in response to the turning of the big wheel at Boulder Dam. Stop the big wheel, and all the wheels stop; the lights go out. They really are connected.

Yet there is more. The same phenomena that take the tremendous power of the river and spread it through the countryside, until a few drops of the water run into the dentist's drill, come again into the building of extremely fine mechanisms . . . for the detection of incredibly small amounts of current . . . for the transmission of voices, music, and pictures . . . for computers . . . for automatic machines of fantastic precision.

All this is possible because of carefully designed arrangements of copper and iron—efficiently oriented magnetic fields . . . blocks of soft iron six feet in diameter whirling with clearances of 1/16 of an inch . . . careful proportions of copper for the optimum efficiency . . . strange shapes all serving a purpose, like the curve of the dam.

If some future archaeologist unearths Boulder Dam, we may guess that he would admire the beauty of its curves. But also the explorers from some great future civilization will look at the generators and transformers and say: "Notice that every iron piece has a beautifully efficient shape. Think of the thought that has gone into every piece of copper!"

This is the power of engineering and the careful design of our electrical technology. There has been created in the generator something which exists nowhere else in nature. It is true that there are forms of induction in other places. Certainly in some places around the sun and stars there are effects of electromagnetic induction. Perhaps also (though it's not certain) the magnetic field of the earth is maintained by an analog of an electric generator that operates on circulating currents in the interior of the earth. But nowhere have there been pieces put together with moving parts to generate electrical power as is done in the generator—with great efficiency and regularity.

You may think that designing electric generators is no longer an interesting subject, that it is a dead subject because they are all designed. Almost perfect generators or rotors can be taken from a shell. Even if this were true, we can admire the wonderful accomplishment of a problem solved to near perfection. But there remain as many unfinished problems. Even generators and transformers are not living as problems. It is likely that the whole field of low temperatures and superconductors will soon be applied to the problem of electric power distribution. With a radically new factor in the problem, new optimum designs will have to be evolved. Power networks of the future may have little resemblance to those of today.

You can see that there is an endless number of applications and problems that one could take up while studying the laws of induction. The study of the design of electrical machinery is a big work in itself. We cannot go very far in that direction, but we should be aware of the fact that when we have discovered the law of induction, we have suddenly connected our theory to an enormous practical development. We must, however, leave that subject to the engineers and applied scientists who are interested in working out the details of particular applications. Physics only supplies the base—the basic principles don't apply, so to speak what. (We have not yet completed the base, because we have yet to consider in detail the properties of areas of copper. Physics has something to say about these as we will see a little later.)

Modern electrical technology began with Faraday's discoveries. The useless hobby developed into a prodigy and changed the face of the earth in ways no man farther could have imagined.

The Laws of Induction

17-1 The physics of induction

In the last chapter we described many phenomena which show that the effects of induction are quite complicated and interesting. Now we want to discuss the fundamental principles which govern these effects. We have already defined the emf in a conducting circuit as the total accumulated force on the charges throughout the length of the loop. More specifically, it is the tangential component of the force per unit charge, integrated along the wire once around the circuit. This quantity is equal, therefore, to the total work done on a single charge that travels once around the circuit.

We have also given the "flux rule," which says that the emf is equal to the rate at which the magnetic flux through such a conducting circuit is changing. Let's see if we can understand why that might be. First, we'll consider a case in which the flux changes because a circuit is moved in a steady field.

In Fig. 17-1 we show a simple loop of wire whose dimensions can be changed. The loop has two parts, a fixed U-shaped part (a) and a movable crossbar (b) that can slide along the two legs of the U. There is always a complete circuit, but its area is variable. Suppose we now place the loop in a uniform magnetic field with the plane of the U perpendicular to the field. According to the rule, when the crossbar is moved there should be in the loop an emf that is proportional to the rate of change of the flux through the loop. This emf will cause a current in the loop. We will assume that there is enough resistance in the wire that the currents are small. Then we can neglect any magnetic field from this current.

The flux through the loop is Φ_B , so the "flux rule" would give for the emf—which we write as ϵ

$$\epsilon = -\Phi_B \frac{dI}{dt} = -\Phi_B v,$$

where v is the speed of translation of the crossbar.

Now we should be able to understand this result from the magnetic $v \times B$ forces on the charges in the moving crossbar. These charges will feel a force, tangential to the wire, equal to vB per unit charge. To is constant along the length a of the crossbar and zero elsewhere, so the integral is

$$\epsilon = -vAB,$$

which is the same result we got from the rate of change of the flux.

The argument just given can be extended to any case where there is a fixed magnetic field and the wires are moved. One can prove, in general, that for any circuit whose parts move in a fixed magnetic field the emf is the time derivative of the flux, regardless of the shape of the circuit.

On the other hand, what happens if the loop is stationary and the magnetic field is changed? We cannot deduce the answer to this question from the same argument. It was Faraday's discovery, from experiment—that the "flux rule" is still correct no matter why the flux changes. The force on electric charges is given in complete generality by $F = q(E + v \times B)$; there are no new special "forces due to changing magnetic fields." Any forces on charges at rest in a stationary wire come from the E term. Faraday's observations led to the discovery that electric and magnetic fields are related by a new law: in a region where the magnetic field is changing with time, electric fields are generated. It is this electric

Fig. 17-1. An emf ϵ is induced in a loop if the flux is changed by varying the area of the circuit.

field which drives the electrons around the wire, and so is responsible for the emf in a static circuit when there is a changing magnetic flux.

The general law for the electric field associated with a changing magnetic field is

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}. \quad (17.1)$$

We will call this Faraday's law. It was discovered by Faraday but was first written in differential form by Maxwell, as one of his equations. Let's see how this equation gives the "flux rule" for circuits.

Using Stokes' theorem, this law can be written in integral form as

$$\oint_C \mathbf{E} \cdot d\mathbf{s} = \int_S (\mathbf{E} \times \mathbf{B}) \cdot n \, dA = - \int_S \frac{\partial \mathbf{B}}{\partial t} \cdot n \, dA, \quad (17.2)$$

where, as usual, C is any closed curve and S is any surface bounded by C . Here, remember, C is a *conventional* curve fixed in space and S is a flat surface. Right, the time derivative can be taken outside the integral and we have

$$\begin{aligned} \oint_C \mathbf{E} \cdot d\mathbf{s} &= - \frac{\partial}{\partial t} \int_S \mathbf{B} \cdot n \, dA \\ &= - \frac{\partial}{\partial t} (\text{Flux through } S). \end{aligned} \quad (17.3)$$

Applying this relation to a curve C that follows a fixed circuit of conductor, we get the "flux rule" once again. The integral on the left is the emf, and that on the right is the negative rate of change of the flux linked by the circuit C . So Eq. (17.1) applied to a fixed circuit is equivalent to the "flux rule."

So the "flux rule" that the emf in a circuit is equal to the rate of change of the magnetic flux through the circuit applies whether the flux changes because the field changes or because the circuit moves through it. The two possible lines "current changes" or "local charges" are not distinguishable in the statement of the rule. Yet again, application of the rule we have used two completely distinct laws for the two cases: $\nabla \times \mathbf{B}$ for "current changes" and $\nabla \times \mathbf{E} = -\partial \mathbf{B} / \partial t$ for "field changes."

We know of no other place in physics where such a simple and elegant general principle requires for its real understanding an analysis in terms of two different parameters. (Similarly such a beautiful generalization is found to stem from using a deeper underlying principle. Nevertheless, in this case there does not appear to be any such extended interpretation.) We have to understand the "rule" as the combination of two quite separate phenomena.

We must look at the "flux rule" in the following way. In general, the force on unit charge is $F = q(\mathbf{E} + \mathbf{v} \times \mathbf{B})$. In moving waves there is the force from the second term. Also, there is an E -field if there is somewhere a changing magnetic field. They are independent effects, but the end result for loops of wire is always equal to the sum of currents times magnetic flux through it.

17.2 Exceptions to the "flux rule"

We will now give some examples, due in part to Faraday, which show the importance of keeping clearly in mind the distinction between the two effects responsible for induced emfs. Our examples involve situations to which the "flux rule" cannot be applied, either because there is no wire at all or because the path taken by induced currents moves about within an extended volume of a conductor.

We begin by making an important point: The sum of currents that comes from the B -field does not depend on the existence of a physical wire (as does the $\mathbf{E} \times \mathbf{B}$ part). The A -field can exist in free space, and its line integral around any arbitrary line fixed in space is the rate of change of the flux of B through that line. (Note that this is quite unlike the A -field produced by static charges, for in that case the line integral of B around a closed loop is always zero.)

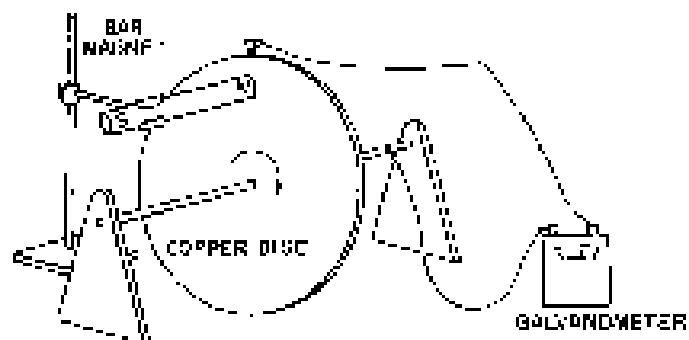

Fig. 17-2. When the disc rotates there is an emf, $\nabla \times B$, but with no change in the linked flux.

Now we will describe a situation in which the flux through a circuit does not change, but there is nevertheless an emf. Figure 17-2 shows a conducting disc which can be rotated on a fixed axis in the presence of a magnetic field. One contact is made to the shaft and another rests on the outer periphery of the disc. A circuit is completed through a galvanometer. As the disc rotates, the "current," in the sense of the place or source where the current starts, is always the same. But the part of the "circuit" in this case is an material which is moving. Although the joint through the "circuit" is constant, there is still an emf, as can be observed by the deflection of the galvanometer. Clearly, here is a case where $\nabla \times B$ force in the moving disc gives rise to an emf which cannot be equated to a change of flux.

Now we consider, as an opposite example, a somewhat unusual situation in which the flux through a "circuit" (even in the sense of the place where the current is) changes but where there is no emf. Imagine two metal plates with slightly curved edges, as shown in Fig. 17-3, placed in a uniform magnetic field perpendicular to their surfaces. Each plate is connected to one of the terminals of a galvanometer, as shown. The plates make contact at one point P , so there is a complete circuit if the plates are now rocked through a small angle; the point of contact will move to P' . If we now give the "circuit" to be completed (around the plates on the dotted line shown in the figure), the magnetic flux through this circuit changes by a large amount as the plates are rocked back and forth. Yet the reading can be done with small meters, so that $\nabla \times B$ is very small and there is practically no emf. The "flux rule" does not work in this case. It must be applied to circuits in which the material of the circuit remains the same. When the material of the circuit is changing, we must return to the basic law. The correct physics is always given by the flux rule!

$$F = \mu(E + v \times B).$$

$$\nabla \times E = -\frac{\partial B}{\partial t}$$

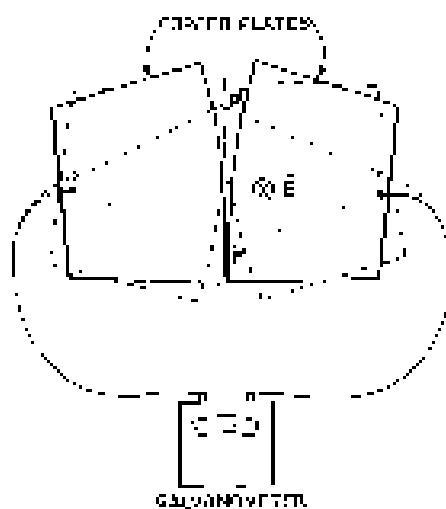

Fig. 17-3. When the plates are rocked in a uniform magnetic field, there can be a large change in the flux linkage without the generation of an emf.

17-3 Particle acceleration by an induced electric field; the betatron

We have seen that the electromagnetic fields produced by a changing magnetic field can exist even with no conductors. Just as $\nabla \times B$ can apply to an empty void with no wires, we may still have an electro-magnetic field existing in a "vacuum" (mathematically empty space). It is believed by just an educated guess that F integrated around the curve, Faraday's law says that the line integral is equal to the rate of change of the magnetic flux through the closed curve, Eq. (17-3)

As an example of the effect of such an unshielded field, we want to try to consider the motion of an electron going through a magnetic field. We imagine a magnetic field which, say, in a plane, points in a vertical direction, as shown in Fig. 17-4. The magnetic field is produced by a solenoid, etc., but we will not worry about the details. For our example we will assume that the magnetic field is uniform about some axis, i.e., that the strength of the magnetic field B depends only on the distance from the axis. The magnetic field is also varying with time. We can imagine an electron that is moving in the field on a path that is a circle of constant radius with the center at the axis of the field. (We will see later

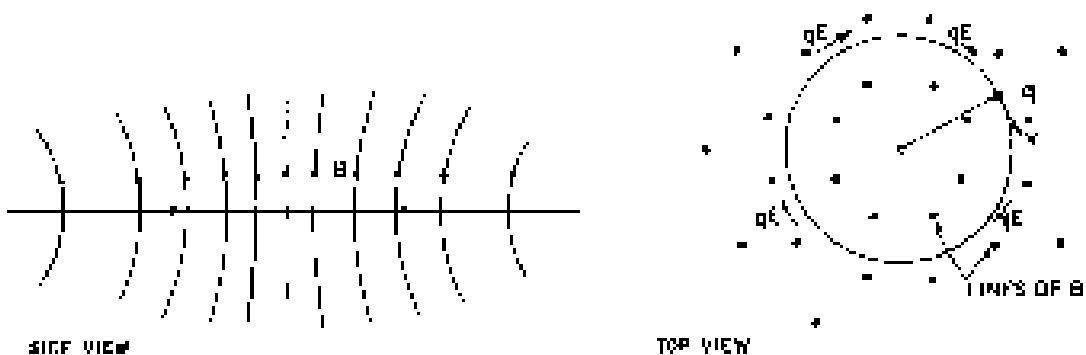

Fig. 17-4. An electron accelerating in an axially symmetric, time-varying magnetic field.

now this motion and be accelerated. Because of the changing magnetic field, there will be no electric field E tangential to the electron's orbit which will cause it to leave the circle. Because of the symmetry, this electric field will have the same value everywhere on the circle. If the electron's orbit has the radius r , the line integral of E around the orbit is equal to the rate of change of the magnetic flux through the circle. The line integral of E is just the component tangential to the electron's orbit of the electric field E . The magnetic flux must, in general, be obtained from an integral. For the moment, we let B_{av} represent the average magnetic field in the interior of the circle; then the flux is this average magnetic field times the area of the circle. We will have

$$2\pi r E = \frac{d}{dt} (B_{av} \cdot \pi r^2)$$

Since we are assuming r is constant, E is proportional to the time derivative of the average field:

$$E = \frac{1}{2} \frac{dB_{av}}{dt} \quad (17.3)$$

The electron will feel the electric force qE and will be accelerated by it. Remembering that the relativistically correct equation of motion is that the rate of change of the momentum is proportional to the force, we have

$$qE = \frac{dp}{dt} \quad (17.4)$$

For the circular orbit we have noticed, the electric force on the electron is always in the direction of its motion, so its total momentum will be increasing at the rate given by Eq. (17.4). Combining Eqs. (17.3) and (17.4), we may relate the rate of change of momentum to the change of the average magnetic field:

$$\frac{dp}{dt} = \frac{q}{2} \frac{d\theta_{av}}{dt} \quad (17.5)$$

Integrating with respect to t , we find for the electron's momentum

$$p = p_0 + \frac{q}{2} \Delta \theta_{av} \quad (17.6)$$

where p_0 is the momentum with which the electrons start out, and $\Delta \theta_{av}$ is the subsequent change in θ_{av} . The operation of a betatron - a machine for accelerating electrons to high energies - is based on this idea.

To see how the betatron operates in detail, we must now examine how the electron can be constrained to move on a circle. We have discussed in Chapter 15 of Vol. I the principle involved. If we arrange that there is a magnetic field B at the orbit of the electron, there will be a transverse force $qv \times B$ which, for a suitable

as by choice, B , can cause the electron to keep moving on its assigned orbit. In the derivation thus far, no force causes the electron to move in a circular orbit of constant radius. We can find out what the magnetic field at the orbit must be by using again the relativistic equation of motion, but this time for the transverse component of the force. In the betatron case (Fig. 17-4), B is straight, angular at $\pi/2$, so the force is $qvB \sin \theta = qvB$. Thus the force is equal to the rate of change of the transverse component p_θ of the momentum:

$$qvB = \frac{dp_\theta}{dt}. \quad (17.2)$$

When a particle e is moving in a circle, the rate of change of its transverse momentum is equal to the magnitude of the tangential velocity v , the angular velocity of rotation (following the arguments of Chapter 11, Vol. I),

$$\frac{dp_\theta}{dt} = vp_\theta, \quad (17.3)$$

where, since the motion is circular,

$$\omega = \frac{v}{r}. \quad (17.4)$$

Setting the magnetic force equal to the transverse acceleration, we have

$$qvB_{\text{ext}} = p_\theta \omega, \quad (17.5)$$

where B_{ext} is the field at the radius r .

As the motion increases, the momentum of the electron grows in proportion to B_{ext} , according to Eq. (17.3), and if the electron is to continue to move in its proper circle, Eq. (17.5) must continue to hold as the momentum of the electron increases. The value of B_{ext} must increase in proportion to the momentum p . Comparing Eq. (17.5) with Eq. (17.2), which determines p , we see that the following relation must hold between B_{ext} , the average magnetic field inside the orbit at the radius r , and the magnetic field B_{ext} at the orbit:

$$AB_{\text{ext}} = 3.2B_{\text{ext}}. \quad (17.6)$$

The correct operation of a betatron requires that the average magnetic field inside the orbit increase at twice the rate of the magnetic field at the orbit itself. In these circumstances, as the energy of the particle is increased by the induced electric field the magnetic field at the orbit increases at just the rate required to keep the particle moving in a circle.

The betatron is used to accelerate electrons to energies of tens of millions of volts, or even to hundreds of millions of volts. However, it becomes impractical for the acceleration of electrons to energies much higher than a few hundred million volts for several reasons. One of them is the practical difficulty of obtaining the required high average value for the magnetic field inside the orbit. Another is that Eq. (17.6) is no longer correct at very high energies because it does not include the loss of energy from the particle due to its radiation of electromagnetic energy (the so-called synchrotron radiation discussed in Chapter 36, Vol. I). For these reasons, the acceleration of electrons to the highest energies—“many billions of” electron volts—is accomplished by means of a different kind of machine, called a *synchrotron*.

17-4 A paradox

We would now like to describe for you an apparent paradox. A paradox is a situation which gives one answer when analyzed one way, and a different answer when analyzed another way, so that we are left in somewhat of a quandary as to actually what would happen. Of course, in physics there are never any real paradoxes because there is only one correct answer, at least we believe that now we will

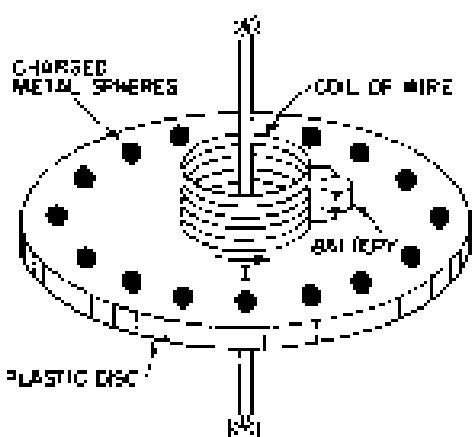

Fig. 17-5. Will the disc rotate if the current I is stopped?

in only one way (and that is the right way, naturally). So in physics it is always better to confine our own understanding. Here's our paradox.

Imagine that we construct a device like that shown in Fig. 17-5. There is a thin, circular plastic disc suspended on a vertical shaft with excellent bearings, so that it is quite free to rotate. In the center is a coil of wire in the form of a short solenoid concentric with the axis of rotation. This coil carries a steady current I provided by a small battery, as shown. Next, the edge of the disc and center (in fact, a small bar magnet) attract each other since all metal spheres scattered on a mesh grid just below the bottom of the disc. Each of these small conducting spheres is charged with the same negative charge Q . Everything is up to snuffing, and the disc is at rest. Suppose now that by some accident, or by pure happenstance, the current in the solenoid is interrupted, whether by intervention from the outside. Suddenly, when current ceases, there was no magnetic field through the solenoid, more or less parallel to the axis of rotation. When the current is interrupted, this has nothing to do. There will, therefore, be no electric field induced which will cause motion in either direction of the axis. The charged spheres at the perimeter of the disc will all experience an electric field tangential to the perimeter of the disc. This electric force is in the same sense toward the charges and so will result in a net torque on the disc. From these arguments we would expect that as the current in the solenoid ceases, the disc would begin to rotate. If we knew the magnitude of gravity (that is, the current in the solenoid, and the charges on, I usually think, we could not give the resulting angular velocity).

But we could also make a different argument. Using the principles of thermodynamics of a great civilization, we could say that the total moment of all the disc with all its equipment is nearly zero, and so the only disturbance in the system should stop it at once. We should be in rotation when the current is stopped. Which argument is correct? Well, the disc rotates or will it not? We will leave this question for you to think about.

We should warn you that the correct answer does not depend on any misconception of mine, such as the asymmetric position of a battery, for example. In fact, you can imagine several situations such as the following. The solenoid is made of a permanent magnet through which there is a current. After the current has been fully passed off, the temperature of the solenoid is allowed to rise slowly while the ferromagnetic of the core reaches the transition temperature between superconductivity and resistivity. Immediately, the current in the solenoid will be brought to zero by the resistance of the core. Finally, as before, let us generate there with an electric field through the axis. We should also warn you that the situation is not easy, or a simple trick. When you figure it out, you will have the crown of a laurel in the annals of electromagnetism.

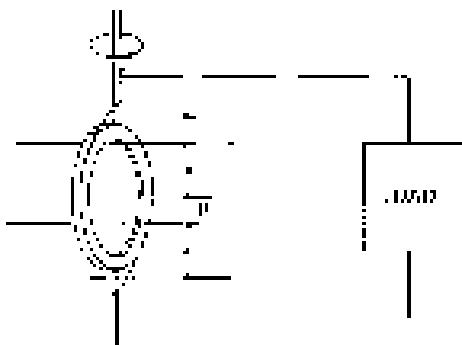

Fig. 17-6. A coil of wire rotating in a uniform magnetic field—the basic idea of the *dc* generator.

17-5 Alternating-current generator

In the remainder of this chapter we apply the principles of Section 17-4 to analyze numerous of the phenomena discussed in Chap. 16. We first look in more detail at the alternating-current generator. Such a generator consists basically of a coil of wire rotating in a uniform magnetic field. The same as drawn may be achieved by a fixed coil in a magnetic field whose direction rotates at the frequency described in the last chapter. We will consider only the latter case. Suppose we have a circular coil of wire which can be turned out at a constant rate of rotation. Let this coil be located in a uniform magnetic field perpendicular to the plane of rotation, as in Fig. 17-6. We also imagine that the two ends of the coil are brought to external connections through brushes kind of guy wires.

Due to the rotation of the coil, the magnetic flux through it will be changing. The current of the coil will therefore have an effect. Let θ be the angle of the coil and δ the angle between the magnetic field and the normal to the plane of the coil.⁴

⁴ Note that we are using the letter δ for the *W* in $\sin \delta$ instead of ϕ , θ , and ψ for a surface area.

The flux through the coil is then

$$\text{flux} = \int B \cdot d\mathbf{A} \quad (17.13)$$

If the coil is rotating at the uniform angular velocity ω , θ varies with time as $\theta = \omega t$. The curl \mathbf{E} in the coil is then

$$\begin{aligned} \mathbf{E} &= -\frac{d}{dt} (\text{flux}) = -\frac{d}{dt} (BS \cos \omega t) \\ &= BS \omega \sin \omega t. \end{aligned} \quad (17.14)$$

If we bring the wires from the generator to a point some distance from the rotating coil, where the magnetic field is zero, or at least is not varying with time, the curl of \mathbf{E} in this region will be zero and we can define an electric potential. In fact, if there is no current being drawn from the generator, the potential difference V between the two wires will be equal to the emf in the rotating coil. That is,

$$V = BS \omega \sin \omega t = E_0 \sin \omega t.$$

The potential difference between the wires varies sinusoidally. Such a varying potential difference is called an alternating voltage.

Since there is an electric field between the wires, they must be electrically charged. It is clear that the emf of the generator has passed some excess charge out of the wire until the electric field from E_0 is strong enough to exactly completely balance the induction force. Since far outside the generator, the two wires appear as though they had been electrically charged to the potential difference V , but as though the charge was being carried with time to give an alternating longitudinal voltage. There is also mutual induction between the two wires. If we require the generator to generate a constant potential difference V , we find that the self-losses are great if the wires try to be discharged but continue to provide charge to the wires as current is drawn from them, attempting to keep the wires always at the same potential difference. If, in fact, the generator is connected in a circuit whose total resistance is R , the current through the circuit will be proportional to the emf of the generator and inversely proportional to R . So the emf has sinusoidal time variation, so also does the current. There is an alternating current

$$I = \frac{E}{R} = \frac{V_0}{R} \sin \omega t.$$

The schematic diagram of such a circuit is shown in Fig. 17-7.

We can also see just the end determines how much energy is supplied by the generator. Each charge in the wire is receiving energy at the rate $F \cdot v$, where F is the force on the charge and v is its velocity. Now let q represent all moving charges per unit length of the wire be w . Then the power being delivered into any element ds of the wire is

$$F \cdot v \cdot ds.$$

For a wire, v is always along ds , so we can rewrite the power as

$$q e F \cdot ds.$$

The total power being delivered to the complete circuit is the integral of this expression around the complete loop:

$$\text{Power} = \oint q e F \cdot ds. \quad (17.15)$$

Now remember that $q ds$ is the current I , and that the emf is defined as the integral of $E \cdot ds$ around the circuit. We get the result:

$$\text{Power from a generator} = VI \quad (17.16)$$

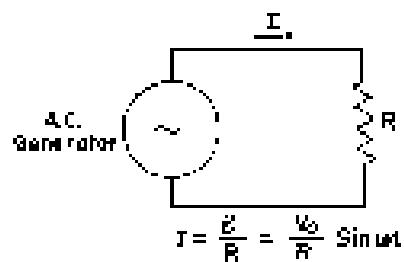

Fig. 17-7. A circuit with an ac generator and a resistor.

When there is a current in the coil of the generator, there will also be mechanical forces on it. In fact, we know that the torque on the coil is proportional to its magnetic moment, to the magnetic field strength B , and to the sine of the angle between. The magnetic moment is the current in the coil times its area. Therefore the torque is

$$\tau = 130 \sin \theta. \quad (17.17)$$

The rate at which mechanical work must be done to keep the coil at θ is the angular velocity ω times the torque

$$\frac{dE}{dt} = \omega \tau = \omega B D \sin \theta. \quad (17.18)$$

Comparing this equation with eq. (17.14), we see that the rate of mechanical work required to move the coil against the magnetic forces is just equal to E_t , the rate at which electrical energy is delivered by the emf of the generator. All of the mechanical energy used up in the generator appears as electrical energy in the circuit.

As a second example of the currents and forces due to an induced emf, let's analyze what happens in the set-up described in Section 12, and shown in Fig. 17.1. There are two parallel wires and a sliding crossbar located in a uniform magnetic field perpendicular to the plane of the parallel wires. Now let's assume that the "bottom" of the L (the left side in the figure) is made of wires of high resistance, while the "two side wires" are made of a good conductor like copper. Then we don't need to worry about the change of the circuit resistance as the crossbar is moved. As before, the emf in the circuit is

$$e = vBw. \quad (17.19)$$

The current in the circuit is proportional to this emf and inversely proportional to the resistance of the circuit:

$$I = \frac{e}{R} = \frac{vBw}{R}. \quad (17.20)$$

Because of this current there will be a magnetic force on the crossbar that is proportional to its length, to the current in it, and to the magnetic field, such that

$$F = BIp. \quad (17.21)$$

Taking s from eq. (17.06), we have for the force

$$F = \frac{B^2 w^2}{R} s. \quad (17.22)$$

We see that the force is proportional to the velocity of the crossbar. The direction of the force, as you can easily see, is opposite to its velocity. Such a "velocity-dependent" force, which is like the force of viscosity, is found whenever induced currents are produced by moving conductors in a magnetic field. The examples of eddy currents we gave in the last chapter also produced forces on the conductors proportional to the velocity of the conduction, even though such situations are general, give a complicated distribution of currents which is difficult to analyze.

It is often convenient in the design of mechanical systems to have damping forces which are proportional to the velocity. Eddy-current forces permit one of the most convenient ways of getting such a velocity-dependent force. An example of the application of such a force is found in the conventional domestic wattmeter. In the wattmeter there is a thin aluminum disc that rotates between the poles of a permanent magnet. This disc is driven by a small electric motor whose torque is proportional to the power being consumed in the electrical circuit, of the house. Because of the eddy-current forces in the disc, there is a resistive force proportional to the velocity. In equilibrium, the velocity is therefore proportional to the rate of consumption of electrical energy. By means of a counter attached to the rotating disc, a record is kept of the number of revolutions it makes. This counts is an indication of the total energy consumption, i.e., the number of "watt-hours" used.

We may also point out that Eq. (17.22) shows that the force from induced emf—that is, the eddy-current force—is inversely proportional to the resistance. The force will be larger the better the conductivity of the material. The series, of course, is that an emf produces more current if the resistance is low, and the stronger current represents greater mechanical forces.

We can also see from our formulas how mechanical energy is converted into electrical energy. As before, the electrical energy supplied to the resistance of the circuit is the product IR . The rate at which work is done in moving the conducting mass is the force on the bar times its velocity. Using Eq. (17.21) for the force, the rate of doing work is

$$\frac{dW}{dt} = \frac{\epsilon^2 R^2 v^2}{R}.$$

We see that this is indeed equal to the product of the work we would get from Eqs. (17.19) and (17.20). Again the mechanical work appears as electrical energy.

17-6 Mutual Inductance

We now want to consider a situation in which there are fixed coils of wire bar changing magnetic fields. When we described the production of magnetic fields by currents, we considered only the case of steady currents. But so long as the currents are changed slowly, the magnetic field will in each inductor be nearly the same as the magnetic field of a steady current. We will assume in the discussion of this section that the currents are always varying sufficiently slowly that this is true.

In FIG. 17.8 is shown an arrangement of two coils which demonstrates the basic effects responsible for the operation of a transformer. Coil 1 consists of a conductive wire wound in the form of a long solenoid. Around this coil 1 and insulated from it—is wound coil 2, consisting of a few turns of wire. If now a current is passed through coil 1, we know that a magnetic field will appear inside it. This magnetic field also passes through coil 2. As the current in coil 1 is varied, the magnetic flux will also vary, and there will be an induced emf in coil 2. We will now calculate this induced emf.

We have seen in Section 17-5 that the magnetic field inside a long solenoid is uniform and has the magnitude

$$B = \frac{1}{\epsilon_0 c^2} N_1 I_1, \quad (17.21)$$

where N_1 is the number of turns in coil 1, I_1 is the current through it, and c is its length. Let's say that the cross-sectional area of coil 1 is A_1 . Then the flux of B is its magnitude times A_1 . If coil 2 has N_2 turns, this flux links the coil N_2 times. Therefore the emf in coil 2 is given by

$$e_2 = -N_2 \frac{d\Phi}{dt}. \quad (17.22)$$

The only quantity in Eq. (17.22) which varies with time is I_1 . The emf is therefore given by

$$e_2 = -\frac{N_1 N_2 A_1}{\epsilon_0 c^2} \frac{dI_1}{dt}. \quad (17.23)$$

We see that the emf in coil 2 is proportional to the rate of change of the current in coil 1. The constant of proportionality, which is basically a measure factor of the two coils, is called the mutual inductance, and is usually designated M_{12} . Equation (17.23) is then written

$$e_2 = M_{12} \frac{dI_1}{dt}. \quad (17.24)$$

Suppose now that we were to pass a current through coil 2 and ask about the emf in coil 1. We would compute the magnetic field, which is everywhere

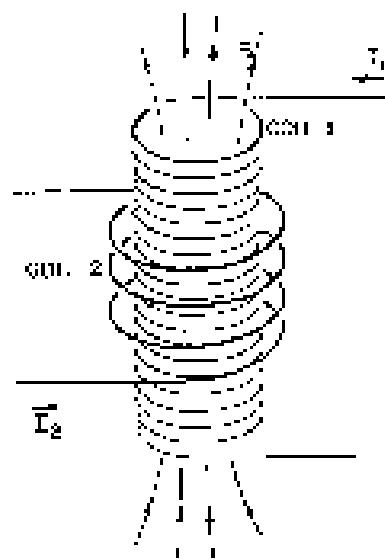

Fig. 17.8. A current in coil 1 produces a magnetic field through coil 2.

proportional to the current I_2 . The flux linkage through coil 1 would depend on the geometry, but would be proportional to the current I_2 . The emf in coil 1 would, therefore, again be proportional to all I_2 's! We can write

$$\mathcal{E}_1 = M_{12} \frac{dI_2}{dt}. \quad (17.27)$$

The computation of M_{12} would be more difficult than the computation we have just done for M_{21} , but we can do it through their computation now, because we will show later in this chapter that M_{12} is necessarily equal to M_{21} .

Since for any coil its field is proportional to its current, the same kind of result would be obtained for any two coils of wire. The equations (17.26) and (17.27) would have the same form; only the constants M_{21} and M_{12} would be different. Their values would depend on the shapes of the coils and their relative positions.

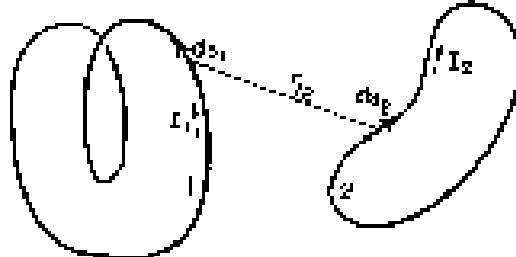

Fig. 17-9. Any two coils have a mutual inductance M_{12} proportional to the integral of $d\phi_1/ds_2 ds_2/ds_1$.

Suppose that we wish to find the mutual inductance between any two arbitrary coils—for example, those shown in Fig. 17-9. We know that the general expression for the emf in coil 1 can be written as

$$\mathcal{E}_1 = - \frac{d}{dt} \int_{C_1} \mathbf{B} \cdot d\mathbf{s}_1,$$

where \mathbf{B} is the magnetic field and the integral is to be taken over a surface bounded by circuit 1. We have seen in Section 14-3 that such a surface integral of \mathbf{B} can be related to a line integral of the vector potential. In particular,

$$\int_{C_1} \mathbf{B} \cdot d\mathbf{s}_1 = \oint_{C_1} \mathbf{A} \cdot d\mathbf{s}_1,$$

where \mathbf{A} represents the vector potential and ds_1 is an element of circuit 1. The last integral is to be taken around closed circuit 1. The emf in coil 1 can therefore be written as

$$\mathcal{E}_1 = - \frac{d}{dt} \oint_{C_1} \mathbf{A} \cdot d\mathbf{s}_1. \quad (17.28)$$

Now let's assume that the vector potential \mathbf{A} of coil 1 comes from currents in circuit 2. Then it can be written as a line integral around circuit 2:

$$\mathbf{A} = \frac{1}{4\pi\mu_0 c^2} \oint_{C_2} \frac{I_2 ds_2}{r_{21}}, \quad (17.29)$$

where I_2 is the current in circuit 2, and r_{21} is the distance from the element of the circuit ds_2 to the point 1 on circuit 1, at which we are evaluating the vector potential. (See Fig. 17-9.) Considering Eqs. (17.28) and (17.29), we can express the emf in circuit 1 as a double line integral:

$$\mathcal{E}_1 = - \frac{1}{4\pi\mu_0 c^2} \frac{d}{dt} \oint_{C_1} \oint_{C_2} \frac{I_2 ds_2}{r_{21}} \frac{\partial \mathbf{A}_2}{\partial s_1} \cdot d\mathbf{s}_1.$$

In this equation the integrals are all taken with respect to stationary circuits. The only variable quantity is the current I_2 , which does not depend on the variables of 17-10.

integration. We may therefore take it out of the integral. The emf can then be written as

$$\mathcal{E}_1 = M_{12} \frac{dI_2}{dt},$$

where the coefficient M_{12} is

$$M_{12} = -\frac{1}{4\pi\epsilon r^2} \oint_{C_1} \oint_{C_2} d\sigma_1 d\sigma_2, \quad (17.30)$$

We see from this integral that M_{12} depends only on the circuit geometry. It depends on a kind of average separation of the two circuits, with the average weighted over parallel segments of the two coils. Our equation can be used for calculating the mutual inductance of any two circuits of arbitrary shape. Also, it shows that the integral for M_{12} is identical to the integral for M_{21} . We have therefore shown that the two coefficients are identical. For a system with only two coils, the coefficients M_{12} and M_{21} are often represented by the symbol M without subscripts, called simply the *mutual inductance*:

$$\mathcal{E}_{12} = \mathcal{E}_{21} = M.$$

17-7 Self-inductance

In discussing the induced electromotive forces in the two coils of figs. 17-8 or 17-9, we have considered only the case in which there was a current in one coil or the other. If there are currents in the two coils simultaneously, the magnetomotive force in either coil will be the sum of the contributions which would exist separately because the law of superposition applies for magnetic fields. The total current in coil 1 will therefore be proportional not only to the change of the current in the other coil, but also to the change in the current of the coil itself. Thus the total emf in coil 2 should be written*

$$\mathcal{E}_2 = M_{22} \frac{df}{dt} + M_{12} \frac{dI_1}{dt}. \quad (17.31)$$

Similarly, the emf in coil 1 will depend not only on the changing current in coil 2, but also on the changing current in itself:

$$\mathcal{E}_1 = M_{12} \frac{dI_2}{dt} + M_{21} \frac{dI_2}{dt}. \quad (17.32)$$

The coefficients M_{22} and M_{11} are always negative numbers. It is usual to write

$$M_{11} = -S_1, \quad M_{22} = -S_2, \quad (17.33)$$

where S_1 and S_2 are called the *self-inductances* of the two coils.

The self-induced emf will, of course, exist even if we have only one coil. Any coil by itself will have a self-inductance S . The emf will be proportional to the rate of change of the current in it. For a single coil, it is usual to adopt the convention that the emf and the current are considered positive if they are in the same direction. With this convention, we may write for the emf of a single coil

$$\mathcal{E} = -S \frac{di}{dt}. \quad (17.34)$$

The negative sign indicates that the emf opposes the change in current. It is often called a "back emf".

Since any coil has a self-inductance which opposes the change in current, the emf in the coil has a kind of inertia. In fact, if we wish to change the current in

* The signs of " M_{11} " and " M_{22} " in Eqs. (17.31) and (17.32) depends on the arbitrary choices for the sense of a positive current in the two coils.

in coil we must overcome the inertia of connecting the coil to some external voltage source such as a battery or a generator, as shown in the schematic diagram of Fig. 17-10(a). In such a circuit, the current I depends on the voltage V according to the relation

$$V = L \frac{dI}{dt}. \quad (17.18)$$

This equation has the same form as Newton's law of motion for a particle in one dimension. We can therefore study it by the principle that "the same quantities have the same solutions." Thus, if we make the externally applied voltage V correspond to an externally applied force F , and the current I to a coil current i , to the velocity v of a particle, the inductance L of the coil corresponds to the mass m of the particle.* See Fig. 17-10(b). We can make the following table of corresponding quantities.

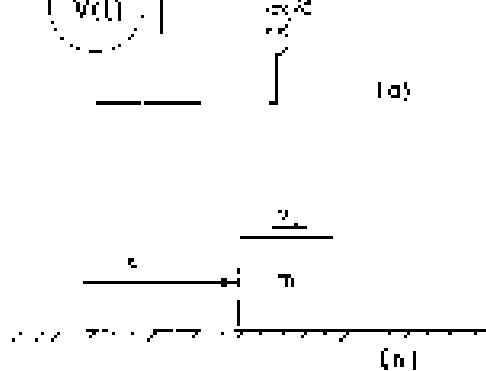

Fig. 17-10 (a) A circuit with a voltage source and an inductance. (b) An analogous mechanical system.

Particle	Coin
A (Force)	Gravitational potential energy
v (velocity)	Kinetic energy
x (displacement)	Work
$F = m \frac{dv}{dt}$	$\dot{x} = \frac{dx}{dt}$
net (kinetic energy)	$\frac{1}{2}m$
$\frac{1}{2}mv^2$ (kinetic energy)	$\frac{1}{2}x\dot{x}$ (magnetic energy)

17-8 Inductance and magnetic energy

Continuing with the analogy of the preceding section, we would expect that corresponding to the mechanical momentum $p = mv$, whose rate of change is the applied force, there would be an analogous quantity equal to Li , whose rate of change is V . We have no right, otherwise, to say that Li is the total momentum of the circuit, if i , in fact, is right. The whole circuit may be standing still and have no momentum. It is only that Li corresponds to the momentum in the sense of satisfying the corresponding equations. In the same way, to the kinetic energy mv^2 , there corresponds an analogous quantity Li^2 . But there will be a surprise. This Li^2 is really the energy in the circuit; however, this is because the rate of doing work in the inductance is Li , and in the mechanical system it is F , the expression of the quantity. Therefore, in the case of the energy, the quantity is not only correspondingly mathematically, but also has the same physical meaning as well.

We may see this in more terms as follows. As we found in Eq. (17.16), the rate of electrical work by an applied force is the product of the electromotive force and the current:

$$\frac{dW}{dt} = VI$$

Replacing E by its expression in terms of the current (from Eq. (17.14)), we have

$$\frac{dW}{dt} = -LI \frac{dI}{dt} \quad (17.19)$$

Integrating this equation, we find that the energy required from an external source to overcome the end in the self-inductance while building up the current (which must equal the energy stored, U) is

$$-W = U = \frac{1}{2}LI^2 \quad (17.20)$$

Therefore the energy stored in an inductor is $\frac{1}{2}LI^2$.

* This is, incidentally, not the only way a correspondence can be set up between mechanics and electromagnetism.

† We are neglecting any energy loss to heat from the current in the resistance of the coil. Such losses require additional energy from the source that is not changing the energy which goes into the inductor.

Applying the same arguments to a pair of coils such as those in Figs. 17-8 or 17-5, we can show that the total electrical energy of the system is given by

$$U = \frac{1}{2} L_1 I_1^2 + \frac{1}{2} L_2 I_2^2 + M I_1 I_2. \quad (17.38)$$

For, starting with $I = 0$ on both coils, we could increase the current I_1 in coil 1, with $I_2 = 0$. The work done is just $\frac{1}{2} L_1 I_1^2$. But now, on turning up I_2 , we not only do the work $\frac{1}{2} L_2 I_2^2$ against the field in circuit 2, but also an additional contribution $M I_2$, which is the integral $[M dI_2/dt]$ in circuit 1 times the new dI_2/dt due to I_1 in circuit 1.

Suppose we now wish to find the force between any two coils carrying the currents I_1 and I_2 . We might at first expect that we could use the principle of virtual work, by taking the derivative in the energy of Eq. (17.38). We must remember, of course, that as we change the relative position of the coils, the only quantity which varies is the ratio L_1/L_2 , whence M . We might then write the expression of virtual work as

$$\cdot F \Delta x = \Delta U = I_1 I_2 \Delta \theta \text{ (wrong).}$$

But this equation is wrong, because, as we have seen earlier, it reflects only the change in the energy of the two coils and not the change in the energy of the sources which are maintaining the currents I_1 and I_2 at their constant values. We can now understand that these sources must supply energy against the induced currents in the coils as they are moved. If we wish to apply the principle of virtual work correctly, we must also include these energies. As we have seen, however, we may take a short cut and use the principle of virtual work by remembering that the total energy is the negative of what we have called U , or the "natural energy". We can therefore write by the force

$$F \Delta x = -\Delta U_{\text{natural}} = -\Delta U. \quad (17.39)$$

The force between two coils is also given by

$$F \Delta x = I_1 I_2 \Delta \theta.$$

Equation (17.38) for the energy of a system of two coils can be used to show that an interesting inequality exists between mutual inductance M and the self-inductances L_1 and L_2 of the two coils. It is clear that the energy of two coils must be positive. If we begin with zero currents in the coils and increase these currents to static values, we have been adding energy to the system. If not, the currents would spontaneously increase with release of energy to the rest of the world—an unlikely thing, so happen! Now our energy equation, Eq. (17.38), can equally well be written in the following form:

$$U = \frac{1}{2} L_1 \left(I_1 - \frac{M}{L_2} I_2 \right)^2 + \frac{1}{2} \left(L_2 - \frac{M^2}{L_1} \right) I_2^2. \quad (17.40)$$

This is just an algebraic form of the first. This quantity must always be positive for any values of I_1 and I_2 . In particular, it must be positive if I_2 should happen to have the special value

$$I_2 = -\frac{L_1}{M} I_1. \quad (17.41)$$

But with this current for I_2 , the first term in Eq. (17.40) is zero. If the energy is to be positive, the last term in (17.40) must be greater than zero. We know the requirement that

$$L_2 > M^2/L_1.$$

We have thus proved the general result that the magnitude of the mutual inductance of any two coils is necessarily less than or equal to the geometric mean of the two L inductances. (This M may be positive or negative, depending on the sign

conventions for the currents i_1 and i_2)

$$V_{AB} = \sqrt{L_1 L_2} \quad (17.43)$$

The relationship between V_{AB} and the self-inductances is usually written as

$$V_{AB}^2 = L_1 L_2. \quad (17.44)$$

The constant C is called the coefficient of coupling. If most of the flux from one coil links the other coil, the coefficient of coupling is near one; we say the coils are "highly coupled." If the coils are far apart or otherwise arranged so that there is very little mutual flux linkage, the coefficient of coupling is near zero and the mutual inductance is very small.

For calculating the mutual inductance of two coils, we take profit in Eq. (17.40) a formula which is a double line integral around the two circuits. We might think that the same formula could be used to get the self-inductance of a single coil by carrying out both line integrals around the same coil. This, however, will not work, because in integrating around the two coils, the denominator r_{12} of the integrand will go to zero when the two line elements are at the same point. The self-inductance obtained from this formula is infinite. The reason is that this formula is an approximation that is valid only when the cross sections of the wires of the two circuits are small compared with the distance from one circuit to the other. Clearly, this approximation does not hold for a single coil. It is, in fact, true that the inductance of a single coil tends logarithmically to infinity as the diameter of its wire is made smaller and smaller.

We must, then, look for a different way of calculating the self-inductance of a single coil. It is necessary to take into account the distribution of the currents within the wires because the area of the wire is an important parameter. We should therefore ask not what is the inductance of a "circuit," but what is the inductance of a distribution of conductors. Perhaps the easiest way to find this inductance is to make use of the magnetic energy. We found earlier, in Section 15-5, an expression for the magnetic energy of a distribution of stationary currents:

$$U = \frac{1}{2} \int j \cdot A dV. \quad (17.45)$$

If we know the distribution of current density j , we can compute the vector potential A and then evaluate the integral of Eq. (17.45) to get the energy. This energy is equal to the inductive energy of the self-inductance, $\frac{1}{2}L^2$. Equating the two gives us a formula for the inductance:

$$L = \frac{1}{j^2} \int j \cdot A dV. \quad (17.46)$$

We expect, of course, that the inductance is a number depending only on the geometry of the circuit and not on the current I in the circuit. The formula of Eq. (17.46) will indeed give such a result, because the integral in this equation is proportional to the square of the current—the current appears once through j and again through the vector potential A . The integral divided by I^2 will depend on the geometry of the circuit, but not on the current I .

Equation (17.46) for the energy of a current distribution can be put in a quite different form which is sometimes more convenient for calculation. Also, as we will see later, it's a form that is important because it is more generally valid. In the energy equation, Eq. (17.45), both j and A can be related to B , so we can hope to express the energy in terms of the magnetic field. Just as we were able to relate the electromagnetic energy to the electric field, we begin by replacing j by $i_B r^2 \nabla \times B$. We cannot replace A so easily, since $B = -\nabla \times A$ cannot be inverted to give A in terms of B . Anyway, we can write

$$U = \frac{1}{2} \int (\nabla \times B) \cdot r^2 B dV. \quad (17.47)$$

The interesting thing is that, with some restrictions, this integral can be written as

$$U = \frac{c\epsilon_0^2}{2} \int \mathbf{B} \cdot (\nabla \times \mathbf{A}) dV. \quad (17.47)$$

To see this, we write out in detail a typical term. Suppose that we take the term $(\nabla \times \mathbf{B})_{\phi}$, which occurs in the integral of Eq. (17.46). Writing out the components, we get

$$\int \left(\frac{\partial B_x}{\partial x} - \frac{\partial B_z}{\partial y} \right) A_\phi dx dy dz.$$

(There are, of course, two more integrals of the same kind.) We now integrate the first term with respect to x , integrating by parts. That is, we can say

$$\int \frac{\partial B_x}{\partial x} A_\phi dx = B_x A_\phi - \int B_x \frac{\partial A_\phi}{\partial x} dx.$$

Now suppose that our system—measuring the sources and fields—is finite, so that as we go to large distances all fields go to zero. Then if the integrals are carried out over all space, evaluating the term $B_x A_\phi$ at the limits will give zero. We have left only the term with $B_x \partial A_\phi / \partial x$, which is evidently one part of $\mathbf{B}_x (\nabla \times \mathbf{A})_x$, and, therefore, of $\mathbf{B} \cdot (\nabla \times \mathbf{A})$. If you work out the other five terms, you will see that Eq. (17.47) is indeed equivalent to Eq. (17.46).

That shows we can replace $(\nabla \times \mathbf{A})$ by \mathbf{B} , to get

$$U = \frac{c\epsilon_0^2}{2} \int \mathbf{B} \cdot \mathbf{B} dV. \quad (17.48)$$

We have expressed the energy of a magnetostatic situation in terms of the magnetic field only. The expression corresponds directly to the formula we found for the electrostatic energy:

$$U = \frac{c\epsilon_0}{2} \int \mathbf{E} \cdot \mathbf{E} dV. \quad (17.49)$$

One reason for emphasizing these two energy formulas is that sometimes they are more convenient to use. More important, it turns out that for dynamic fields (when E and B are changing with time) the two expressions (17.48) and (17.49) remain true, whereas the other formulas we have given for electric or magnetic energies are no longer correct—they hold only for static fields.

If we know the magnetic field \mathbf{B} of a single coil, we can find the self-inductance by equating the energy expression (17.48) to $\frac{1}{2} L I^2$. Let's see how this works by finding the self-inductance of a long solenoid. We have seen earlier that the magnetic field inside a solenoid is uniform and B outside is zero. The magnitude of the field inside is $B = \mu_0 n I^2$, where n is the number of turns per cm. length in the winding and I is the current. If the radius of the coil is r and its length is L (we take L very long, so that we can neglect end effects, i.e., $L \gg r$), the volume inside is $\pi r^2 L$. The magnetic energy is therefore

$$U = \frac{c\epsilon_0^2}{2} B^2 \cdot (\nabla dV) = \frac{n^2 I^2}{2 \mu_0 c^2} \pi r^2 L,$$

which is equal to $\frac{1}{2} L I^2$. Or,

$$L = \frac{\pi r^2 n^2}{c \epsilon_0} L. \quad (17.50)$$

The Maxwell Equations

18-1 Maxwell's equations

In this chapter we come back to the complete set of the four Maxwell equations that we took as our starting point in Chapter 1. Until now, we have been studying Maxwell's equations in bits and pieces; it is time to add one final piece, and to put them all together. We will then have the complete and correct story for electro-magnetic fields that may be changing with time in any way. Anything said in this chapter that contradicts something said earlier is true and what was said earlier is false—because what was said earlier applied to such special situations as, for instance, steady currents or static charges. Although we have been very careful to point out the restrictions whenever we write an equation, it is easy to forget all of the qualifications and to learn lots well the wrong equations. Now we are ready to give the whole truth, with no qualifications (or almost none).

The complete Maxwell equations are written in Table 18-1, in words as well as in mathematical symbols. The fact that the words are equivalent to the equations should by this time be familiar—you should be able to translate back and forth from one form to the other.

The first equation—that the divergence of E is the charge density over ϵ_0 —is true in general. In dynamic as well as in static fields, Gauss' law is always valid. The flux of B through any closed surface is proportional to the charge inside. The third equation is the corresponding general law for magnetic fields. Since there are no magnetic charges, the flux of B through any closed surface is always zero. The second equation, that the curl of E is $-\partial B/\partial t$, is Faraday's law and was discussed in the last two chapters. It also is generally true. The last equation is something new. We have seen before only the part of it which holds for steady currents. In that case we said that the curl of B is $J/e\epsilon_0^2$, but the current general equation has a new part that was discovered by Maxwell.

Until Maxwell's work, the known laws of electricity and magnetism were those we have studied in Chapters 3 through 17. In particular, the equation for the magnetic field of steady currents was known only as

$$\nabla \times B = \frac{\rho}{\epsilon_0 c^2}. \quad (18.1)$$

Maxwell began by combining these known laws and expressing them as differential equations, as we have done here. (Although the ∇ notation was not yet invented, it is mainly due to Maxwell that the importance of the combinations of derivatives, which we today call the curl and the divergence, first became apparent.) He then noticed that there was something strange about Eq. (18.1). If one takes the divergence of this equation, the left-hand side will be zero, because the divergence of a curl is always zero. So this equation requires that the divergence of J also be zero. But if the divergence of J is zero, then the total flux of current out of any closed surface is also zero.

The flux of current through a closed surface is the decrease of the charge inside the surface. This quantity cannot in general be zero because we know that the charges can be moved from one place to another. The equation

$$\nabla \cdot j = -\frac{\delta \rho}{\delta t} \quad (18.2)$$

has, in fact, been almost our definition of j . This equation expresses the very funda-

Maxwell's equations

$$\text{I. } \nabla \cdot \mathbf{E} = \frac{\rho}{\epsilon_0} \quad (\text{Flux of } \mathbf{E} \text{ through a closed surface}) = (\text{Charge inside})/\epsilon_0$$

$$\text{II. } \nabla \times \mathbf{B} = -\frac{\partial \mathbf{E}}{\partial t} \quad (\text{Line integral of } \mathbf{B} \text{ around a loop}) = -\frac{d}{dt} (\text{Flux of } \mathbf{B} \text{ through the loop})$$

$$\text{III. } \nabla \cdot \mathbf{B} = 0 \quad (\text{Flux of } \mathbf{B} \text{ through a closed surface}) = 0$$

$$\text{IV. } \epsilon^2 \nabla \times \mathbf{B} = \frac{j}{\epsilon_0} + \frac{\partial \mathbf{E}}{\partial t} \quad \epsilon^2 (\text{Integral of } \mathbf{B} \text{ around a loop}) = (\text{Current through the loop})/\epsilon_0 \\ + \frac{1}{\epsilon_0} (\text{Flux of } \mathbf{E} \text{ through the loop})$$

Conservation of charge

$$\nabla \cdot \mathbf{j} = -\frac{\partial \rho}{\partial t} \quad (\text{Flux of current through a closed surface}) = -\frac{d}{dt} (\text{Charge inside})$$

Force law

$$\mathbf{F} = q(\mathbf{E} + \mathbf{v} \times \mathbf{B})$$

Law of motion

$$\frac{d}{dt}(\mathbf{p}) = \mathbf{F}, \quad \text{where} \quad \mathbf{p} = \frac{mv}{\sqrt{1 - v^2/c^2}} \quad (\text{Newton's law, with Einstein's modification})$$

Gravitation

$$\mathbf{F} = -G \frac{m_1 m_2}{r^2} \mathbf{e}_r$$

initial law that electric charge is conserved—any law of charge must come from some supply. Maxwell appreciated this difficulty and proposed that it could be avoided by adding the term $\partial \mathbf{E}/\partial t$ to the right-hand side of Eq. (18.1); he then got the fourth equation in Table 18-1:

$$\text{IV. } \epsilon^2 \nabla \times \mathbf{B} = \frac{j}{\epsilon_0} + \frac{\partial \mathbf{E}}{\partial t}$$

It was far yet customary in Maxwell's time to think in terms of abstract fields. Maxwell discussed his ideas in terms of a model in which the vacuum was like an elastic medium. He also tried to explain the meaning of his new equations in terms of the mechanical model. There was much reluctance to accept his theory, first because of the model, and second because there was at first no experimental justification. Today, we understand better that what survives the equations themselves, and not the model used to get them. We may only question whether the equations are true or false. This is answered by doing experiments, and until numbers of experiments have confirmed Maxwell's equations, if we take away the scaffolding he used to build it, we find that Maxwell's beautiful edifice stands on its own. He brought together all of the laws of electricity and magnetism and made one complete and beautiful theory.

Let us show that the extra term is just what is necessary to strengthen our law differently Maxwell discovered. Taking the divergence of his equation (IV in Table 18-1), we must have that the divergence of the right-hand side is zero:

$$\nabla \cdot \frac{j}{\epsilon_0} + \nabla \cdot \frac{\partial \mathbf{E}}{\partial t} = 0. \quad (18.3)$$

In the second term, the order of the derivatives with respect to coordinates and time can be reversed, so the equation can be rewritten as

$$\nabla \cdot j - \epsilon_0 \frac{\partial}{\partial t} (\nabla \cdot E) = 0. \quad (18.4)$$

But the first of Maxwell's equations says that the divergence of E is ρ/ϵ_0 . Inserting this equality in Eq. (18.4), we get back Eq. (18.2), which we know is true. Conversely, if we accept Maxwell's equations—and we do because no one has ever found an experiment that disagrees with them—we must conclude that charge is always conserved.

The laws of physics have no answer to the question: "What happens if a charge is suddenly created at this point—what electromagnetic effects are produced?" No answer can be given because our equations say it doesn't happen. If it were to happen, we would need new laws, but we cannot say what they would be. We have not had the chance to observe how a world without charge conservation behaves. According to our equations, if you suddenly place a charge at some point, you had to carry it there from somewhere else. In that case, we can say what would happen.

When we added a new term to the equation for the curl of E , we found that a whole new class of phenomena was described. We shall see that Maxwell's little addition to the equation for $\nabla \times B$ also has far-reaching consequences. We can touch on only a few of them in this chapter.

18-2 How the new term works

As our first example we consider what happens with a spherically symmetric radial distribution of current j . Suppose we imagine a little sphere with radioactive material in it. This radioactive material is ejecting out some charged particles. (Or we could imagine a large block of jello with a small hole in the center into which some charge had been injected with a hypodermic needle and from which the charge is slowly leaking out.) In either case we would have a current that is everywhere radially outward. We will assume that it has the same magnitude in all directions.

Let the total charge inside any radius r be $Q(r)$. If the radial current density at the same radius is $j(r)$, then Eq. (18.2) requires that Q decreases at the rate

$$\frac{dQ(r)}{dr} = -4\pi r^2 j(r). \quad (18.5)$$

We now ask about the magnetic field produced by the currents in this situation. Suppose we draw some loop C on a sphere of radius r , as shown in Fig. 18-1. There is some current through this loop, so we might expect to find a magnetic field circulating in the direction shown.

But we are already in difficulty. How can the B have any particular direction on the sphere? A different choice of C would allow us to conclude that its direction is exactly opposite to that shown. So how can there be any circulation of B around the currents?

We are saved by Maxwell's equation. The circulation of B depends not only on the total current through C but also on the rate of change with time of the magnetic flux through it. It must be that these two parts just cancel. Let's see if that works out.

The electric field at the radius r must be $Q(r)/4\pi\epsilon_0 r^2$ —so long as the charge is spherically distributed, as we assume. It is radial, and its rate of change is taken

$$\frac{\partial E}{\partial r} = \frac{1}{4\pi\epsilon_0 r^2} \frac{dQ}{dt}. \quad (18.6)$$

Comparing this with Eq. (18.5), we see that at any radius

$$\frac{\partial E}{\partial r} = -\frac{j}{\epsilon_0}. \quad (18.7)$$

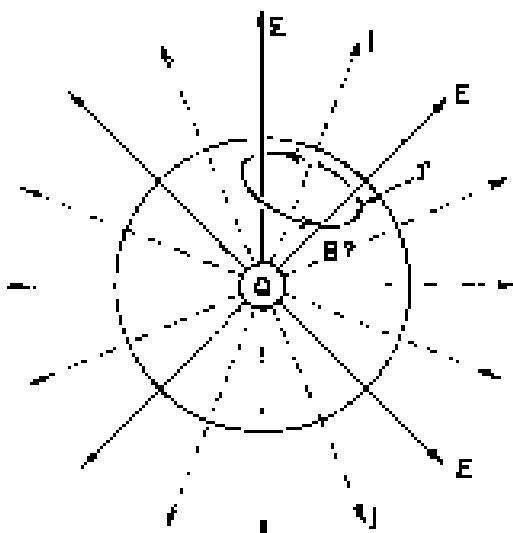

Fig. 18-1. What is the magnetic field of a spherically symmetric current?

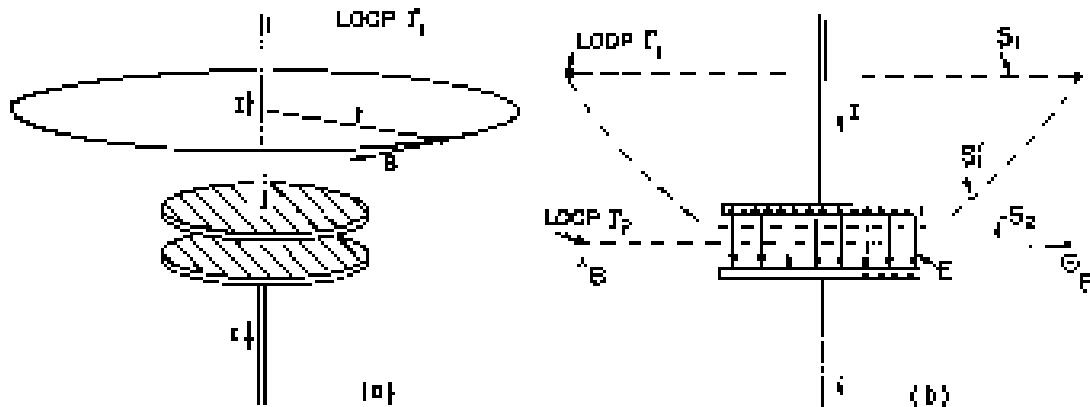

Fig. 18-2. The magnetic field near a charging capacitor.

In Eq. 14 the two source terms cancel and the end of \mathbf{B} is always zero. There is no magnetic field in our example.

As our second example, we consider the magnetic field of a wire used to charge a parallel-plate condenser (see Fig. 18-2). If the charge Q on the plates is changing with time (but not too fast), the current in the wires is equal to dQ/dt . We would expect that this current will produce a magnetic field that encircles the wire. Surely, the current close to the wire must produce the normal magnetic field—it cannot depend on where the current is going.

Suppose we take a loop Γ_1 , which is a circle with radius r , as shown in part (a) of the figure. The line integral of the magnetic field should be equal to the current I divided by $c_0 r^2$. We have

$$\oint_{\Gamma_1} \mathbf{B} \cdot d\mathbf{l} = \frac{I}{c_0 r^2}. \quad (18.8)$$

This is what we would get for a steady current, but it is also correct with Maxwell's addition, because if we consider the plane surface S_1 inside the circle, there are no electric fields on it (assuming the wire to be a very good conductor). The surface integral of $\mathbf{E} \cdot d\mathbf{l}_S$ is zero.

Suppose, however, that we now slowly move the curve Γ downward. We get always the same result until we draw even with the plates of the condenser. Then the current I goes to zero. Does the magnetic field disappear? That would be quite strange. Let's see what Maxwell's equation says for the curve Γ_2 , which is a circle of radius r whose plane passes between the condenser plates [Fig. 18-2(b)]. The line integral of \mathbf{B} around Γ_2 is $2\pi r B$. This must equal the time derivative of the flux of \mathbf{E} through the plane circular surface S_2 . This flux of \mathbf{E} , we know from Gauss' law, must be equal to $1/c_0$ times the charge Q on one of the condenser plates. We have

$$r^2 2\pi r B = \frac{d}{dt} \left(\frac{Q}{c_0} \right). \quad (18.9)$$

That is very convenient. It is the same result we found in Eq. (18.6). Integrating over the changing electric field gives the same magnetic field as does integrating over the current in the wire. Of course, that is just what Maxwell's equation says. It is easy to see that this must always be so by applying our same arguments to the two surfaces S_1 and S_2 that are bounded by the same circle Γ_1 in Fig. 18-2(b). Through S_1 there is the current I , but no electric flux. Through S_2 there is no current, but an electric flux changing at the rate I/c_0 . The same B is obtained if we use Eq. 14 with either surface.

From our discussion so far of Maxwell's new term, you may have the impression that it doesn't add much—that it just fixes up the equations to agree with what we already expect. It is true that if we just consider Eq. 14 by itself, nothing particularly new comes out. The words "by itself" are, however, all-important. Maxwell's small change in Eq. 14, when combined with the other equations, does indeed produce much that is new and important. Before we take up these matters, however, we want to speak more about Table 18-1.

18-3 All of classical physics

In Table 18-1 we have all that was known of fundamental classical physics, that is, the physics that was known by 1905. Here it all is, in one table. With these equations we can understand the complete realm of classical physics.

First we have the Maxwell equations—written in both the expanded form and the short mathematical form. Then there is the conservation of charge, which is even written in parentheses, because the moment we have the complete Maxwell equations, we can deduce from them the conservation of charge. So the table is even a little redundant. Next, we have written the force law, because having all the electric and magnetic fields doesn't tell us anything until we know where they do to charges. Knowing E and B , however, we can find the force on an object with the charge q moving with velocity v . Finally, having the force doesn't tell us anything until we know what happens when a force pushes on something; we need the law of motion, which is that the force is equal to the rate of change of the momentum. (Remember? We had that in Volume I.) We even include relativity effects by writing the momentum as $p = m_0 v / \sqrt{1 - v^2/c^2}$.

If we really want to be complete, we should add one more law—Newton's law of gravitation—but we put that at the end.

Therefore in one small table we have all the fundamental laws of classical physics—even with room to write them out in words and with some redundancy. This is a great moment. We have climbed a great peak. We are on the top of K-2—we are nearly ready for Mount Everest, which is quantum mechanics. We have climbed the peak of a "Great Divide," and now we can go down the other side.

We have mainly been trying to learn how to understand the equations. Now that we have the whole thing put together, we are going to study what the equations mean—what new things they say that we haven't already seen. We've been working hard to get up to this point. It has been a great effort, but now we are going to have nice coasting downhill as we see all the consequences of our accomplishment.

18-4 A travelling field

Now for the new consequences. They come from putting together all of Maxwell's equations. First, let's see what would happen in a circumstance which we pick to be particularly simple. By assuming that all the quantities vary only in one coordinate, we will have a one-dimensional problem. The situation is shown in Fig. 18-1. We have a sheet of charge located on the yz -plane. The sheet is first at rest. Then instantaneously given a velocity v in the x -direction, and kept moving with this constant velocity. You might worry about having such an "infinite" acceleration, but it doesn't really matter; just imagine that the velocity is brought to a very quickly. So we have suddenly a surface current J (J is the current per unit

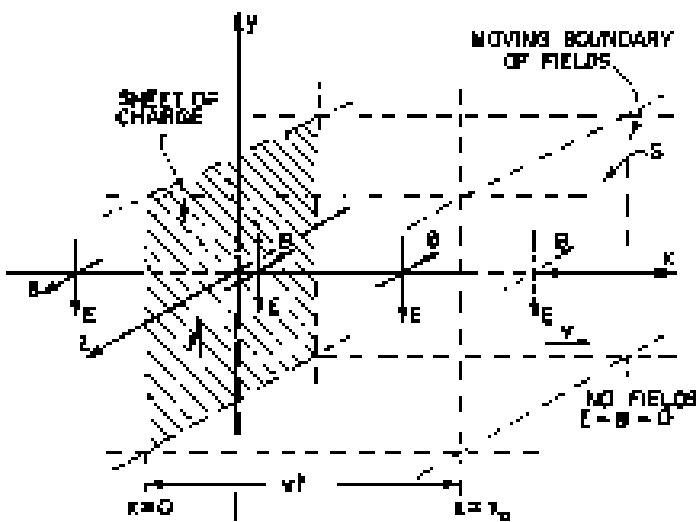

Fig. 18-3. An infinite sheet of charge is suddenly set into motion parallel to itself. There are magnetic and electric fields that propagate out from the sheet at a constant speed.

width in the z -direction). To keep the problem simple, we suppose that there is also a stationary sheet of charge of opposite sign superposed to the y -plane, so that there are no electrostatic effects. Also, although in the figure we show only what is happening in a finite region, we imagine that the sheet extends to infinity in $-y$ and $+z$. In other words, we have a situation where there is no current, and then suddenly there is a uniform sheet of current. What will happen?

Well, when there is a sheet of current in the plus y -direction, there is, as we know, a magnetic field generated which will be in the minus z -direction for $x > 0$ and in the opposite direction for $x < 0$. We could find the magnitude of B by using the fact that the line integral of the magnetic field will be equal to the current over πw^2 . We would get that $B = J/2\pi w^2$ (since the current J in a strip of width w is Jw and the line integral of B is $2B\pi$).

This gives us the field next to the sheet—for small x —but since we are imagining an infinite sheet, we would expect the same argument to give the magnetic field further out for larger values of x . However, that would mean that the moment we turn on the current, the magnetic field is suddenly changed from zero to a finite value everywhere. But wait! If the magnetic field is suddenly changed, it will produce tremendous electrical effects. (If it changes in any way, there are electrical effects.) So because we turned the sheet of charge, we make a changing magnetic field, and therefore electric fields must be generated. If there are electric fields generated, they had to start from zero and change to something else. There will be some dE/dt that will make a contribution, together with the current J , to the production of the magnetic field. So through the various equations there is a big interaction, and we have to try to solve for all the fields at once.

By looking at the Maxwell equations alone, it is not easy to see directly how to get the solution. So we will first show you what the answer is and then verify that it does indeed satisfy the equations. The answer is the following: The field B that we computed is, in fact, generated right next to the current sheet (for small x) It must be so, because if we make a tiny loop around the sheet, there is no result for any electric flux to go through it. But the field B out farther—for large x —is, at first, zero. It stays zero for awhile, and then suddenly turns on. In short, we turn on the current and the magnetic field immediately next to it turns on to a constant value B ; then the turning on of B spreads out from the source region. After a certain time, there is a uniform magnetic field everywhere out to some value x , and then zero beyond. Because of the symmetry, it spreads in both the y and z directions.

The E -field does the same thing. Before $t = 0$ (when we turn on the current), the field is zero everywhere. Then after the time t , both E and B are uniform out to the distance $x \approx w$, and zero beyond. The fields make their way forward like a tidal wave, with a front moving at a uniform velocity which turns out to be c , but for a while we will just call it v . A graph of the magnitude of E or B versus x , as they appear at the time t , is shown in Fig. 18-4(a). Looking again at Fig. 18-3, at the time t , the region between $x = -w$ is “filled” with the fields, but they have not yet reached beyond. We emphasize again that we are assuming that the current sheet and, therefore, the fields E and B , extend infinitely far in both the y - and z -directions. (We cannot draw an infinite sheet, so we have shown only what happens in a finite area.)

We want now to analyze qualitatively what is happening. To do that, we want to look at two cross-sectional views, a top view looking down along the y -axis, as shown in Fig. 18-5, and a side view looking back along the x -axis, as shown in Fig. 18-6. Suppose we start with the side view. We see the charged sheet moving up; the magnetic field points into the page for $+x$, and out of the page for $-x$, and the electric field is downward everywhere—out to $x = \pm w$.

Let's see if these fields are consistent with Maxwell's equations. Let's first draw one of those loops that we will be able to calculate a line integral, say the rectangle R shown in Fig. 18-6. You notice that one side of the rectangle is in the region where there are fields, but one side is in the region the fields have still not reached. There is some capacitive flux through this loop. If E is changing, there should be an emf around it. If the wavelength is w , we will have a changing magnetic

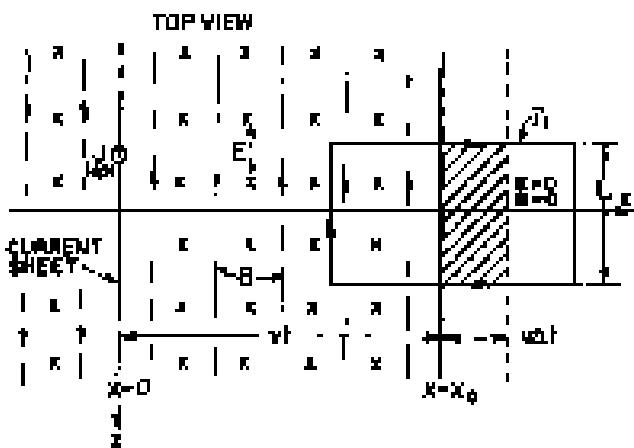

Fig. 18-5. Top view of Fig. 18-3.

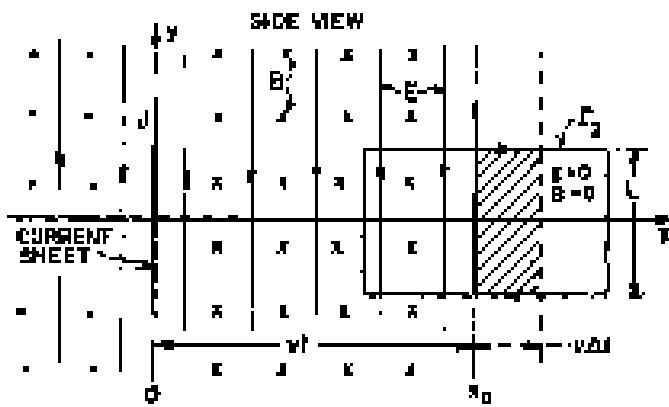

Fig. 18-6. Side view of Fig. 18-3.

flux, because the area in which B exists is progressively increasing at the velocity v . The flux inside I_2 is B times the part of the area inside I_2 which has a magnetic field. The rate of change of the flux, since the magnitude of B is constant, is the magnitude times the rate of change of the area. The rate of change of the area is easy. If the width of the rectangle I_2 is L , the area in which B exists changes by $L \cdot \Delta x$ in the time Δt . (See Fig. 18-6.) The rate of change of flux is then $B L v$. According to Faraday's law, this should equal the line integral of E around I_2 , which is just $E L$. We have the equation

$$E = vB. \quad (18.10)$$

So if the ratio of E to B is v , the fields we have assumed will satisfy Faraday's equation.

But that is not the only equation, we have the other equation relating E and B :

$$c^2 \nabla \times B = \frac{d}{dt} + \frac{\partial E}{\partial t}. \quad (18.11)$$

To apply this equation, we look at the top view in Fig. 18-5. We have seen that this equation will give us the value of B next to the current sheet. Also, for any loop drawn outside the sheet but behind the wavefront, there is no curl of B nor any j or changing E , so the equation is correct there. Now let's look at what happens for the curve I_1 that intersects the wavefront, as shown in Fig. 18-5. There there are no currents, so Eq. (18.11) can be written—in integral form—as

$$c^2 \oint_{I_1} B \cdot d\mathbf{s} = \frac{d}{dt} \int_{\text{inside } I_1} \mathbf{E} \cdot d\mathbf{s}. \quad (18.12)$$

The line integral of B is just B times L . The rate of change of the flux of E is due only to the advancing wavefront. The area inside I_1 , where E is not zero, is increasing at the rate vL . The right-hand side of Eq. (18.12) is then vLE . That equation becomes

$$c^2 B = Lv. \quad (18.13)$$

We have a solution in which we have a constant B and a constant E behind the front, both at right angles to the direction in which the front is moving and at right angles to each other. Maxwell's equations specify the ratio of E to B . From Eqs. (18.10) and (18.13),

$$E = vB, \quad \text{and} \quad E = \frac{c^2}{v} B.$$

But one moment! We have found two different conditions on the ratio E/B . Can such a field as we describe really exist? There is, of course, only one velocity v for which both of these equations can hold, namely $v = c$. The wavefront must travel with the velocity c . We have no example in which the electrical influence from a current propagates at a certain finite velocity v .

Now let's ask what happens if we suddenly stop the motion of the charged sheet after it has been on for a short time T . We can see what will happen by the principle of superposition. We had a current that was zero and then was suddenly turned on. We knew the solution for that case. Now we are going to add another set of fields. We take another charged sheet and suddenly start it moving, in the opposite direction with the same speed, only at the time T after we started the first current. The total current of the two added together is first zero, then on for a time T , then off again—because the two currents cancel. We have a square "pulse" of current.

The new negative current produces the same fields as the positive one, only with all the signs reversed and, of course, delayed in time by T . A wave front again travels out at the velocity c . At the time t it has reached the distance $x = c(t - T)$, as shown in Fig. 18-4(b). So we have two "blocks" of field traveling out at the speed c , as in parts (a) and (b) of Fig. 18-4. The combined fields are as shown in part (c) of the figure. The fields are zero for $x > ct$; they are constant (with the values we found above) between $x = ct - T$ and $x = ct$, and again zero for $x < c(t - T)$.

In short, we have a little piece of field—a block of thickness cT —which has left the current source and is travelling through space all by itself. The fields have "taken off"; they are propagating freely through space, no longer connected in any way with the source. The caterpillar has turned into a butterfly!

How can this bundle of electric and magnetic fields sustain itself? The answer is: by the combined effects of the Faraday law, $\nabla \times E = -\partial B/\partial t$, and the new term of Maxwell, $c^2 \nabla \times B = \partial E/\partial t$. They cannot help maintaining themselves. Suppose the magnetic field were to disappear. There would be a changing magnetic field which would produce an electric field. If this electric field tried to go away, the changing electric field would create a magnetic field back again. So by a perpetual interplay—by the switching back and forth from one field to the other—they must go on forever. It is impossible for them to disappear.* They sustain themselves in a kind of a dance—one making the other, the second making the first—propagating outward through space.

18-5 The speed of light

We have a wave which leaves the spherical source and goes outward at the velocity c , which is the speed of light. But let's go back a moment. From a historical point of view, it wasn't known that the coefficient c in Maxwell's equations was also the speed of light propagation. There was just a constant in the equations. We have called it c from the beginning, because we knew what it would turn out to be. We didn't think it would be sensible to make you learn the formulas with a different constant and then go back to substitute c wherever it belonged. From the point of view of electricity and magnetism, however, we just start out with two constants, ϵ_0 and c^2 , that appear in the equations of electrostatics and magnetostatics;

$$\nabla \cdot B = \frac{\rho}{\epsilon_0} \quad (18.14)$$

and

$$\nabla \times B = \frac{j}{\epsilon_0 c^2}. \quad (18.15)$$

If we take any arbitrary definition of a unit of charge, we can determine experimentally the constant ϵ_0 required in Eq. (18.14)—say by measuring the force between two unit charges at rest, using Coulomb's law. We must also determine experimentally the constant c, c^2 that appears in Eq. (18.15), which we can do, say, by measuring the force between two unit currents. (A unit current means one unit of charge per second.) The ratio of these two experimental constants is c^2 , just another "electromagnetic constant!"

* Well, not quite. They can be "absorbed" if they get to a region where there are charges. By which we mean that other fields can be produced somewhere which superpose on these fields and "cancel" them by destructive interference (see Chapter 21, Vol. I).

Notice now that this constant c^2 is the same no matter what we choose for our unit of charge. If we put twice as much "charge"—say twice as many proton charges—in our "unit" of charge, ϵ_0 would need to be one-fourth as large. When we pass two of these "unit" currents through two wires, there will be twice as much "charge" per second in each wire, so the force between two wires is four times larger. The constant $\epsilon_0 c^2$ must be reduced by one-fourth. But the ratio $\epsilon_0 c^2 / \mu_0$ is unchanged!

So just by experiments with charges and currents we find a number c^2 which turns out to be the square of the velocity of propagation of electromagnetic influences. From static measurements—by measuring the forces between two unit charges and between two unit currents—we find that $c = 3.00 \times 10^8$ meters/sec. When Maxwell first made this calculation with his equations, he said that bundles of electric and magnetic fields should be propagated at this speed. He also remarked on the mysterious coincidence that this was the same as the speed of light. "We can scarcely avoid the inference," said Maxwell, "that light consists in the transverse vibrations of the same medium which is the cause of electric and magnetic phenomena!"

Maxwell had made one of the great unifications of physics. Before his time, there was light, and there was electricity and magnetism. The latter two had been unified by the experimental work of Faraday, Oersted, and Ampere. Then, all of a sudden, light was no longer "something else," but was only electricity and magnetism in the new form—little pieces of electric and magnetic fields which propagate through space on their own.

We have called your attention to some characteristics of this special solution, which turn out to be true, however, for any electromagnetic wave: that the magnetic field is perpendicular to the direction of motion of the wavefront; that the electric field is likewise perpendicular to the direction of motion of the wavefront; and that the two vectors E and B are perpendicular to each other. Furthermore, the magnitude of the electric field E is equal to c times the magnitude of the magnetic field B . These three facts—that the two fields are transverse to the direction of propagation, that B is perpendicular to E , and that $E = cB$ —are generally true for any electromagnetic wave. (One special case is a good one—it shows all the main features of electromagnetic waves.)

18-6 Solving Maxwell's equations; the potentials and the wave equation

Now we would like to do something mathematical; we want to write Maxwell's equations in a simpler form. You may consider that we are complicating them, but if you will be patient a little bit, they will suddenly become simpler. Although by this time you are thoroughly used to each of the Maxwell equations, there are many places that must all be put together. That's what we want to do.

We begin with $\nabla \cdot B = 0$ —the simplest of the equations. We know that it implies that B is the curl of something. So, if we write

$$\mathbf{B} = \nabla \times \mathbf{A}, \quad (18.16)$$

we have already solved one of Maxwell's equations. (Incidentally, you hypothesize that it remains true that another vector A' would be just as good if $A' = A - \nabla\phi$ —where ϕ is any scalar field—because the curl of $\nabla\phi$ is zero, and B is still the same. We have talked about that before.)

We take next the Faraday law, $\nabla \times E = -\partial B / \partial t$, because it doesn't involve any currents or charges. If we write B as $\nabla \times A$ and differentiate with respect to t , we can write Faraday's law in the form

$$\nabla \times E = -\frac{\partial}{\partial t} \nabla \times A.$$

Since we can differentiate either with respect to time or to space first, we can also write this equation as

$$\nabla \times \left(E + \frac{\partial A}{\partial t} \right) = 0. \quad (18.17)$$

We see that $\mathbf{E} = \partial \mathbf{A} / \partial t$ is a vector whose curl is equal to zero. Therefore that vector is the gradient of something. When we worked on electrostatics, we had $\nabla \times \mathbf{B} = 0$, and then we decided that \mathbf{B} itself was the gradient of something. We took it to be the gradient of $-\phi$ (the minus for technical convenience). We do the same thing for $\mathbf{E} + \partial \mathbf{A} / \partial t$: we set

$$\mathbf{E} + \frac{\partial \mathbf{A}}{\partial t} = -\nabla \phi. \quad (18.18)$$

We use the same symbol ϕ so that, in the electrostaticic case where nothing changes with time and the $\partial \mathbf{A} / \partial t$ term disappears, \mathbf{E} will be our old $-\nabla \phi$. So Faraday's equation can be put in the form

$$\mathbf{E} = -\nabla \phi - \frac{\partial \mathbf{A}}{\partial t}. \quad (18.19)$$

We have solved two of Maxwell's equations already, and we have found that to describe the electromagnetic fields \mathbf{E} and \mathbf{B} , we need four potential functions: a scalar potential ϕ and a vector potential \mathbf{A} , which is, of course, three functions.

Now that \mathbf{A} determines part of \mathbf{E} , as well as \mathbf{B} , what happens when we change \mathbf{A} to $\mathbf{A}' = \mathbf{A} + \nabla \psi$? In general \mathbf{E} would change if we didn't take some special precautions. We can, however, still allow \mathbf{A} to be changed in this way without affecting the fields \mathbf{E} and \mathbf{B} : that is, without changing the physics—if we always change \mathbf{A} and ϕ together by the rules

$$\mathbf{A}' = \mathbf{A} + \nabla \psi, \quad \phi' = \phi - \frac{\partial \psi}{\partial t}. \quad (18.20)$$

Then neither \mathbf{B} nor \mathbf{E} , obtained from Eq. (18.19), is changed.

Previously, we chose to make $\nabla \cdot \mathbf{A} = 0$, to make the equations of statics somewhat simpler. We are not going to do that now; we are going to make a different choice. But we'll wait a bit before saying what the choice is, because later it will be clear why the choice is made.

Now we return to the two remaining Maxwell equations which will give us relations between the potentials and the sources ρ and \mathbf{j} . Once we can determine \mathbf{A} and ϕ from the currents and charges, we can always get \mathbf{E} and \mathbf{B} from Eqs. (18.16) and (18.19), so we will have another form of Maxwell's equations.

We begin by substituting Eq. (18.19) into $\nabla \cdot \mathbf{E} = \rho / \epsilon_0$; we get

$$\nabla \cdot \left(-\nabla \phi - \frac{\partial \mathbf{A}}{\partial t} \right) = \frac{\rho}{\epsilon_0},$$

which we can write also as

$$-\nabla^2 \phi - \frac{\partial}{\partial t} \nabla \cdot \mathbf{A} = \frac{\rho}{\epsilon_0}. \quad (18.21)$$

This is one equation relating ϕ and \mathbf{A} to the sources.

Our final equation will be the most complicated. We start by rewriting the fourth Maxwell equation as

$$c^2 \nabla \times \mathbf{B} - \frac{\partial \mathbf{E}}{\partial t} = \frac{\mathbf{j}}{\epsilon_0},$$

and then substitute for \mathbf{B} and \mathbf{E} in terms of the potentials, using Eqs. (18.16) and (18.19):

$$c^2 \nabla \times (\nabla \times \mathbf{A}) - \frac{\partial}{\partial t} \left(-\nabla \phi - \frac{\partial \mathbf{A}}{\partial t} \right) = \frac{\mathbf{j}}{\epsilon_0}.$$

The first term can be rewritten using the algebraic identity: $\nabla \times (\nabla \times \mathbf{A}) = \nabla(\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A}$; we get

$$-c^2 \nabla^2 \mathbf{A} + c^2 \nabla(\nabla \cdot \mathbf{A}) + \frac{\partial}{\partial t} \nabla \phi - \frac{\partial^2 \mathbf{A}}{\partial t^2} = \frac{\mathbf{j}}{\epsilon_0}. \quad (18.22)$$

It's not very simple!

Fortunately, we can now make use of our freedom to choose arbitrarily the divergence of A . What we are going to do is to use our choice to fix things so that the equations for A and for ϕ are separated but have the same form. We can do this by taking*

$$\nabla \cdot A = - \frac{1}{c^2} \frac{\partial \phi}{\partial t}. \quad (18.23)$$

When we do this, the two middle terms in A and ϕ in Eq. (18.22) cancel, and that equation becomes much simpler:

$$\nabla^2 A - \frac{1}{c^2} \frac{\partial^2 A}{\partial t^2} = - \frac{j}{\epsilon_0 c^2}. \quad (18.24)$$

And our equation for ϕ —Eq. (18.21)—takes on the same form:

$$\nabla^2 \phi - \frac{1}{c^2} \frac{\partial^2 \phi}{\partial t^2} = - \frac{\rho}{\epsilon_0}. \quad (18.25)$$

What a beautiful set of equations! They are beautiful, first, because they are nicely separated—with the charge density, plus ϕ , with the current, plus A . Furthermore, although the left side looks a little funny—a Laplacian together with a $(\partial/\partial t)^2$ —when we unfold it we see

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + \frac{\partial^2 \phi}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2 \phi}{\partial t^2} = - \frac{\rho}{\epsilon_0}. \quad (18.26)$$

It has a nice symmetry in x , y , z —the $-1/c^2$ is necessary because, of course, time and space are different; they have different units.

Maxwell's equations have led us to a new kind of equation for the potentials ϕ and A but to the same mathematical form for all four functions ϕ , A_x , A_y , and A_z . Once we learn how to solve these equations, we can get B and E from $\nabla \times A$ and $-\nabla \phi - \partial A/\partial t$. We have another form of the electromagnetic laws exactly equivalent to Maxwell's equations, and in many situations they are much simpler to handle.

We have, in fact, already solved an equation much like Eq. (18.26). When we studied sound in Chapter 17 of Vol. I, we had an equation of the form

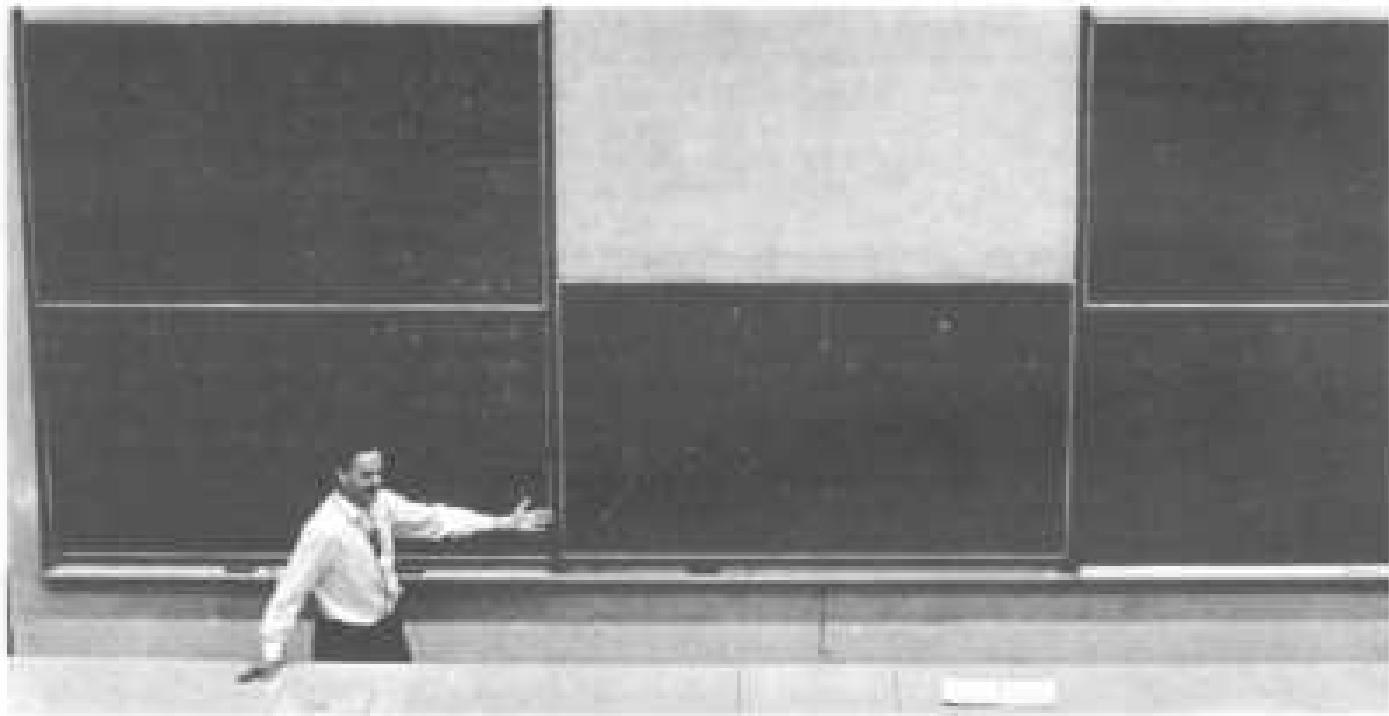

$$\frac{\partial^2 \psi}{\partial x^2} = \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2},$$

and we saw that it described the propagation of waves in the x -direction at the speed c . Equation (18.26) is the corresponding wave equation for three dimensions. So in regions where there are no longer any charges and currents, the solution of these equations is not that ϕ and A are zero. (Although that is indeed one possible solution.) There are solutions in which there is some set of ϕ and A which are changing in time but always moving out at the speed c . The fields travel outward through free space, as in our example at the beginning of the chapter.

With Maxwell's new term in Eq. 1V, we have been able to write the field equations in terms of A and ϕ in a form that is simple and thus makes immediately apparent that there are electromagnetic waves. For many practical purposes, it will still be convenient to use the original equations in terms of E and B . But they are on the other side of the mountain we have already climbed. Now we are ready to cross over to the other side of the peak. Things will look different—we are ready for some new and beautiful views.

* Choosing the $\nabla \cdot A$ is called "choosing a gauge." Changing A by adding $\nabla \phi$ is called a "gauge transformation." Equation (18.23) is called "the Lorenz gauge."

The Principle of Least Action

A special lecture—almost verbatim*

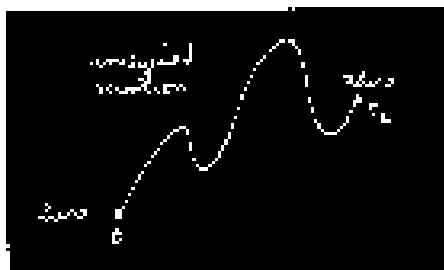

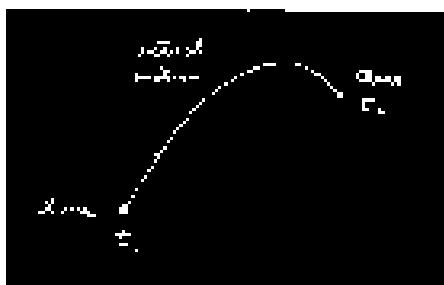

"When I was in high school, my physics teacher—whose name was Mr. Bader—called me down one day after physics class and said, 'You look bored; I want to tell you something interesting.' Then he told me something which I found absolutely fascinating, and have, since then, always found fascinating. Every time the subject comes up, I work on it. In fact, when I began to prepare this lecture I found myself making more analyses on the thing. Instead of worrying about the lecture, I got involved in a new problem. The subject is this—the principle of least action.

"Mr. Bader told me the following: Suppose you have a particle (in a gravitational field, for instance) which starts somewhere and moves to some other point by free motion—you draw it, and it goes up and comes down.

It goes from the original place to the final place in a certain amount of time. Now, you try a different curve. Suppose that to get from here to there, it would take

but put there is just the same amount of time. There is only this: If you calculate the kinetic energy at every instant on the path, take away the potential energy, and integrate it over the time during the whole path, you'll find that the number you'll get is bigger than that for the actual motion.

* Later chapters depend largely on the material of this special lecture—which is intended to be for "entertainment."

"In other words, the laws of Newton could be stated not in the form $\ddot{x} = F$, but in the form: the average kinetic energy less the average potential energy is as little as possible for the path of an object going from one point to another.

"Let me illustrate a little bit better what I mean. If you have an idea of the particle form's field, then if the particle has the path $x(t)$ let's take the difference for a moment: we take a trajectory like goes up and down and just sideways), where x is the height above the ground, the kinetic energy is $\frac{1}{2}m(\dot{x})^2$, and the potential energy at any time is mgh . Now I take the kinetic energy minus the potential energy at every moment along the path and integrate that with respect to time from the initial time to the final time. Let's suppose that at the original time t_0 we start at some height and at the end of the time t_f we are definitely ending at some other place.

"Then the integral is

$$\int_{t_0}^{t_f} \left[\frac{1}{2}m\left(\frac{dx}{dt}\right)^2 - mgh \right] dt$$

The whole motion is some kind of a curve—it's a parabola if we plot against the time—and gives a certain value for the integral. But we could imagine some other motion that went very high and came up and down in some peculiar way.

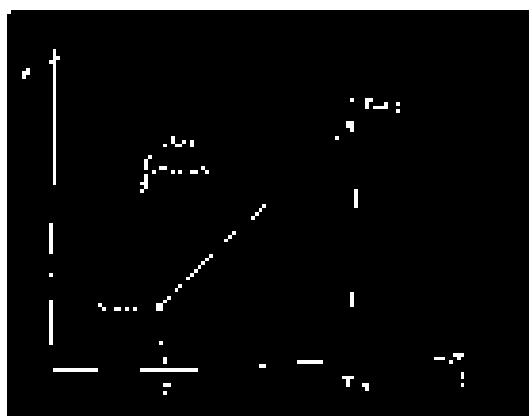

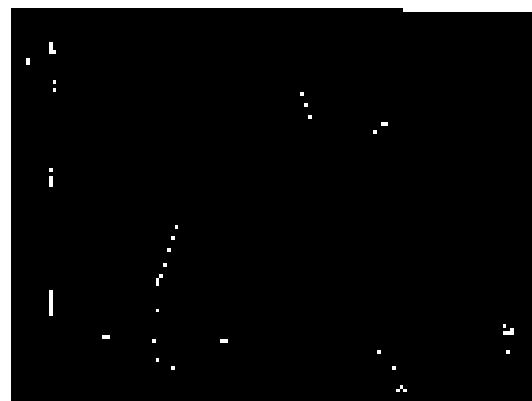

We can calculate the kinetic energy minus the potential energy and integrate for such a path... or for any other path we want. The remark is that the true path is the one for which this integral is least.

"Let's try it out. First, suppose we take the case of a free particle for which there is no potential energy at all. Then the rule says that in going from one point to another in a given amount of time, the kinetic energy integral is least, so it must go at uniform speed. (We know that's the right answer—because it's a uniform speed.) Why is that? Because if the particle were to go any other way, the velocities would be sometimes higher and sometimes lower than the average. The average velocity is the same for every case because it has to get from 'here' to 'there' in a given amount of time.

"As an example, say your job is to start from home and get to school in a given length of time with this car. You can do it several ways: You can加速 a little mad in the beginning and slow down with the brakes near the end, or you can go at a uniform speed, or you can go backwards for a while and then go forward, and so on. The thing is that average speed has got to be, of course, the total distance that you have gone over the time. But if you do anything but go at a uniform speed, then sometimes you are going too fast and sometimes you are going too slow. Now the mean square of something that deviates around an average, as you know, is always greater than the square of the mean: so the kinetic energy integral would always be higher than with your velocity than if you went the uniform velocity. So we see that the integral is a minimum, if the velocity is a constant (when there are no forces). The curve path is like this.

"Now, an object thrown up in a gravitational field does rise faster first and then slows down. That is because there is also the potential energy, and we must have the least difference of kinetic and potential energy on the average. However the potential energy does as we go to a space, we will get a little different. So we can get as much as possible up to where there is a high potential energy. Then we can take that potential away from the kinetic energy and get a lower average. So it is better to take a path which goes up and gets a lot of negative stuff from the potential energy.

"On the other hand, you can't go up too fast, or you fall because you will then have too much kinetic energy involved: you have to go very low to get very up and come down again in the fixed amount of time available. So you don't want to go too far up, but you want to go up some. So it turns out that the solution is some kind of balance between trying to get more potential energy with the least amount of extra kinetic energy. Try to find the differences, to take minus the potential, as small as possible.

"That is all my teacher told me, because he was a very good teacher and knew when to stop talking. But I don't know when to stop talking. So instead of leaving it as an interesting remark, I am going to horrify and disgust you with the complexities of life by proving that it is so. The kind of mathematical problem we will have is very difficult and a new kind. We have a certain quantity which is called the action, S . It is the kinetic energy, minus the potential energy, integrated over time.

$$\text{Action} = S = \int_{t_1}^{t_2} (KE - PE) dt.$$

Remember that the PE and KE are both functions of time. For each different possible path you get a different number for this action. Our mathematical problem is to find out for what curve that number is the least.

"You say—Oh, that's just the ordinary calculus of maxima and minima. You calculate the action and just differentiate to find the minimum.

"But watch out. Ordinarily we just have a function of some variable, and we have to find the value of that variable where the function is least or most. For instance, we have a rod which has been heated in the middle and the heat is spread around. For each point on the rod we have a temperature, and we want find the point at which that temperature is largest. But now for each path in space we have a number—quite a different thing—and we have to find the path in space for which the number is the minimum. That is a completely different branch of mathematics. It is not the ordinary calculus. In fact, it is called the calculus of variations.

"There are many problems in this kind of mathematics. For example, the circle is usually defined as the locus of all points at a constant distance from a fixed point, but another way of defining a circle is this: a circle is that curve of given length which encloses the biggest area. Any other curve encloses less area for a given perimeter than the circle does. So if we give the problem: find that curve which encloses the greatest area for a given perimeter, we would have a problem of the calculus of variations—a different kind of calculus than you're used to.

"So we make the calculation for the path of an object. Here is the way we are going to do it. The idea is that we imagine that there is a true path and that any other curve we draw is a false path, so that if we calculate the action for the false path we will get a value that is bigger than if we calculate the action for the true path.

"Problem: Find the true path. Where is it? One way, of course, is to calculate the action for millions and millions of paths and look at which one is lowest. When you find the lowest one, that's the true path.

"That's a possible way. But we can do it better than that. When we have a quantity which has a minimum—for instance, in an ordinary function like the temperature—one of the properties of the minimum is that if we go away from the minimum in the first order, the derivative of the function from its minimum value is only second order. At any place else on the curve, if we move a small distance the value of the function changes also in the first order. But at a minimum, a tiny motion away makes, in the first approximation, no difference.

"That is what we are going to use to calculate the true path. If we have the true path, a curve which differs only a little bit from it will, in the first approximation, make no difference in the action. Any difference will be in the second approximation, if we really have a minimum.

"That is easy to prove. If there is a change in the first order when I deviate the curve a certain way, there is a change in the action that is proportional to the deviation. The change presumably makes the action greater; otherwise we haven't got a minimum. But then if the change is proportional to the deviation, reversing the sign of the deviation will make the action less. We would get the action to increase one way and to decrease the other way. The only way that it could really be a minimum is that in the first approximation it doesn't make any change, that the changes are proportional to the square of the deviations from the true path.

"So we work in this way: We call $x(t)$ (without underbrace) the true path—the one we are trying to find. We take some trial path $\underline{x}(t)$ that differs from the true path by a small amount which we will call $\eta(t)$ (eta of t)."

"Now the idea is that if we calculate the action S for the path $x(t)$, then the difference between that S and the action that we calculated for the path $\underline{x}(t)$ —to simplify the writing we can call it \underline{S} —the difference of S and \underline{S} must be zero in the first-order approximation of small η . It can differ in the second order, but in the first order the difference must be zero."

"And that cannot be true for any η at all. Well, not quite. The method doesn't mean anything unless you consider paths which all begin and end at the same two points—each path begins at a certain point at t_1 and ends at a certain other point at t_2 , and those points and times are kept fixed. So the deviations in our η have to be zero at each end, $\eta(t_1) = 0$ and $\eta(t_2) = 0$. With that condition, we have specified our mathematical problem."

"If you didn't know any calculus, you might do the same kind of thing to find the minimum of an ordinary function $f(x)$. You could discuss what happens if you take $f(x)$ and add a small amount δ to x and argue that the correction to $f(x)$ in the first order in δ must be zero at the minimum. You would substitute $x + \delta$ for x and expand out to the first order in δ . . . just as we are going to do with η .

"The idea is then that we substitute $\underline{x}(t) = x(t) + \eta(t)$ in the formula for the action:

$$S = \int \left[\frac{m}{2} \left(\frac{dx}{dt} \right)^2 - V(x) \right] dt,$$

where I call the potential energy $V(x)$. The derivative dx/dt is, of course, the derivative of $\underline{x}(t)$ plus the derivative of $\eta(t)$, so for the action S get this expression:

$$S = \int_{t_1}^{t_2} \left[\frac{m}{2} \left(\frac{dx}{dt} + \frac{d\eta}{dt} \right)^2 - V(x + \eta) \right] dt.$$

"Now I must write this out in more detail. For the squared term I get

$$\left(\frac{dx}{dt} \right)^2 + 2 \frac{dx}{dt} \frac{d\eta}{dt} + \left(\frac{d\eta}{dt} \right)^2.$$

But wait. I'm not worrying about higher than the first order, so I will take all the terms which involve η^2 and higher powers and put them in a little box called 'second and higher order.' From this term I get only second order, but there will be more from something else. So the kinetic energy part is

$$\frac{m}{2} \left(\frac{dx}{dt} \right)^2 = m \frac{dx}{dt} \frac{d\eta}{dt} + (\text{second and higher order}).$$

"Now we need the potential V at $x + \eta$. I consider η small, so I can write $V(x)$ as a Taylor series. It is approximately $V(x)$: in the next approximation (from the ordinary nature of derivatives) the correction is η times the rate of change of V with respect to x , and so on:

$$V(x + \eta) = V(x) + \eta V'(x) + \frac{\eta^2}{2} V''(x) + \dots$$

I have written V' for the derivative of V with respect to x in order to save writing. The term in η^2 and the ones beyond fall into the 'second and higher order' category and we don't have to worry about them. Putting it all together,

$$S = \int_{t_1}^{t_2} \left[\frac{m}{2} \left(\frac{dx}{dt} \right)^2 - V(x) + m \frac{dx}{dt} \frac{d\eta}{dt} - \eta V'(x) + (\text{second and higher order}) \right] dt.$$

Now if we look carefully at the thing, we see that the first two terms which I have arranged here correspond to the action of that I would have calculated with the true path x . The thing I want to concentrate on is the change in S —the difference between the S and the \bar{S} that we would get for the right path. This difference we will write as δS , called the variation in S . Leaving out the 'second and higher order' terms, I have for δS

$$\delta S = \int_{x_1}^{x_2} \left[m \frac{dx}{dt} \frac{d\eta}{dx} + \eta V(x) \right] dt.$$

"Now the problem is this: Here is a certain integral. I don't know what the x is yet, but I do know that no matter what η is, this integral must be zero. Well, you think, the only way that that can happen is that what multiplies η must be zero. But what about the first term with $d\eta/dx$? Well, after all, if η can be anything at all, its derivative is anything also, so you conclude that the coefficient of $d\eta/dx$ must also be zero. That isn't quite right. It isn't quite right because there is a connection between η and its derivative; they are not absolutely independent, because $\eta(x)$ must be zero at both x_1 and x_2 .

"The method of solving all problems in the calculus of variations always uses the same general principle. You make the shift in the thing you want to vary (as we did by adding η); you look at the first-order terms, then you always arrange things in such a form that you get an integral of the form 'some kind of stuff times the shift (η)', but with no other derivatives (no $d\eta/dt$). It must be rearranged so it is always 'something' times η . You will see the great value of that in a minute. (There are formulas that tell you how to do this in some cases without actually calculating, but they are not general enough to be worth bothering about: the best way is to calculate it just this way.)

"How can I rearrange the term in $d\eta/dt$ to make it have an η ? I can do that by integrating by parts. It turns out that the whole trick of the calculus of variations consists of writing down the variation of S and then integrating by parts so that the derivatives of η disappear. It is always the same in every problem in which derivatives appear.

"You remember the general principle for integrating by parts. If you have any function f times $d\eta/dt$ integrated with respect to t , you write down the derivative of tf :

$$\frac{d}{dt}(tf) = \eta \frac{df}{dt} + f \frac{d\eta}{dt}.$$

The integral you want is over the last term, so

$$\int f \frac{d\eta}{dt} dt = -tf + \int \eta \frac{df}{dt} dt.$$

"In our formula for δS , the function f is m times dx/dt ; therefore, I have the following formula for δS :

$$\delta S = m \frac{dx}{dt} \eta(t) \Big|_{x_1}^{x_2} - \int_{x_1}^{x_2} \frac{d}{dt} \left(m \frac{dx}{dt} \right) \eta(t) dt - \int_{x_1}^{x_2} V(x) \eta(t) dt.$$

The first term must be evaluated at the two limits x_1 and x_2 . Then I must have the integral from the rest of the integration by parts. The last term is brought down without change.

"Now comes something which always happens—the integrated part disappears. (In fact, if the integrated part does not disappear, you restate the principle, adding conditions to make sure it does!) We have already said that η must be zero at both ends of the path, because the principle is that the action is a minimum provided that the varied curve begins and ends at the chosen points. The condition is that

$\eta(t_1) = 0$ and $\eta(t_2) = 0$. So the integral term is zero. We collect the other terms together and obtain this:

$$S = \int_{t_1}^{t_2} \left[-m \frac{d^2x}{dt^2} - F'(x) \right] \eta(t) dt.$$

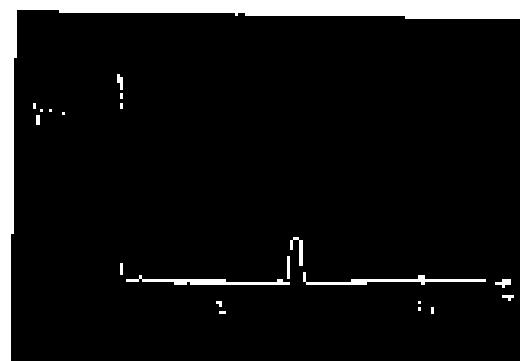

The variation in S is now the way we wanted it—there is the stuff in brackets, say F , all multiplied by $\eta(t)$ and integrated from t_1 to t_2 .

"We have that an integral of something or other times $\eta(t)$ is always zero:

$$\int F(t) \eta(t) dt = 0.$$

I have some function of t ; I multiply it by $\eta(t)$; and I integrate it from one end to the other. And no matter what the η is, I get zero. That means that the function $F(x)$ is zero. That's obvious, but anyway I'll show you one kind of proof.

"Suppose that for $\eta(t)$ I took something which was zero for all t except right near one particular value. It stays zero until it gets to this t ,

then it blips up for a moment and blips right back down. When we do the integral of this η times any function F , the only place that you get anything other than zero was where $\eta(t)$ was blipping, and then you get the value of F at that place times the integral over the blip. The integral over the blip alone isn't zero, but when multiplied by F it has to be; so the function F has to be zero where the blip was. But the blip was anywhere I wanted to put it, so F must be zero everywhere.

"We see that if our integral is zero for any η , then the coefficient of η must be zero. The action integral will be a minimum for the path that satisfies this complicated differential equation:

$$\left[-m \frac{d^2x}{dt^2} - F'(x) \right] = 0.$$

It's not really so complicated; you have seen it before. It's just $F = -ma$. The first term is the mass times acceleration, and the second is the derivative of the potential energy, which is the force.

"So, for a conservative system at least, we have demonstrated that the principle of least action gives the right answer; it says that the path that has the *minimum* action is the one satisfying Newton's law.

"One remark: I did not prove it was a minimum—maybe it's a maximum. In fact, it doesn't really have to be a minimum. It is quite analogous to what we found for the 'principle of least time' which we discussed in optics. There also, we said at first it was 'least' time. It turned out, however, that there were situations in which it wasn't the least time. The fundamental principle was that for any first-order variation away from the optical path, the change in time was zero; it is the same story. What we really mean by 'least' is that the first-order change in the value of S , when you change the path is zero. It is not necessarily a minimum."

"Next, I remark on some generalizations. In the first place, the thing can be done in three dimensions. Instead of just x , I would have x , y , and z as functions of t ; the action is then complicated. For three-dimensional motion, you have to use the complete kinetic energy $(m/2)$ times the whole velocity squared. That is,

$$KE = \frac{m}{2} \left| \left(\frac{dx}{dt} \right)^2 + \left(\frac{dy}{dt} \right)^2 + \left(\frac{dz}{dt} \right)^2 \right|.$$

Also, the potential energy is a function of x , y , and z . And what about the path? The path is some general curve in space, which is not so easily drawn, but the idea is the same. And what about the η ? Well, η can have three components. You could shift the path in x , or in y , or in z —or you could shift in all three directions simultaneously. So η would be a vector. This doesn't really complicate things too much, though. Since only the first-order variation has to be zero, we can do the calculation by three successive shifts. We can shift x only in the x -direction and

say that coefficient never be zero. We get one equation. Then we shift it in the y -direction and get another. And in the z -direction and get another. Or, of course, in any order that you want. Anyway, you get three equations. And, of course, Newton's law is really three equations in the three dimensions—one for each component. I think that you can practically see that it is bound to work, but we will leave you to show for yourself that it will work for three dimensions. Indeed, you might use any coordinate system you want, polar or otherwise, and get Newton's laws appropriate in that system right off by seeing what happens if you have the shift τ in radius, or in angle, etc.

"Similarly, the method can be generalized to any number of particles. If you have, say, two particles with a force between them, so that there is a mutual potential energy, then you just add the kinetic energy of both particles and take the potential energy of the mutual interaction. And what do you vary? You vary the paths of both particles. Then, for two particles moving in three dimensions, there are six equations. You can vary the position of particle 1 in the x -direction, in the y -direction, and in the z -direction, and similarly for particle 2; so there are six equations. And that's as it should be. There are the three equations that determine the acceleration of particle 1 in terms of the force on it and three for the acceleration of particle 2, from the force on it. You follow the same game through, and you get Newton's law in three dimensions for any number of particles.

"I have been saying that we get Newton's law. That is not quite true, because Newton's law includes nonconservative forces like friction. Newton said that $m\ddot{x}$ is equal to say F . But the principle of least action only works for conservative systems—where all forces can be gotten from a potential function. You know, however, that at a microscopic level—on the deepest level of physics—there are no nonconservative forces. Nonconservative forces, like friction, appear only because we neglect microscopic complications—there are just too many particles to analyze. But the fundamental laws can be put in the form of a principle of least action.

"Let me generalize still further. Suppose we ask what happens if the particle moves relativistically. We did not get the right relativistic equations of motion; $F = ma$ is only right nonrelativistically. The question is: Is there a corresponding principle of least action for the relativistic case? There is. The formula in the case of relativity is the following:

$$S = -mc^2 \int_{t_1}^{t_2} \sqrt{1 - v^2/c^2} dt - q \int_{r_1}^{r_2} [\phi(r, \dot{r}, z, t) - \mathbf{A} \cdot \mathbf{dr}] dt.$$

The first part of the action integral is the rest mass m , times c^2 times the integral of a function of velocity, $\sqrt{1 - v^2/c^2}$. Then instead of just the potential energy, we have an integral over the scalar potential ϕ and over v times the vector potential A . Of course, we are then including only electromagnetic forces. All electric and magnetic fields are given in terms of ϕ and A . This action function gives the complete theory of relativistic motion of a single particle in an electromagnetic field.

"Of course, whenever I have written v , you understand that before you try to figure anything out, you must substitute dx/dt for v_x and so on for the other components. Also, you put the path along the path at time t , $x(t), y(t), z(t)$ where I wrote simply x, y, z . Properly, it is only after you have made these replacements for the v 's that you have the formula for the action for a relativistic particle. I will leave to the more advanced of you the problem to demonstrate that this action formula does, in fact, give the correct equations of motion for relativity. May I suggest you do it first without the A , that is, for no magnetic field? Then you should get the components of the equation of motion, $dv/dt = -q \nabla \phi$, where, you remember, $\rho = mv/\sqrt{1 - v^2/c^2}$.

"It is much more difficult to include even the case with a vector potential. The variations get much more complicated. But in the end, the force term does turn out equal to $q(E + \mathbf{v} \times \mathbf{B})$, as it should. But I will leave that for you to play with.

"I would like to emphasize that in the general case, for instance in the relativistic formula, the action integral no longer has the form of the kinetic energy

minus the potential energy. That's only true in the non-relativistic approximation. For example, the term $m\epsilon c^2 \sqrt{1 - v^2/c^2}$ is not what we have called the kinetic energy. The question of what the action should be for any particular case must be determined by some kind of trial and error. It is just the same problem as determining what are the laws of motion in the first place. You just have to fiddle around with the equations that you know and see if you can get them into the form of the principle of least action.

"One other point on terminology. The function that is integrated over time to get the action S is called the Lagrangian, L , which is a function only of the velocities and positions of particles. So the principle of least action is also written

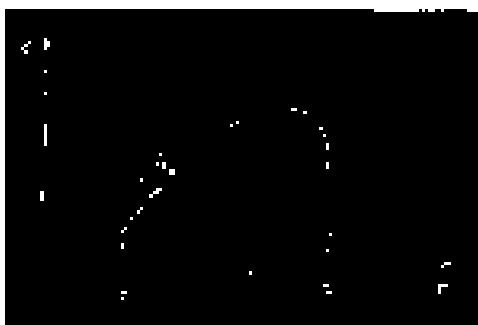

$$S = \int_{t_1}^{t_2} L(x_i, \dot{x}_i) dt,$$

where by x_i and \dot{x}_i are meant all the components of the positions and velocities. So if you hear someone talking about the 'Lagrangian,' you know they are talking about the function that is used to find S . For relativistic motion in an electromagnetic field

$$\mathcal{L} = m\epsilon c^2 \sqrt{1 - \frac{\dot{x}^2}{c^2}} - q(\phi - \mathbf{A} \cdot \mathbf{x}).$$

"Also, I should say that S is not really called the 'action' by the most precise and pedantic people. It is called 'Hamilton's first principal function.' Now I have to give a lecture on 'the-principle-of-least-Hamilton's-first-principal-function.' So I call it 'the action.' Also, more and more people are calling it the action. You see, historically something else which is not quite as useful was called the action, but I think it's more sensible to change to a newer definition. So now you too will call the new function the action, and pretty soon everybody will call it by that simple name.

"Now I want to say some things on this subject which are similar to the discussions I gave about the principle of least time. There is quite a difference in the characteristic of a law which says a certain integral from one place to another is a minimum—which tells something about the whole path—versus a law which says that as you go along, there is a force that makes it accelerate. The second way tells how you took your way along the path, and the other is a stated statement about the whole path. In the case of light, we talked about the connection of these two. Now, I would like to explain why it is true that there are differential laws when there is a least action principle of this kind. The reason is the following: Consider the usual path in space and time. As before, let's take only one dimension, so we can plot the graph of x as a function of t . Along the true path, S is a minimum. Let's suppose that we have the true path and that it goes through some point a in space and time, and also through another nearby point b .

Now if the entire integral from t_1 to t_2 is a minimum, it is also necessary that the integral along the little section from a to b is also a minimum. It can't be that the path from a to b is a little bit more. Otherwise you could just jingle with just that piece of the path and make the whole integral a little lower.

"So every subsection of the path must also be a minimum. And this is true no matter how short the subsection. Therefore the principle that the whole path gives a minimum can be stated also by saying that an infinitesimal section of path along has a curve such that it has a minimum action. Now if we take a short enough section of path—between two points a and b very close together—how the potential varies from one place to another far away is not the important thing, because you are staying almost in the same place over the whole little piece of the path. The only thing that you have to discuss is the first-order change in the potential. The answer can only depend on the derivative of the potential and not on the potential everywhere. So the statement about the gross property of the whole path becomes a statement of what happens for a short section of the path—a differential statement. And this differential statement only involves the derivatives of the potential, that is, the force at a point. That's the qualitative explanation of the relation between the gross law and the differential law.

"In the case of light we also discussed the question: How does the particle find the right path? From the differential point of view, it is easy to understand. Every moment it gets an acceleration, and knows only what to do at that instant. But all your instincts or values and effect go haywire when you say that the particle decides to take the path that is going to give the minimum action. Does it 'smell' the neighboring paths to find out whether or not they have more action? In the case of light, when we put blocks in the way so that the photons could not test all the paths, we found that they couldn't figure out which way to go, and we had the phenomenon of diffraction.

"Is the same thing true in mechanics? Is it true that the particle doesn't just 'take the right path' but that it looks at all the other possible trajectories? And if by having blocks in the way, we don't let it look, that we will get an analog of diffraction? The miracle of it all is, of course, that it does just that. That's what the laws of quantum mechanics say. So our principle of least action is incompletely stated. It isn't that a particle takes the path of least action but that it smells all the paths in the neighborhood and chooses the one that has the least action by a method analogous to the one by which light chose the shortest time. You remember that the way light chose the shortest time was this: If it went on a path that took a different amount of time, it would arrive at a different phase. And the total amplitude at some point is the sum of contributions of amplitude for all the different ways the light can arrive. All the paths that give wildly different phases don't add up to anything. But if you can find a whole sequence of paths which have phases almost all the same, then the little contributions will add up and you get a reasonable total amplitude to arrive. The important path becomes the one for which there are many nearby paths which give the same phase.

"It is just exactly the same thing for quantum mechanics. The complete quantum mechanics (for the nonrelativistic case and neglecting electron spin) works as follows: The probability that a particle starting at point 1 at the time t_1 will arrive at point 2 at the time t_2 is the square of a probability amplitude. The total amplitude can be written as the sum of the amplitudes for each possible path—for each way of arrival. For every path that we could have—for every possible trajectory—we have to calculate an amplitude. Then we add them all together. What do we take for the amplitude for each path? Our action integral tells us what the amplitude for a single path ought to be. The amplitude is proportional to some constant times $e^{iS/\hbar}$, where S is the action for that path. That is, if we represent the phase of the amplitude by a complex number, the phase angle is S/\hbar . The action S has dimensions of energy times time, and Planck's constant \hbar has the same dimensions. It is the constant that determines when quantum mechanics is important.

"Here is how it works: Suppose that for all paths, S is very large compared to \hbar . One path contributes a certain amplitude. For a nearby path, the phase is quite different, because with an enormous S even a small change in S means a completely different phase—because \hbar is so tiny. So nearby paths will normally cancel their effects out in taking the sum—except for one region, and that is where a path and a nearby path will give the same phase in the first approximation (more precisely, the same action within \hbar). Only those paths will be the important ones. So in the limiting case in which Planck's constant \hbar goes to zero, the correct quantum-mechanical laws can be summarized by simply saying: 'Forget about all these probability amplitudes. The particle does go on a special path, namely, that one for which S does not vary in the first approximation.' That's the relation between the principle of least action and quantum mechanics. The fact that quantum mechanics can be formulated in this way was discovered in 1942 by a student of that same teacher, Radler, I spoke of at the beginning of this lecture. [Quantum mechanics was originally formulated by giving a differential equation for the amplitude (Schrödinger) and also by some other people (mathematicians (Heisenberg).)]

"Now I want to talk about other minimum principles in physics. There are many very interesting ones. I will not try to list them all now but will only describe one more. Later on, when we come to a physical phenomenon which has a nice minimum principle, I will tell about it then. I want now to show that we can de-

scribe electrostatics, not by giving a differential equation for the field, but by saying that a certain integral is a maximum or a minimum. First, let's take the case where the charge density is known everywhere, and the problem is to find the potential ϕ everywhere in space. You know that the answer should be

$$\nabla^2\phi = -\rho/\epsilon_0.$$

But another way of stating the same thing is this: Calculate the integral U^* , where

$$U^* = \frac{\epsilon_0}{2} \int (\nabla\phi)^2 dV - \int \rho\phi dV,$$

which is a volume integral to be taken over all space. This thing is a minimum for the correct potential distribution $\phi(x, y, z)$.

We can show that the two statements about electrostatics are equivalent. Let's suppose that we pick any function ϕ . We want to show that when we take for ϕ the correct potential ϕ , plus a small deviation f , then in the first order, the change in U^* is zero. So we write

$$\phi = \phi_0 + f.$$

The ϕ is what we are looking for, but we are making a variation of it to find what it has to be so that the variation of U^* is zero to first order. For the first part of U^* , we need

$$(\nabla\phi)^2 = (\nabla\phi_0)^2 + 2\nabla\phi \cdot \nabla f + (\nabla f)^2.$$

The only first-order term that will vary is

$$2\nabla\phi \cdot \nabla f.$$

In the second term of the quantity U^* , the integrand is

$$\rho\phi = \rho\phi_0 + \rho f,$$

whose variable part is ρf . So, keeping only the variable parts, we need the integral

$$\Delta U^* = \int (\epsilon_0 \nabla\phi_0 \cdot \nabla f - \rho f) dV.$$

Now, following the old general rule, we have to get the damn thing all clear of derivatives of f . Let's look at what the derivatives are. The dot product is

$$\frac{\partial \phi}{\partial x} \frac{\partial f}{\partial x} + \frac{\partial \phi}{\partial y} \frac{\partial f}{\partial y} + \frac{\partial \phi}{\partial z} \frac{\partial f}{\partial z},$$

which we have to integrate with respect to x , to y , and to z . Now here is the trick: to get rid of $\partial f / \partial x$ we integrate by parts with respect to x . That will carry the derivative over onto the ϕ . It's the same general idea we used to get rid of derivatives with respect to z . We use the equality

$$\int \frac{\partial \phi}{\partial x} \frac{\partial f}{\partial x} dx = f \frac{\partial \phi}{\partial x} - \int f \frac{\partial^2 \phi}{\partial x^2} dx.$$

The integrated term is zero, since we have to make f zero at infinity. (That corresponds to making ϕ zero at x_1 and x_2 . So our principle should be more accurately stated: U^* is best for the true ϕ than for any other $\phi(x, y, z)$ having the same values at infinity.) Then we do the same thing for y and z . So our integral ΔU^* is

$$\Delta U^* = \int (-\epsilon_0 \nabla^2 \phi_0 - \rho) f dV.$$

In order for this variation to be zero for any f , no matter what, the coefficient of f must be zero and, therefore,

$$\nabla^2 \phi = -\rho/\epsilon_0.$$

We get back our old equation. So our "minimum" proposition is correct.

"We can generalize our proposition if we do our algebra in a little different way. Let's go back and do our integration by parts without taking components. We start by looking at the following equality:

$$\nabla \cdot (f \nabla \phi) = \nabla f \cdot \nabla \phi + f \nabla^2 \phi.$$

If I differentiate out the left-hand side, I can show that it is just equal to the right-hand side. Now we can use this equation to integrate by parts. In our integral ΔU^* , we replace $-\nabla \phi \cdot \nabla f$ by $\nabla^2 \phi \cdot \nabla f$, which gets integrated over volume. The divergence term integrated over volume can be replaced by a surface integral:

$$\int \nabla \cdot (f \nabla \phi) dV = \int f \nabla \phi \cdot n d\sigma.$$

Since we are integrating over all space, the surface over which we are integrating is at infinity. There, f is zero and we get the same answer as before.

"Only now we see how to solve a problem when we don't know where all the charges are. Suppose that we have conductors with charges spread out on them, in some way. We can still use our minimum principle if the potentials of all the conductors are fixed. We carry out the integral for ΔU^* only in the space outside of all conductors. Then, since we can't vary ϕ on the conductor, f is zero on all those surfaces, and the surface integral

$$\int f \nabla \phi \cdot n d\sigma$$

is still zero. The remaining volume integral

$$\Delta U^* = \int (-\epsilon_0 \nabla^2 \phi - \rho \phi) dV$$

is only to be carried out in the spaces between conductors. Of course, we get Poisson's equation again,

$$\nabla^2 \phi = -\rho/\epsilon_0$$

So we have shown that our original integral U^* is also a minimum if we evaluate it over the space outside of conductors all at fixed potentials (that is, such that any trial $\phi(x, y, z)$ must equal the given potential of the conductor, which x, y, z is a point on the surface of a conductor).

"There is an interesting case when the only charges are on conductors. Then

$$U^* = \frac{\epsilon_0}{2} \int (\nabla \phi)^2 dV.$$

Our minimum principle says that in the case where there are conductors set at certain given potentials, the potential between them adjusts itself so that integral U^* is least. What is this integral? The term $\nabla \phi$ is the electric field, so the integral is the electrostatic energy. The true field is the sum of all those coming from the gradient of a potential, with the minimum total energy.

"I would like to use this result to calculate something particular to show you that these things are really quite practical. Suppose I take two conductors in the form of a cylindrical condenser.

The inside conductor has the potential V , and the outside is at the potential zero. Let the radius of the inside conductor be a and that of the outside, b . Now we can suppose any distribution of potential between the two. If we use the correct ϕ , and calculate $\epsilon_0/2 \int (\nabla \phi)^2 dV$, it should be the energy of the system, $\frac{1}{2}CV^2$.

So we can also calculate C by our principle. But if we use a wrong distribution of potential and try to calculate the capacity C by this method, we will get a capacity that is too big, since V is specified. Any assigned potential ϕ that is not the exactly correct one will give a fake C that is larger than the correct value. But if my false ϕ is any rough approximation, the C will be a good approximation, because the error in C is second order to the error in ϕ .

"Suppose I don't know the capacity of a cylindrical condenser. I can use this principle to find it. I just guess at the potential function ϕ until I get the lowest C . Suppose, for instance, I pick a potential that corresponds to a constant field. (You know, of course, that the field isn't really constant here; it varies as $1/r$.) A field which is constant means a potential which goes linearly with distance. To fit the conditions at the two conductors, it must be

$$\phi = V \left(1 - \frac{r-a}{b-a} \right).$$

This function is V at $r = a$, zero at $r = b$, and in between has a constant slope equal to $-V/(b-a)$. So what one does is find the integral $\int d^3r$ is multiply the square of this gradient by $\epsilon_0/2$ and integrate over all volume. Let's do this calculation for a cylinder of unit length. A volume element at the radius r is $2\pi r dr$. Doing the integral, I find that my first try at the capacity gives

$$\frac{1}{2} C V^2 (\text{first try}) = \frac{\epsilon_0}{2} \int_a^b \frac{V^2}{(b-a)r} 2\pi r dr.$$

The integral is easy; it is just

$$\pi V^2 \left(\frac{b+a}{b-a} \right).$$

So I have a formula for the capacity which is not the true one but is an approximate job:

$$\frac{C}{2\pi\epsilon_0} = \frac{b+a}{2(b-a)}.$$

It is, naturally, different from the correct answer $C = 2\pi a \sqrt{b/a}$, but it's not too bad. Let's compare it with the right answer for several values of b/a . I have computed out the answers in this table:

a	$\frac{C_{\text{true}}}{2\pi\epsilon_0}$	$\frac{C(\text{first approx})}{2\pi\epsilon_0}$
2	1.4423	1.900
4	0.721	0.833
10	0.454	0.612
100	0.267	0.31
1.5	2.4662	2.50
1.1	10.492070	10.500000

Even when b/a is as big as 2—which gives a pretty big variation in the field compared with a linearly varying field—I get a pretty fair approximation. The answer is, of course, a little too high, as expected. The thing gets much worse if you have a tiny wire inside a big cylinder. Then the field has enormous variations and if you represent it by a constant, you're not doing very well. With $b/a = 100$, we're off by nearly a factor of two. Things are much better for small b/a . To take the opposite extreme, when the conductors are not very far apart—say $b/a = 1.1$ —then the constant field is a pretty good approximation, and we get the correct value for C to within a tenth of a percent.

"Now I would like to tell you how to improve such a calculation. (Of course, you know the right answer for the cylinder, but the method is the same for some other field shapes, where you may not know the right answer.) The next step is to try a better approximation to the unknown true ϕ . For example, we might try a

constant plus an exponential ϕ , etc. But how do you know when you have a better approximation unless you know the true ϕ ? Answer: You calculate C ; the lowest C is the value nearest the truth. Let us try this idea out. Suppose that the potential is not linear but say quadratic in r —that the electric field is not constant but linear. The most general quadratic form that fits $\phi = 0$ at $r = b$ and $\phi = V$ at $r = a$ is

$$\phi = V \left[1 + \alpha \left(\frac{r-a}{b-a} \right) - (1+\alpha) \left(\frac{r-a}{b-a} \right)^2 \right],$$

where α is any constant number. This formula is a little more complicated. It involves a quadratic term in the potential as well as a linear term. It is very easy to get the field out of it. The field is just

$$E = -\frac{d\phi}{dr} = -\frac{\alpha V}{b-a} + 2(1+\alpha) \frac{(r-a)V}{(b-a)^2}.$$

Now we have to square this and integrate over volume. But wait a moment. What should I take for α ? I can take a parabola for the ϕ ; but what parabola? Here's what I do: Calculate the capacity with an arbitrary α . When I get to

$$\frac{C}{2\pi\epsilon_0} = \frac{\alpha}{b-a} \left[\frac{b}{a} \left(\frac{a^3}{b^2} + \frac{2a}{b} + 1 \right) + \frac{1}{6} \alpha^2 + 1 \right].$$

It looks a little complicated, but it occurs out of integrating the square of the field. Now I can pick any α . I know that the truth lies somewhere between anything that I am going to calculate, so whatever I put in for α is going to give me an answer too big. But if I keep playing with α and get the lowest possible value (say, that lowest value is nearer to the truth than any other value). So what I do next is to pick the α that gives the minimum value for C . Working it out by ordinary calculus, I get that the minimum C occurs for $\alpha = -2b/(b+a)$. Substituting that value into the formula, I obtain for the minimum capacity

$$\frac{C}{2\pi\epsilon_0} = \frac{b^2 + 4ab + a^2}{3(b^2 - a^2)}.$$

"I've worked out what this formula gives for C for various values of b/a . I call these numbers $C_{\text{quadratic}}$. Here is a table that compares $C_{\text{quadratic}}$ with the true C .

$\frac{b}{a}$	$\frac{C_{\text{true}}}{2\pi\epsilon_0}$	$\frac{C_{\text{quadratic}}}{2\pi\epsilon_0}$
2	1.4423	1.444
4	0.721	0.733
10	0.434	0.475
100	0.267	0.346
1.5	2.4662	2.4667
1.1	10.492070	10.492065

"For example, when the ratio of the radii is 2 to 1, I have 1.444, which is a very good approximation to the true answer, 1.4423. Even for larger b/a , it stays pretty good—it is much, much better than the first approximation. It is even fairly good, only off by 10 percent, when b/a is 10 to 1. But when it gets to be 100 to 1—well, things begin to go wild. I get that C is 0.346 instead of 0.267. On the other hand, for a ratio of radii of 1.5, the answer is excellent; and for a b/a of 1.1, the answer comes out 10.492065 instead of 10.492070. Where the answer should be good, it is very, very good."

"I have given these examples, first, to show the theoretical value of the principles of minimum action and minimum principles in general and, second, to show their practical utility—not just to calculate a capacity when we already know the answer. For any other shape, you can guess an approximate field with some unknown parameters like α and adjust them to get a minimum. You will get excellent numerical results for otherwise intractable problems."

A note added after the lecture

"I should like to add something that I didn't have time for in the lecture. (I always seem to prepare more than I have time to tell about.) As I mentioned earlier, I got interested in a problem while working on this lecture. I want to tell you what that problem is. Among the minimum principles that I could mention, I noticed that most of them sprang in one way or another from the least action principle of mechanics and electrodynamics. But there is also a class that does not. As an example, if currents are made to go through a piece of material obeying Ohm's law, the currents distribute themselves inside the piece so that the rate at which heat is generated is as little as possible. Also we can say (if things are kept Euclidean) that the rate at which energy is generated is a minimum. Now, this principle also holds, according to classical theory, in determining even the distribution of velocities of the electrons inside a metal which is carrying a current. The distribution of velocities is not exactly the equilibrium distribution [Chapter 40, Vol. I; Eq. (40.6)] because they are drifting sideways. The new distribution can be found from the principle that it is the distribution for a given current for which the energy developed per second by collisions is as small as possible. The true description of the electrons' behavior ought to be by quantum mechanics, however. The question is: Does the same principle of minimum entropy generation also hold when the situation is described quantum-mechanically? I haven't found that yet.

"The question is interesting academically, of course. Such principles are fascinating, and it is always worth while to try to see how general they are. But also from a more practical point of view, I want to know. I, with some colleagues, have published a paper in which we calculated by quantum mechanics approximately the electrical resistance left by an electron moving through an ionic crystal like NaCl. [Feynman, Hellworth, Hedges, and Platman, "Mobility of Slow Electrons in a Polar Crystal," *Phys. Rev.* 127, 1004 (1962).] But if a minimum principle existed, we could use it to make the results much more accurate, just as the minimum principle for the capacity of a condenser permitted us to get such accuracy for that capacity even though we had only a rough knowledge of the electric field."

Solutions of Maxwell's Equations in Free Space

20-1 Waves in free space; plane waves

In Chapter 18 we had reached the point where we had 1 to Maxwell's equations in complete form. All that is left now is to know what the classical theory of the electric and magnetic fields can tell us of the joint equations:

$$\text{I. } \nabla \cdot E = \frac{\rho}{\epsilon_0}$$

$$\text{II. } \nabla \times E = -\frac{\partial B}{\partial t}$$

$$\text{III. } \nabla \cdot B = 0$$

$$\text{IV. } c\nabla \times B = \frac{j}{\epsilon_0} + \frac{\partial E}{\partial t} \quad (20.1)$$

When we put all these equations together, a remarkable new phenomenon occurs: fields generated by moving charges can leave the sources and travel alone through space. We considered a special example in which an infinite current sheet is suddenly turned on. After the current has been on for the time t , there are uniform electric and magnetic fields extending out the distance $c(t)$ from the source. Suppose that the current sheet lies in the xy -plane with a surface current density j going toward positive x . The electric field will have only a y -component, and the magnetic field, only a z -component. The magnitude of the field components is given by

$$E_y = cB_z = \frac{j}{2\epsilon_0 c} \quad (20.2)$$

for positive values of x less than $c(t)$. For larger x the fields are zero. There are, of course, similar fields extending the same distance from the current sheet in the negative x direction. In Fig. 20-1 we show a graph of the magnitude of the fields as a function of x at the instant t . As time goes on, the "wavefront" at $c(t)$ moves outward in x at the constant velocity c .

Now consider the following sequence of events. We turn on a current of unit strength for a while, then suddenly increase the current strength to three units, and hold it constant at this value. What do the fields look like then? We can see what the fields will look like in the following way. First, we imagine a current of unit strength that is turned on at $x = 0$ and left constant forever. The fields for positive x are then given by the graph in part (a) of Fig. 20-2. Next, we ask what would happen if we turn on a steady current of two units at the time t_1 .

The fields in this case will be twice as high as before, but will extend out in x only the distance $c(t - t_1)$, as shown in part (b) of the figure. When we add these two solutions, using the principle of superposition, we find that the sum of the two sources is a current of one unit for the time from zero to t_1 , and a current of three units for times greater than t_1 . At the time t the fields will vary with x as shown in part (c) of Fig. 20-2.

Now let's take a more complicated problem. Consider a current which is turned on to one unit for a while, then turned up to three units, and later turned off to zero. What are the fields for such a current? We can find the solution in the same way - by adding the solutions of three separate problems. First, we find the fields for a step current of unit strength. (We have solved that problem already.) Next, we find the fields produced by a step current of two units. Finally, we solve for the fields of a step current of seven three units. When we add the three solutions, we will have a current which is one unit strong from $x = 0$ to some later time, say t_1 , then three units strong until a still later time t_2 , and then turned off—(or

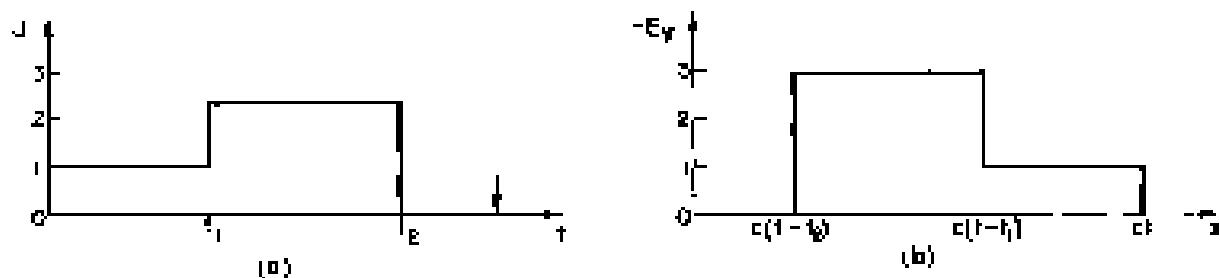

Fig. 20-3. If the current source strength varies as shown in (a), then at the time t shown by the arrow the electric field as a function of x is as shown in (b).

is to zero. A graph of the current as a function of time is shown in Fig. 20-3(a). When we find the three solutions for the electric field, we find that its variation with x , at a given instant t , is as shown in Fig. 20-3(b). The field is no valid representation of the current. The field distribution in space is a nice graph of current variations with time, only drawn backwards. As time goes on, the whole picture moves outward at the speed c , so there is a little blob of field travelling toward positive x , which contains a completely detailed memory of the history of all the current variations. If we were to stand miles away, we could tell from the variation of the electric or magnetic field exactly how the current had varied at the source.

You will also notice that long after all activity at the source has completely stopped and all charges and currents are zero, the blob of field continues to travel through space. We have a distribution of electric and magnetic fields that exist independently of any charges or currents. That is the new effect that comes from the complete set of Maxwell's equations. If we want, we can give a complete mathematical representation of the analysis we have just done by writing that the electric field at a given place and a given time is proportional to the current at the source, only not at the same time, but at the earlier time $t - x/c$. We can write

$$E_y(t) = \frac{J(t-x/c)}{2\epsilon_0 c} \quad (20.5)$$

We have, believe it or not, already derived this same equation from another point of view in Vol. I, when we were dealing with the theory of the index of refraction. Then, we had to figure out what fields were produced by a thin layer of oscillating dipoles in a sheet of dielectric material, with the dipoles set in motion by the electric field of an incoming electromagnetic wave. Our problem was to calculate the combined fields of the original wave and the waves emitted by the oscillating dipoles. How could we have calculated the fields produced by moving charges when we didn't have Maxwell's equations? At that time we took as our starting point (without any derivation) a formula for the radiation fields produced at large distances from an accelerating point charge. If you will look in Chapter 41 of Vol. I, you will see that Eq. (21.10) there is just the same as the Eq. (20.5) that we have just written down. Although our earlier derivation was correct only at large distances from the source, we see now that the same result continues to be correct even right up to the source.

We want now to look in a general way at the behavior of electric and magnetic fields in empty space far away from the sources, i.e., from the currents and charges. Very near the sources—near enough so that during the delay in transmission, the source has not had time to change much—the fields are very much the same as we have found in what we called the electrostatic or magnetostatic cases. If we go out to distances large enough so that the delays become important, however, the nature of the fields can be radically different from the solutions we have found. In a sense, the fields begin to lose some character of their own when they have gone a long way from all the sources. So we can begin by discussing the behavior of the fields in a region where there are no currents or charges.

Suppose we ask: What kind of fields can there be in regions where ρ and j are both zero? In Chapter 15 we saw that the physics of Maxwell's equations could also be expressed in terms of differential equations for the scalar and vector potentials:

$$\nabla^2\phi - \frac{1}{c^2} \frac{\partial^2\phi}{\partial t^2} = -\frac{\rho}{\epsilon_0}, \quad (20.4)$$

$$\nabla^2A - \frac{1}{c^2} \frac{\partial^2A}{\partial t^2} = -\frac{j}{\epsilon_0 c^2}. \quad (20.5)$$

If ρ and j are zero, these equations take on the simpler form

$$\nabla^2\phi - \frac{1}{c^2} \frac{\partial^2\phi}{\partial t^2} = 0, \quad (20.6)$$

$$\nabla^2A - \frac{1}{c^2} \frac{\partial^2A}{\partial t^2} = 0. \quad (20.7)$$

In free space the scalar potential ϕ and each component of the vector potential A all satisfy the same mathematical equation. Suppose we let ψ (phi) stand for any one of the four quantities ϕ, A_x, A_y, A_z ; then we want to investigate the general solutions of the following equation:

$$\nabla^2\psi - \frac{1}{c^2} \frac{\partial^2\psi}{\partial t^2} = 0. \quad (20.8)$$

This equation is called the three-dimensional wave equation (three-dimensions), because the function ψ may depend in general on x, y , and z , and we need to worry about variations in all three coordinates. This is made clear if we write out explicitly the three terms of the Laplacian operator:

$$\frac{\partial^2\psi}{\partial x^2} + \frac{\partial^2\psi}{\partial y^2} + \frac{\partial^2\psi}{\partial z^2} - \frac{1}{c^2} \frac{\partial^2\psi}{\partial t^2} = 0. \quad (20.9)$$

In free space, the electric fields E and B also satisfy the same equation. For example, since $B = \nabla \times A$, we can get a differential equation for B by taking the curl of Eq. (20.7). Since the Laplacian is a scalar operator, the order of the Laplacian and curl operations can be interchanged:

$$\nabla \times (\nabla^2A) = \nabla^2(\nabla \times A) = \nabla^2B.$$

Similarly, the order of the operations curl and $\partial/\partial t$ can be interchanged:

$$\nabla \times \frac{1}{c^2} \frac{\partial^2A}{\partial t^2} = \frac{1}{c^2} \frac{\partial^2}{\partial t^2}(\nabla \times A) = \frac{1}{c^2} \frac{\partial^2B}{\partial t^2}.$$

Using these results, we get the following differential equation for B :

$$\nabla^2B - \frac{1}{c^2} \frac{\partial^2B}{\partial t^2} = 0. \quad (20.10)$$

So each component of the magnetic field B satisfies the three-dimensional wave equation. Similarly, using the fact that $E = -\nabla\phi - dA/dt$, it follows that the electric field E in free space also satisfies the three-dimensional wave equation:

$$\nabla^2E - \frac{1}{c^2} \frac{\partial^2E}{\partial t^2} = 0. \quad (20.11)$$

All of our electromagnetic fields satisfy the same wave equation, Eq. (20.8). We might well ask: What is the most general solution to this equation? However, rather than tackling that difficult question right away, we will look first at what can be said in general about those solutions in which nothing varies in y and z . (Always do an easy case first so that you can see what is going to happen, and then you can go to the more complicated cases.) Let's suppose that the magnitudes

of \mathbf{B} fields depend only upon x —but there are no restrictions of the fields with y and z . We are, of course, considering plane waves along x . We should expect to get results something like those in the previous section. In fact, we will find precisely the same answers. You may ask: "Why do that over again?" It is important to do it again, first, because we did not show that the waves we found were the most general solutions for plane waves, and second, because we found the fields only from a very particular kind of current source. We would like to ask now: What is the most general kind of one-dimensional wave there can be in free space? We cannot find that by seeing what happens for the one-dimensional waves you must work with greater generality. Also we are going to work this time with differential equations instead of with integral forms. Although we will get the same results, it is a way of practicing back and forth to show that it doesn't make any difference which way you go. You should know how to do things every which way, because when you get a hard problem, you will often find that only one of the various ways is tractable.

We could consider directly the solution of the wave equation for some electromagnetic quantity. Instead, we want to start right from the beginning with Maxwell's equations in free space so that you can see their close relationship to the electromagnetic waves. So we start with the equations in (20.1), setting the charges and currents equal to zero. They become

$$\begin{aligned} \text{I. } \nabla \cdot \mathbf{E} &= 0 \\ \text{II. } \nabla \times \mathbf{E} &= -\frac{\partial \mathbf{B}}{\partial t} \\ \text{III. } \nabla \cdot \mathbf{B} &= 0 \\ \text{IV. } \epsilon' \nabla \times \mathbf{B} &= \frac{\partial \mathbf{E}}{\partial t} \end{aligned} \quad (20.12)$$

We write the first equation out in components:

$$\nabla \cdot \mathbf{E} = \frac{\partial E_x}{\partial x} + \frac{\partial E_y}{\partial y} + \frac{\partial E_z}{\partial z} = 0. \quad (20.13)$$

We are assuming that there are no variations with y and z , so the last two terms are zero. This equation then tells us that

$$\frac{\partial E_x}{\partial x} = 0. \quad (20.14)$$

The solution is that E_x , the component of the electric field in the x direction, is a constant in space. If you look at IV in (20.12), suppose no B -variation in y and z either, you can see that E is also constant in time. Such a field would be the steady x field from some charged condenser plates a long distance away. We are not interested now in such an uninteresting static field; we are at the moment interested only in dynamically varying fields. For $dynamic$ fields, $E_x = 0$.

We have then the important result that for the propagation of plane waves in any direction, the electric field must be at right angles to the direction of propagation. It can, of course, still vary in an complicated way with the coordinate x .

The transverse E -field can always be resolved into two components, say the y -component and the z -component. So let's first work out a case in which the electric field has only one transverse component. We'll take first an electric field that is always in the y direction, with zero z -component. Equivalently, if we solve this problem we can also solve for the case where the electric field is always in the z -direction. The general solution can always be expressed as the superposition of two such fields.

How easy our equations now get. The only component of the electric field that is non-zero is E_y , and all derivatives—except those with respect to x —are zero. The rest of Maxwell's equations then become quite simple.

Let's look next at the second of Maxwell's equations [11 of Eq. (20.12)]. Writing out the components of the curl \mathbf{E} , we have

$$(\nabla \times \mathbf{E})_y = \frac{\partial E_x}{\partial y} - \frac{\partial E_y}{\partial z} = 0,$$

$$(\nabla \times \mathbf{E})_y = \frac{\partial E_x}{\partial z} - \frac{\partial E_x}{\partial y} = 0,$$

$$(\nabla \times \mathbf{E})_x = \frac{\partial E_z}{\partial x} - \frac{\partial E_x}{\partial z} - \frac{\partial E_z}{\partial x}.$$

The y -component of $\nabla \times \mathbf{E}$ is zero because the derivatives with respect to y and z are zero. The x -component is also zero; the first term is zero because the derivative with respect to z is zero, and the second term is also because E_x is zero. The only non-zero component of the curl of \mathbf{E} that is not zero is the z -component, which is equal to $\partial E_z / \partial x$. Setting the three components of $\nabla \times \mathbf{E}$ equal to the corresponding components of $-\partial \mathbf{B} / \partial t$, we can conclude the following:

$$\frac{\partial B_z}{\partial t} = 0, \quad \frac{\partial B_z}{\partial z} = 0. \quad (20.15)$$

$$\frac{\partial B_z}{\partial t} = -\frac{\partial E_z}{\partial x}. \quad (20.16)$$

Since the x -component of the magnetic field and the y -component of the magnetic field both have zero time derivatives, these two components are just constant fields and correspond to the magnetostatic solutions we found earlier. Somebody may have left some permanent magnets near where the waves are propagating. We will ignore these constant fields and set B_x and B_y equal to zero.

Incidentally, we would already have concluded that the x -component of \mathbf{B} should be zero for a different reason. Since the divergence of \mathbf{B} is zero (from the third Maxwell equation), applying the same arguments we used above for the electric field, we would conclude that the longitudinal component of the magnetic field can have no variation with x . Since we are ignoring such uniform fields in our wave solutions, we would have set B_x equal to zero. In plane electromagnetic waves the B -field, as well as the E -field, must be directed at right angles to the direction of propagation.

Equation (20.16) gives us the additional propagation that if the electric field has only a y -component, the magnetic field will have only a z -component. So \mathbf{E} and \mathbf{B} are at right angles to each other. This is exactly what happened in the special wave we have already considered.

We are now ready to use the last of Maxwell's equations (or box space [IV of Eq. (20.12)]). Writing out the components, we have

$$c^2 (\nabla \times \mathbf{B})_y = c^2 \frac{\partial B_z}{\partial y} + c^2 \frac{\partial B_y}{\partial z} = \frac{\partial E_x}{\partial t},$$

$$c^2 (\nabla \times \mathbf{B})_y = c^2 \frac{\partial B_z}{\partial z} + c^2 \frac{\partial B_z}{\partial x} = \frac{\partial E_y}{\partial t}, \quad (20.17)$$

$$c^2 (\nabla \times \mathbf{B})_x = c^2 \frac{\partial B_y}{\partial x} - c^2 \frac{\partial B_x}{\partial y} = \frac{\partial E_z}{\partial z}.$$

Of the six derivatives of the components of \mathbf{B} , only the term $\partial B_z / \partial x$ is not equal to zero. So the three equations give us simply

$$-c^2 \frac{\partial B_z}{\partial x} = \frac{\partial E_z}{\partial z}. \quad (20.18)$$

The result of all our work is that only one component each of the electric and magnetic fields is not zero, and that these components linearly satisfy Eqs. (20.16) and (20.18). The two equations can be exchanged into one if we differentiate the first with respect to x and the second with respect to t ; the left-hand sides of the

two equations will then be the same (except for the factor c^2). So we find that ψ satisfies the equation

$$\frac{\partial^2 \psi}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2} = 0. \quad (20.19)$$

We have seen the same differential equation before, when we studied the propagation of sound. It is the wave equation for one-dimensional waves.

You should note that in the process of our derivation we have found something more than is contained in Eq. (20.11). Maxwell's equations have given us the fundamental fact that electromagnetic waves have field components only at right angles to the direction of the wave propagation.

Let's review what we know about the solutions of the one-dimensional wave equation. If any quantity ψ satisfies the one-dimensional wave equation,

$$\frac{\partial^2 \psi}{\partial x^2} - \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2} = 0, \quad (20.20)$$

then one possible solution is a function $\psi(x, t)$ of the form

$$\psi(x, t) \sim R(x - ct), \quad (20.21)$$

that is, some function of the single variable $(x - ct)$. The function $f(x - ct)$ represents a "rigid" pattern in x which travels toward positive x at the speed c (see Fig. 20-4). For example, if the function f has a maximum when its argument is zero, then for $t = 0$ the maximum of ψ will occur at $x = 0$. At some later time, say $t = 10$, ψ will have its maximum at $x = 10c$. As time goes on, the maximum moves toward positive x at the speed c .

Sometimes it is more convenient to say that a solution of the one-dimensional wave equation is a function of $(x - x/c)$. However, this is saying the same thing, because any function of $(x - x/c)$ is also a function of $(x - ct)$:

$$F(t - x/c) = F\left[1 - \frac{x - ct}{c}\right] = f(x - ct).$$

Let's show that $f(x - ct)$ is indeed a solution of the wave equation. Since ψ is a function of only one variable—the variable $(x - ct)$ —we shall let f' represent the first derivative of f with respect to its variable; and f'' represent the second derivative of f . Differentiating Eq. (20.21) with respect to x , we get

$$\frac{\partial \psi}{\partial x} = f'(x - ct),$$

since the derivative of $(x - ct)$ with respect to x is 1. The second derivative of ψ with respect to x is clearly

$$\frac{\partial^2 \psi}{\partial x^2} = f''(x - ct). \quad (20.22)$$

Taking derivatives of ψ with respect to t , we find

$$\begin{aligned} \frac{\partial \psi}{\partial t} &= f'(x - ct)f'(-1), \\ \frac{\partial^2 \psi}{\partial t^2} &= -c^2 f''(x - ct). \end{aligned} \quad (20.23)$$

We see that ψ does indeed satisfy the one-dimensional wave equation.

You may be wondering: "If I have the wave equation, how do I know that I should take $f(x - ct)$ as a solution? I don't like this backward picture. Isn't there some forward way to find the solution?" Well, one good forward way is to know the solution. It is possible to "cook up" an apparently forward mathematical argument, especially because we know what the solution is supposed to be, but with an equation as simple as this we don't have to play games. Soon you will get so that when you see Eq. (20.20), you nearly simultaneously see 20-6

Fig. 20-4. The function $\psi(x - ct)$ represents a constant "shape" that travels toward positive x with the speed c .

$\psi = f(x - ct)$ as a solution. (Just as you see the integral of $x^2 dx$, you know right away that the answer is $x^{1/2}$.)

Actually you should also see a little more. Not only is any function of $(x - ct)$ a solution, but any function of $(x + ct)$ is also a solution. Since the wave equation contains only c^2 , changing the sign of c makes no difference. In fact, the most general solution of the one-dimensional wave equation is the sum of two arbitrary functions, one of $(x - ct)$ and the other of $(x + ct)$:

$$\psi = f(x - ct) + g(x + ct). \quad (20.24)$$

The first term represents a wave travelling toward positive x , and the second term an a chirring wave travelling toward negative x . The general solution is the superposition of two such waves both existing at the same time.

We will leave the following interesting question for you to think about. Take a function ψ of the following form:

$$\psi = \sin kx \cos \omega t.$$

This equation isn't in the form of a function of $(x - ct)$ or of $(x + ct)$. Yet you can easily show that this function is a solution of the wave equation by direct substitution into Eq. (20.23). How can we then say that the general solution is of the form of Eq. (20.24)?

Applying our conclusions about the solution of the wave equation to the y -component of the electric field, E_y , we conclude that E_y can vary with x in any arbitrary fashion. However, the fields which do exist can always be represented as the sum of two patterns. One wave is sailing through space in one direction with speed c , with an associated magnetic field perpendicular to the electric field; another wave is travelling in the opposite direction with the same speed. Such waves correspond to the electromagnetic waves that we know about—light, radio-waves, infrared radiation, ultraviolet radiation, X rays, and so on. We have already discussed the emission of light in great detail in Vol. I. Since everything we learned there applies to any electromagnetic wave, we don't need to consider it in great detail here—the behavior of these waves.

We should perhaps make a few further remarks on the question of the polarization of the electromagnetic waves. In our solution we chose to consider the special case in which the electric field has only a y -component. There is clearly another solution for waves travelling in the plus or minus x -direction, with an electric field which has only a x -component. Since Maxwell's equations are linear, the general solution for one-dimensional waves propagating in the x -direction is the sum of waves of E_y and waves of E_x . This general solution is summarized in the following equations:

$$\begin{aligned} E &= (0, E_y, E_z) \\ E_y &= f(x - ct) + g(x + ct) \\ E_z &= f(x - ct) + g(x + ct) \\ B &= (0, B_y, B_z) \\ cB_z &= f(x - ct) - g(x + ct) \\ cB_y &= -f(x - ct) + g(x + ct). \end{aligned} \quad (20.25)$$

Such electromagnetic waves have an E -vector whose direction is not constant but which gyrates around in some arbitrary way in the yz -plane. At every point the magnetic field is always perpendicular to the electric field and to the direction of propagation.

If there are only waves travelling in one direction, say the positive x -direction, there is a simple rule which tells the relative orientation of the electric and magnetic fields. The rule is that the cross product $E \times B$ which is, of course, a vector at right angles to both E and B , points in the direction in which the wave is travelling. If E is rotated into B by a right-hand screw, the sense of going in the direction of the wave velocity. (We shall see later that the vector $E \times B$ has a special physical significance; it is a vector which describes the flow of energy in an electromagnetic field.)

20-2 Three-dimensional waves

We want now to turn to the subject of three-dimensional waves. We have already seen that the vector E satisfies the wave equation. It is also easy to arrive at the same conclusion by arguing directly from Maxwell's equations. Suppose we start with the equation

$$\nabla \times E = -\frac{\partial B}{\partial t}$$

and take the curl of both sides:

$$\nabla \times (\nabla \times E) = -\frac{\partial}{\partial t}(\nabla \times B). \quad (20.26)$$

You will remember that the curl of the curl of any vector can be written as the sum of two terms, one involving the divergence and the other the Laplacian,

$$\nabla \times (\nabla \times E) = \nabla(\nabla \cdot E) - \nabla^2 E.$$

In free space, however, the divergence of B is zero, so only the Laplacian term remains. Also, from the fourth of Maxwell's equations in free space [Eq. (20.12)] the time derivative of $\epsilon^{-1} \nabla \times B$ is the second derivative of B with respect to t ,

$$-\epsilon^{-1} \frac{\partial}{\partial t}(\nabla \times B) = \frac{\partial^2 B}{\partial t^2}.$$

Equation (20.26) then becomes

$$\nabla^2 E = \frac{1}{\epsilon \mu} \frac{\partial^2 B}{\partial t^2},$$

which is the three-dimensional wave equation. Written out in all its glory, this equation is, of course,

$$\frac{\partial^2 E}{\partial x^2} + \frac{\partial^2 E}{\partial y^2} + \frac{\partial^2 E}{\partial z^2} = \frac{1}{\epsilon \mu} \frac{\partial^2 B}{\partial t^2} = 0. \quad (20.27)$$

How shall we find the general wave solution? The answer is that all the solutions of the three-dimensional wave equation can be represented as a superposition of the one-dimensional solutions we have already found. We obtained the equation for waves which move in the x -direction by supposing that the field did not depend on y and z . Obviously, there are other solutions in which the fields do not depend on y and z , representing waves going in the y -direction. Then there are solutions which do not depend on x and y , representing waves travelling in the z -direction. Or, in general, since we have written our equations in vector form, the three-dimensional wave equation can have solutions which are plane waves moving in any direction at all. Again, since the equations are linear, we may have simultaneously as many plane waves as we wish, travelling in as many different directions. Thus the most general solution of the three-dimensional wave equation is a superposition of all sorts of plane waves moving in all sorts of directions.

Try to imagine what the electric and magnetic fields look like at present in the space in this lecture room. First of all, there is a steady magnetic field; it comes from the currents in the wires in the earth—that is, the earth's steady magnetic field. Then there are some irregular, nearly static electric fields produced perhaps by electric charges generated by friction as various people move about in their

charge and only their ends sheared against the chain atoms. Then there are other magnetic fields produced by oscillating currents in the electrified wires—fields which vary in frequency, ν , cycles per second, in synchronism with the generator or Hertzian (Maxwell) field. But more interesting are the electric and mag. field varying at much higher frequencies. For instance, as light leaves from window to floor and wall to wall, there are little wiggles of the electric and magnetic fields moving along at 186,000 miles per second. Then there are also infrared waves travelling from the waterbedheads to the cold blackboard. And we have forgotten the ultraviolet light, λ -rays, and the radiowaves travelling through the room.

Flying across the room are electromagnetic waves which carry movies of a jacobean. There are waves oscillated by a series of impulses representing pictures of events going on in other parts of the world, or of inspiration aspirine dissolving in imaginary stomachs. To demonstrate the reality of these waves it is only necessary to turn on electronic equipment that converts these waves into pictures and sounds.

If we go into further detail to analyze even the smallest wiggles, there are tiny electromagnetic waves that have traveled to the room from enormous distances. There are now tiny oscillations of the electric field, whose crests are separated by a distance of one foot, that have come from millions of miles away. (Remember to the earth from the Mariner 11 space craft which has just passed Venus. Its signals carry summaries of information it has picked up about the planets (information obtained from electromagnetic waves that travelled from the planet to the space craft).

There are very tiny wiggles of the electric and magnetic fields, but see waves which originated billions of light years away—from galaxies in the remotest corners of the universe. That this is true has been found by “filling the room with wires” by building antennas as large as this room. Such radiowaves have been detected from places in space beyond the range of the greatest optical telescopes. Even they, the optical telescopes, are simply detectors of electromagnetic waves. What we call the stars are only inferences, inferences drawn from the only planet readily we have yet visited, Earth. From them—from a careful study of the exceedingly complex undulations of the electric and magnetic fields reaching us on Earth.

There is, of course, more: the fields produced by lightning bolts, rays, the fields of the charged cosmic ray particles as they zip through the room, and more, and more. What a complicated thing is the electric field in the space around you! Yet it always satisfies the three dimensional wave equation.

20-3 Scientific imagination

I now appeal you to imagine these electric and magnetic fields. What do you do? Do you know how? How do I imagine the electric and magnetic field? What do I actually see? What are the demands of scientific imagination? Is it any different from trying to imagine that the world is full of invisible angels? No, it is not like imagining invisible angels. It requires a yet a higher degree of imagination to understand the electromagnetic field than to understand invisible angels. Why? Because to make invisible angels understandable, all I have to do is to alter their invisibility a little bit—I make them slightly visible, and then I can see the shapes of their wings, and bodies, and faces. Once I succeed in imagining a visible angel, the achievement required—which is to take almost invisible angels and imagine them completely invisible—is relatively easy. So you say, “Professor, please give me an approximate description of the electromagnetic waves, even though it may be slightly inaccurate, so that I too can see them, as well as I can see almost invisible angels. Then I will modify the picture to the necessary characteristic.”

I’m sorry I wait, the first for you. I don’t know how I have no picture of this electromagnetic field that is in any sense accurate. I have known about the electromagnetic field a long time—I was in the same position 20 years ago that you are now, and I have had 20 years more of experience thinking about these wiggling waves. When I start describing the magnetic field moving through space, I speak of the E - and B fields and wave my arms and you sit by listening that I can see them.

I'll tell you what I see: I see some kind of vague shadowy, wiggling lines—here and there is an E and B written on them somehow, and perhaps some of the lines have arrows on them—an arrow here or there which disappears when I look too closely at it. When I talk about the fields swishing through space, I have a visible connection between the symbols I use to describe the objects and the objects themselves. I cannot really make a picture that is even nearly like the true waves. So if you have some difficulty in making such a picture, you should not be worried that your difficulty is unusual.

Our science makes terrible demands on the imagination. The degree of imagination that is required is much more extreme than that required for some of the ancient ideas. The modern ideas are much harder to imagine. We use a lot of tools, though. We use mathematical equations and rules, and make a lot of pictures. What I usually do is that when I talk about the electric and the field in space, I see some kind of a superposition of all of the diagrams which I've ever seen drawn about them. I don't see little bundles of field lines running about, because it worries me that if I run at a different speed, the bundles would disperse. I can't even always see the electric and magnetic fields because sometimes I think I should have made a picture with the vector potential and the scalar potential, for those were perhaps the more physically significant things that were wiggling.

Perhaps the only hope, you say, is to take a mathematical view. Now, what is a mathematical view? From a mathematical view, there is an electric field vector and a magnetic field vector at every point in space; that is, there are six numbers associated with every point. Can you imagine six numbers associated with each point in space? That's too hard. Can you imagine even one number associated with every point? I cannot! I can imagine such a thing as the temperature to a, every point in space. That seems to be understandable. There is a business and evidence that varies from place to place. But I honestly do not understand the idea of a number at every point.

So perhaps we should put the question: Can we represent the electric field by something more like a temperature, say like the displacement of a piece of jelly? Suppose that we were to begin by imagining that the world was filled with this jelly and that the fields represented some distortion, say a stretching or twisting—of the jelly. Then we could visualize the field. After we "see" what it is like we could extract the jelly away. For many years that's what people tried to do. Maxwell, Faraday, Faraday, and others tried to understand electromagnetism this way. (Sometimes they called the abstract jelly "ether.") But it turned out that the attempt to imagine the electromagnetic field in that way was really standing in the way of progress. We are unfortunately limited to abstractions, to using instruments to detect the field, to using mathematical symbols to describe the field, etc. But nevertheless, in some sense the fields are real, because after we are all finished fiddling around with mathematical equations—with or without making pictures and drawings and trying to visualize the thing—we can still make the instruments detect the signals from Mars or from the sun about galaxies a billion miles away, and so on.

The whole question of imagination in science is often misunderstood by people in other disciplines. They try to test our imagination in the following way. They say, "Here is a picture of some people in a situation. What do you imagine will happen next?" When we say, "I can't imagine," they may think we have a weak imagination. They overlook the fact that whatever we are allowed to imagine in science must be consistent with everything else we know; that the electric fields and the waves we talk about are not just some happy thoughts which we are free to state as we wish, but ideas which must be consistent with all the laws of physics we know. We can't allow ourselves to seriously imagine things which are obviously inconsistent with the known facts of nature. And so our kind of imagination is quite a difficult game. One has to have the imagination to think of something that has never been seen before, never been heard of before. At the same time the thoughts are restricted in a straitjacket, so to speak, limited by the conditions that come from our knowledge of the way nature really is. The problem of creating

something which is new, but which is consistent with everything which has been seen before, is one of extreme difficulty.

While I'm on this subject I would talk about whether it will ever be possible to imagine beauty that we can't see. It is an interesting question. When we look at a rainbow, it looks beautiful to us. Everybody says, "Ooh, a rainbow." If you see how scientific I am, I am afraid to say something is beautiful unless I have an experimental way of defining it. But how would we describe a rainbow if we were blind? We would find when we measure the infrared reflection coefficient of sodium chloride, or when we talk about the frequency of the waves that are coming from some galaxy that we can't see - we make a diagram; we make a plot. For instance, for the rainbow, what it probably is the intensity of the light vs. wavelength measured with a spectrophotometer for each direction in the sky. Eventually, such measurements would give a curve that was rather flat. Then some day, someone would discover that for certain directions of the weather, and at certain angles in the sky, the spectrum of intensity as a function of wavelength would behave strangely; it would have a hump. As the angle of the instrument was varied only a little, the maximum of the hump would move from one wavelength to another. Then one day the physical review of the blind men might publish a technical article with the title "The Intensity of Radiation as a Function of Angle under Various Conditions of the Weather." In this article there might appear a graph such as the one in Fig. 20-5. The author would perhaps remark that at the larger angles there was a large variation of wavelength, whereas at the smaller angles the maximum of the radiation moved at shorter wavelengths. From our point of view, we would say that the light at 43° is predominantly green and the light at 42° is predominantly red.

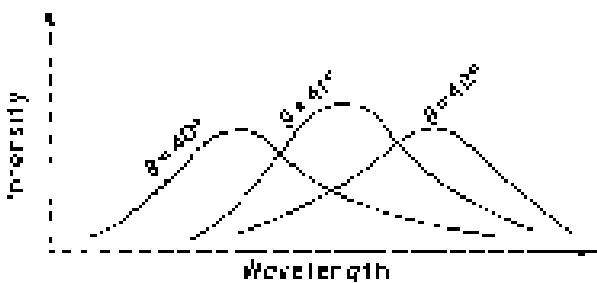

Fig. 20-5. The intensity of electromagnetic waves as a function of wavelength for three angles (measured from the direction opposite the sun, observed only with certain meteorological conditions).

Now if we find the graph of Fig. 20-5 beautiful, I don't know exactly what detail that we appreciate when we look at a rainbow, because our eyes cannot see the exact details in the shape of a spectrum. The eye, however, finds the rainbow beautiful. Do we have enough imagination to see in the spectrum of 1938's sun the beauty we see when we look directly at the sun here? I don't know.

If I suppose I have a graph of the reflection coefficient of a sodium chloride crystal as a function of wavelength in the infrared, and also as a function of angle, I would have a representation of how it would look to my eyes if they could see in the infrared - perhaps some glowing, shiny "Frodo," indeed with reflections from the surfaces of the galaxies! That would be a beautiful thing. But I don't know whether I can see such a graph of the reflection coefficient of NaCl measured with axes I can't see, and say just it has the same beauty.

On the other hand, even if we compare two to an particular microwave source, we can already claim to see a certain beauty in the equations which describe general physical laws. For example, in the wave equation, (20.6), there's a constant, proportional to the reciprocal of the square root of the x , the vector r , and $i\omega/c$. And this constant, being proportional to the x , y , z , and t , suggests to me that such a great beauty must lie in doing the four dimensions, the possibility that space has time, or simultaneous motion, the possibility of analyzing that and the developments of the special theory of relativity. So there is plenty of intellectual beauty associated with the equations.

20-4 Spherical waves

We have seen that there are solutions of the wave equation which correspond to plane waves, and that any electromagnetic wave can be described as a superposition of many plane waves. In certain specific cases, however, it is more convenient to describe the wave field in a different mathematical form. We would like to discuss how the theory of spherical waves, waves which correspond to spherical surfaces that are spreading out from some center. When you drop a stone into a lake, the ripples spread out in regular waves on the surface. They are two-dimensional waves. A spherically wave is a similar thing except that it spreads out in three dimensions.

Before we start describing spherical waves, we need a little mathematics. Suppose we have a function that depends only on the radial distance r from a certain origin—in other words, a function that is spherically symmetric. Let's call the function $\psi(r)$, r being ρ we mean

$$r = \sqrt{x^2 + y^2 + z^2},$$

the radial distance from the origin. In order to find out what functions $\psi(r)$ satisfy the wave equation, we will need an expression for the Laplacian of ψ . So we want to find the sum of the second derivatives of ψ with respect to x , y , and z . We will use the notation that $\psi'(r)$ represents the derivative of ψ with respect to r and $\psi''(r)$ represents the second derivative of ψ with respect to r .

First, we find the derivatives with respect to x . The first derivative is

$$\frac{\partial \psi(r)}{\partial x} = \psi'(r) \frac{\partial}{\partial x}.$$

The second derivative of ψ with respect to x is

$$\frac{\partial^2 \psi}{\partial x^2} = \psi''(r) \left(\frac{\partial r}{\partial x} \right)^2 + \psi' \frac{\partial^2 r}{\partial x^2}.$$

We can evaluate the partial derivatives of r with respect to x from

$$\frac{\partial r}{\partial x} = \frac{x}{r}, \quad \frac{\partial^2 r}{\partial x^2} = \frac{1}{r} \left(1 - \frac{x^2}{r^2} \right).$$

So the second derivative of ψ with respect to x is

$$\frac{\partial^2 \psi}{\partial x^2} = \frac{x^2}{r^2} \psi''(r) + \frac{1}{r} \left(1 - \frac{x^2}{r^2} \right) \psi'. \quad (20.29)$$

Similarly,

$$\frac{\partial^2 \psi}{\partial y^2} = \frac{y^2}{r^2} \psi''(r) + \frac{1}{r} \left(1 - \frac{y^2}{r^2} \right) \psi', \quad (20.30)$$

$$\frac{\partial^2 \psi}{\partial z^2} = \frac{z^2}{r^2} \psi''(r) + \frac{1}{r} \left(1 - \frac{z^2}{r^2} \right) \psi'. \quad (20.31)$$

The Laplacian is the sum of these three derivatives. Remembering that $x^2 + y^2 + z^2 = r^2$, we get

$$r^2 \psi''(r) = \psi''(r) + \frac{2}{r} \psi'(r). \quad (20.32)$$

It is often more convenient to write this equation in the following form:

$$r^2 \psi'' = \frac{1}{r} \frac{d^2}{dr^2} (r \psi). \quad (20.33)$$

If you carry on the differentiation indicated in Eq. (20.33), you will see that the right-hand side is the same as in Eq. (20.31).

If we wish to consider spherically symmetric fields which can propagate as spherical waves, our field quantity must be a function of both r and θ . Suppose

we ask, then, what functions $\psi(r, t)$ are solutions of the three-dimensional wave equation

$$\nabla^2 \psi(r, t) - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} \psi(r, t) = 0. \quad (20.33)$$

Since $\psi(r, t)$ depends only on the spatial coordinates, letting r_1 denote the separation from the \hat{x} -axis we find (above, Eq. (20.32)) that the separation between r_1 and r_2 , since ψ is also a function of r , we could write the derivatives with respect to r as partial derivatives. Then the wave equation becomes

$$\frac{1}{r} \frac{\partial^2}{\partial r^2} (\psi r) - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} (\psi r) = 0.$$

We must now solve this equation, which appears to be much more complicated than the plane wave case. But notice that, if we multiply this equation by r , we get

$$\frac{\partial^2}{\partial r^2} (r\psi) - \frac{1}{c^2} \frac{\partial^2}{\partial t^2} (r\psi) = 0. \quad (20.34)$$

This equation tells us that the function $r\psi$ satisfies the one-dimensional wave equation in the variable r . Using the general principle which we have emphasized so often, that the same equations always have the same solutions, we know that if ϕ is a function only of $(r + ct)$ the ϕ will be a solution of Eq. (20.34). So we know that spherical waves must have the form

$$r\psi(r, t) = f(r - ct).$$

Or, as we have seen before, we can equally well say that $r\psi$ can have the form

$$rk + f(t - r/c).$$

Dividing by r , we find that the field quantity ψ (whatever it may be) has the following form:

$$\psi = \frac{f(t - r/c)}{r}. \quad (20.35)$$

Such a function represents a general spherical wave travelling outward from the origin at the speed c . If we forget about the r in the denominator for a moment, the amplitude of the wave as a function of the distance from the origin at a given time has a certain shape that travels outward at the speed c . The factor r in the denominator, however, says that the amplitude of the wave decreases in proportion to $1/r$ as the wave propagates. In other words, unlike a plane wave in which the amplitude remains constant as the wave runs along, in a spherical wave the amplitude steadily decreases, as shown in Fig. 20-6. This effect is easy to understand from a simple physical argument.

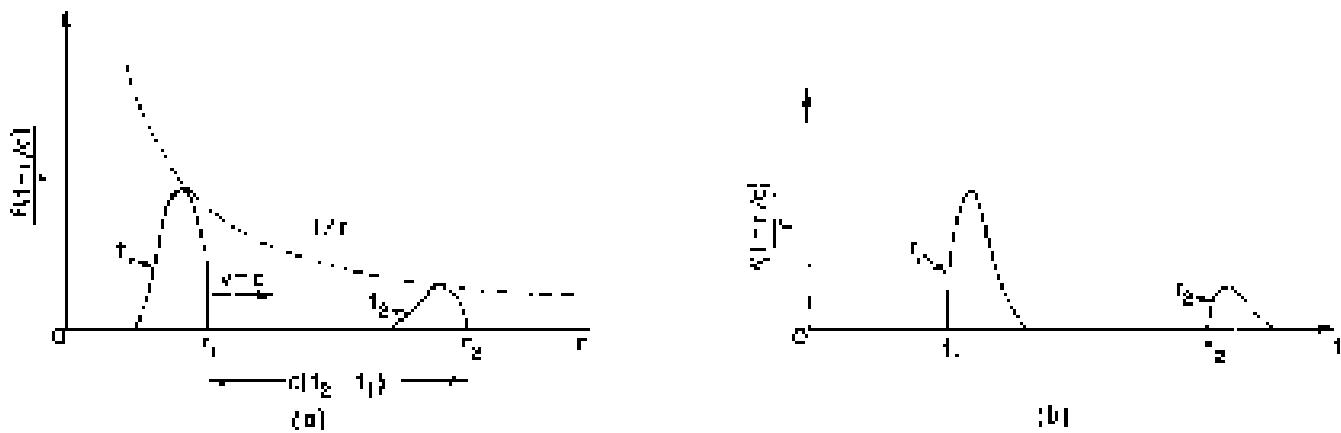

Fig. 20-6. A spherical wave $\psi = f(t - r/c)/r$: (a) ψ as a function of r for $r > r_1$ and the same wave for two later times t_2 ; (b) ψ as a function of t for $r = r_1$ and the same wave after t_1 .

We know that total energy density in a wave depends on the square of the wave amplitude a . As the wave spreads, its energy is spread over larger and larger areas proportional to the radial distance squared. If the total energy is conserved, the energy density must fall as $1/r^2$, and the amplitude of the wave must decrease as $1/r$. So Eq. (20.35) is the "reasonable" form for a spherical wave.

We have discussed the second possible solution to the one-dimensional wave equation:

$$\psi \sim g(r) + h(r),$$

or

$$\psi \sim g(r) + \frac{h(r)}{r}.$$

This also represents a spherical wave, but one which travels toward from large r toward the origin.

We are now going to make a special assumption. We say, without any demonstration whatsoever, that the waves generated by a source are only the waves which go outward. Since we know that waves are caused by the motion of charges, we would like think that the source projects nothing from the charges. It would be quite strange to imagine that before charges were set in motion, a spherical wave emitted out from infinity and arrived at the charges just at the time they began to move. This is a possible solution, but experience shows that when charges are accelerated the waves travel outward from the charges. Although Maxwell's equations would allow either possibility, we will put in an additional fact based on experience: that only the outgoing wave solution makes "physical sense."

We should realize, however, that there is an interesting consequence to this additional assumption: we are changing the symmetry with respect to time that exists in Maxwell's equations. The original equations for E and B , and also the wave equations we derived from them, have the property that if we change the sign of t , the equation is unchanged. These equations say that for every solution corresponding to a wave going in one direction there is an equally valid solution for a wave traveling in the opposite direction. Our statement that we will consider only the outgoing, spherical waves is an important additional assumption. (A formulation of electrodynamics in which this additional assumption is avoided has been recently studied. Surprisingly, in many circumstances it does not lead to physically absurd conclusions, but it would take us too far away to discuss these ideas, not now. We will talk about them a little more in Chapter 28.)

We are going to encounter a important point. In our solution for an outgoing wave, Eq. (20.35), the function ψ is infinite at the origin. That is not really perfect. We would like to find a wave solution which is smooth everywhere. Our solution must represent physically a situation in which there is some source at low energy. In other words, we have inadvertently made a mistake. We have not solved the free wave equation (20.35) everywhere; we have solved Eq. (20.35) with zero on the right everywhere, except at the origin. Our mistake crept in because some of the steps in our derivation are not "legal" when $r = 0$.

Let's show that it is easy to make the same kind of mistake in an electrostatics problem. Suppose we want a solution of the equation for an electrostatic potential in free space $\nabla^2 \phi = 0$. The Lagrangian is equal to zero, because we are assuming that there are no charges anywhere. But what about a spherically symmetric solution to this equation—that is, some function ϕ that depends only on r . Using the formula of Eq. (22.12) for the Laplacian, we have

$$\frac{1}{r} \frac{d^2}{dr^2} (\phi r) = 0.$$

Multiplying this equation by r , we have an equation which is readily integrated:

$$\frac{d^2}{dr^2} (\phi r) = 0.$$

If we integrate once with respect to r , we find that the first derivative of ϕr is a constant. If

constant, which we may call a :

$$\frac{d}{dr}(\alpha) = 0.$$

Integrating again, we find that α is of the form

$$r\phi = ar + b,$$

where b is another constant of integration. So we have found that the following ϕ is a solution for the electrostatic potential in free space:

$$\phi = a + \frac{b}{r}.$$

Somewhat is evidently wrong. In the region where there are no electric charges, we know the solution for the electrostatic potential: the potential is everywhere a constant. That corresponds to the first term in our solution. But we also have the second term, which says that there is a contribution to the potential that varies as one over the distance from the origin. We know, however, that such a potential corresponds to a point charge at the origin. So, although we thought we were solving for the potential in free space, our solution also gives the field for a point source at the origin. Do you see the similarity between what happened now and what happened when we solved for a spherically symmetric solution to the wave equation? If there were really no charges or currents at the origin, there would not be spherical outgoing waves. The spherical waves must, of course, be produced by sources at the origin. In the next chapter we will investigate the connection between the outgoing & incoming electromagnetic waves and the currents and voltages which produce them.

Solutions of Maxwell's Equations with Currents and Charges

21-1 Light and electromagnetic waves

We saw in the last chapter that solving their equations, Maxwell's equations have waves of electric and magnetic. These waves correspond to the phenomena of radio, light, x-rays, and so on, depending on the wavelength. We have already said a little in great detail in Vol. I, but one step we want to take toward the two subjects we want to show that Maxwell's equations can indeed form the basis for our further treatment of the phenomena of light.

When we studied light, we began by writing down an equation for the electric field produced by a charge which moves in any arbitrary way. That equation was

$$\mathbf{E} = \frac{q}{4\pi\epsilon_0 r^2} \left[\hat{\mathbf{e}}_{\perp} + \frac{c}{r} \frac{d}{dt} \left(\hat{\mathbf{e}}_{\perp} \right) - \frac{1}{c^2} \frac{d^2}{dr^2} \hat{\mathbf{e}}_{\perp} \right] \quad (21.1)$$

$$\mathbf{B} = \hat{\mathbf{e}}_{\perp} \times \mathbf{E}.$$

[See Eq. (28.3), Vol. 1.]

If a charge moves in an arbitrary way, the electric field \mathbf{E} , would find out at some point depends only on the position and motion of the charge at now, but at an earlier time— t' , an instant which is earlier by the time it would take light, going at the speed c , to travel the distance r' from the charge to the field point. In other words, if we want the electric field at point (1) at the time t , we must calculate the location (2') of the charge and its motion at the time $(t - r'/c)$, where r' is the distance to the point (1) from the position of the charge (2') at the time $(t - r'/c)$. The prime is to remind you that r' is the "separation" (distance) from the point (2) to the point (1), and not the actual distance between point (2'), the position of the charge at the time t' , and the field point (1) [see Fig. 21.1]. Note that we are using a different convention here for the direction of the unit vector $\hat{\mathbf{e}}$. In Chapters 28 and 36 of Vol. I it was convenient to take $\hat{\mathbf{e}}$ round, hence $\hat{\mathbf{e}}$ pointing toward the source. Now we are following the definition we took for Coulomb's law, in which $\hat{\mathbf{e}}$ is directed from the charge, at (2'), toward the field point at (1). The only difference, of course, is that our new $\hat{\mathbf{e}}$ (and \mathbf{e}) are the negatives of the old ones.

We have also seen that if the velocity v of a charge is always much less than c , and if we consider only points at large distances from the charge, so that only the last term of Eq. (21.1) is important, the fields can also be written as

$$\mathbf{E} = -\frac{q}{4\pi\epsilon_0 c r'^2} \left[\text{acceleration of the charge at } (t - r'/c) \right] \hat{\mathbf{e}}_{\perp} \quad (21.1')$$

and

$$\mathbf{B} = \hat{\mathbf{e}}_{\perp} \times \mathbf{E}$$

Let's look at what the complete equation, Eq. (21.1), says in a little more detail. The vector $\hat{\mathbf{e}}_{\perp}$ is the unit vector to point (1) from the "earlier" position (2'). The first term, then, is what we would expect for the Coulomb field of the charge at its retarded position—we may call this "the retarded Coulomb field." The electric field depends inversely on the square of the distance r' and directly from the retarded position of the charge (the $\hat{\mathbf{e}}_{\perp}$ is in the direction of \mathbf{E}).

But let's look at the first term. The $d/\frac{dt}{dt}$ term tells us that the laws of electricity do not say that all the fields stay the same as the static ones, but instead change (which is what people sometimes like to say). To the "retarded Coulomb field" we must

 Chapter 36, Vol. I, Relativistic Effects on Radiation

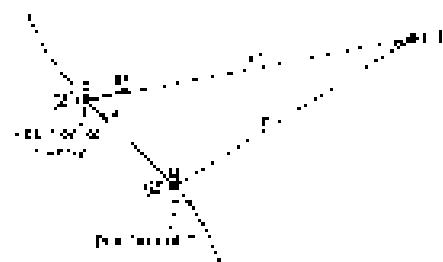

Fig. 21.1. The fields at (1) at the time t depend on the position (2') occupied by the charge q at the time $(t - r'/c)$.

add the other two terms. The second term says that there is a "correction" to the retarded Coulomb field which is the rest of charge of the retarded Coulomb field multiplied by c/ϵ_0 , the retardation delay. In a way of speaking, this term tends to compensate for the retardation in the first term. The first two terms correspond to computing the "retarded Coulomb field" and then extrapolating it forward in time by the amount c/ϵ_0 , that is, "up to the date." The extrapolation is linear, as if we were to assume that the "retarded Coulomb field" would continue to change at the same rate as for the charge at the point (t) . If the field is changing slowly, the effect of the retardation is almost completely removed by the correction term, and the two terms together give us an electric field that is the "instantaneous Coulomb field," that is, the Coulomb field of the charge at the point (t) to a very good approximation.

Finally, there is a third term in Eq. (21.1) which is the second derivative of the unit vector \hat{r} . For our study of the phenomena of light, we made use of the fact that far away from the charge the first two terms went inversely as the square of the distance and, for large distances, became very weak in comparison to the last term, which was $\propto 1/r^3$. So we concentrated initially on the last term, and we know now that it is typical for large distances (proportional to the separation of the source and of the charge). Light happens to be linear of sight. (Again, for most of our work in Vol. I we took the case in which the charges were moving; see earlier stability.) We considered the relativistic effects in only one chapter, Chapter 36.

Now we should try to connect the two things together. We have just Maxwell's equations, and we have Eq. (21.1) for the field of a point source. We should certainly ask whether they are equivalent. If we can deduce Eq. (21.1) from Maxwell's equations, we will really understand the connection between light and wave propagation. To make this connection is the main purpose of this chapter.

It turns out that we won't quite make it—that the mathematical details get too complicated for us to carry through in all their gory details. But, we will get as close as enough so that you should easily see how the connection could be made. The missing pieces will only be in the mathematical details. Some of you may find the mathematics in this chapter rather complicated, and you may not wish to follow the argument very closely. We think it is important, however, to make the connection between what you have learned earlier and what you are learning now, or at least to indicate how such a connection can be made. You will notice, if you look over the earlier chapters, that wherever we have taken a statement as a starting point for a discussion, we have carefully explained whether it is a new "assumption" that is a "basic law," or whether it can ultimately be deduced from some other laws. We hope to give you in the spirit of these lectures to make the connection between light and Maxwell's equations. If it gets difficult in places, well, that's life. There is no other way.

21-2 Spherical waves from a point source

In Chapter 18 we found that Maxwell's equations could be solved by letting

$$E = -\nabla \phi + \frac{\partial A}{\partial t} \quad (21.7)$$

$$\text{and} \quad B = \nabla \times A, \quad (21.8)$$

where ϕ and A must then be solutions of the equations

$$\nabla^2 \phi = \frac{1}{c^2} \frac{\partial^2 \phi}{\partial t^2} = -\frac{\rho}{\epsilon_0} \quad (21.4)$$

$$\text{and} \quad \nabla^2 A = \frac{1}{c^2} \frac{\partial^2 A}{\partial t^2} = -\frac{j}{\mu_0 c^2}, \quad (21.5)$$

and must also satisfy the condition that

$$\nabla \cdot A = -\frac{1}{c^2} \frac{\partial \phi}{\partial t}. \quad (21.6)$$

Now we will find the solution of Eqs. (21.4) and (21.5). To do that we have to find the solution ψ of the equation

$$\nabla^2\psi + \frac{1}{c^2}\frac{\partial^2\psi}{\partial t^2} = -\epsilon, \quad (21.7)$$

where ϵ , which we can take to be negative, is known. Of course, a consequence of $\epsilon < 0$ in Eq. (21.4) is $\epsilon = -\epsilon_0 r^2$ if ψ is to be finite, but we want to solve Eq. (21.7) as a most general problem and consider what ψ and ϵ are physically.

In place of ψ where a and b are zero—in what we have called “free” space—the potentials ϕ and ψ , and the fields E and B , all satisfy the three-dimensional wave equation without sources, whose “einsteinian” form is

$$\nabla^2\psi = \frac{1}{c^2}\frac{\partial^2\psi}{\partial t^2} = 0. \quad (21.8)$$

In Chapter 20 we saw that solutions of this equation can represent waves of various kinds: plane waves in the \hat{z} direction, $\psi = f(z) = e^{ikz}$; plane waves in the \hat{x} or \hat{y} direction, or in any other direction; or spherical waves of the form

$$\psi(r, \theta, \phi) = \frac{f(r - r/c)}{r}. \quad (21.9)$$

(The solutions can be written in still other ways, for example cylindrical waves that spread out from an axis.)

We also remarked that, physically, Eq. (21.9) does not represent a wave in free-space—that there must be charges at the origin to get the outgoing wave started. In other words, Eq. (21.9) is a solution of Eq. (21.8) everywhere except right near $r = 0$, where it cannot be a solution of the complete equation (21.7), including sources. Let's see how that works. What kind of a source ϵ in Eq. (21.7) would give rise to a wave like Eq. (21.9)?

Suppose we have the spherical wave of Eq. (21.9) and look at what's happening for very small r . Then the retardation $-r/c$ in $f(r - r/c)$ can be neglected—provided f is a smooth function—and ψ becomes

$$\psi \sim \frac{f(0)}{r} \quad (r \rightarrow 0). \quad (21.10)$$

So ψ is just like a Coulomb field for a charge at the origin that varies with $1/r$. That is, if we had a truly lumpy bit of charge, bounded in a very small region near the origin, with a density σ , we know that

$$\phi = \frac{Q/4\pi\epsilon_0}{r},$$

where $Q = \int \rho dV$. Now we know that such a ϕ satisfies the equation

$$\nabla^2\phi = -\frac{\rho}{\epsilon_0},$$

Following the same mathematics, we would say that the ψ of Eq. (21.10) satisfies

$$\nabla^2\psi = -\epsilon \quad (r \rightarrow 0), \quad (21.11)$$

where ϵ is related to f by

$$f = \frac{S}{4\pi},$$

with

$$S = \int \sigma dV.$$

The only difference is that in the general case, ψ and, therefore, S , can be a function of time.

Now the important thing is that if ψ satisfies Eq. (21.11) for small r , it also satisfies Eq. (21.7). As we go very close to the origin, the $1/r$ dependence of ψ

causes the space derivatives to become very large. But the time derivative is zero there since sources (1) are just point charges at rest. So we get to zero, the term $\epsilon_0 \nabla^2 \phi_0$ in Eq. (21.7) as the right-hand integral in Eq. (21.5), and Eq. (21.7) becomes equivalent to Eq. (21.11).

To summarize, then, if the source function ϕ_0 of Eq. (21.7) is located at the origin and has the value ϕ_0 , then

$$\Phi(t) = \int \phi(t') dV, \quad (21.12)$$

the solution of Eq. (21.7) is

$$\phi(x_1, y_1, z_1, t) = \frac{1}{4\pi} \frac{\delta(t - t')}{r}, \quad (21.13)$$

The only effect of the term $\epsilon_0 \nabla^2 \phi_0$ in Eq. (21.7) is to introduce the retardation $t - t'$ even in the Coulomb-like potential.

21-5 The general solution of Maxwell's equations

We have found the solution of Eq. (21.2) for a "point" source—the last question is: What is the solution for a piecewise source? That is, why we can think of any source $\phi(x_1, y_1, z_1, t)$ as made up of the sum of many "point" sources, each with a finite element of dV , and each with the source strength $\phi_0(x_1, y_1, z_1)$? Since Eq. (21.2) is linear, the resultant field is the superposition of the fields from all of such source elements.

Using the results of the preceding section (Eq. (21.12)) we know that the field ϕ_0 at the point (x_2, y_2, z_2) at (1) for short r at the time t from a source element with a dipole $\phi_0(x_1, y_1, z_1)$ at (2) for short r' is given by

$$d\phi(1, t) = \frac{\phi_0(x_1, t')}{4\pi r'^2},$$

where r_{12} is the distance from (2) to (1). Adding the contributions from all the pieces of the source means, of course, taking an integral over all regions where $r' \neq 0$; so we have

$$\phi(1, t) = \int \frac{\phi_0(x_1, t')}{4\pi r_{12}^2} dV_2. \quad (21.14)$$

That is, the field at (1) at the time t is the sum of all the spherical waves which leave the source elements at (2) at the times $t' = |x_1 - x_2|/c$. This is the solution of our wave equation for any set of sources.

We are now how to obtain a general solution of Maxwell's equations. If by ϕ we mean the scalar potential ϕ , the wave function ψ becomes ϕ_0 , etc. Or we can let ψ represent any one of the three components of the vector potential A , depending by the corresponding component of $\partial \phi_0 / \partial t$. Thus, if we knew the charge density $\rho(x_1, y_1, z_1)$ and the current density $j(x_1, y_1, z_1, t)$ everywhere, we can immediately write down the solutions of Eqs. (21.9) and (21.5). They are

$$\phi(1, t) = \int \frac{\rho(x_1, t' - r_{12}/c)}{4\pi r_{12}^2} dV_2, \quad (21.15)$$

and

$$A(1, t) = \int \frac{j(x_1, t' - r_{12}/c)}{4\pi c r_{12}^2} dV_2. \quad (21.16)$$

The fields E and B can then be found by differentiating the potentials using Eqs. (21.2) and (21.3). [Incidentally, it is possible to verify that the ϕ and A obtained from Eqs. (21.15) and (21.16) do satisfy the equality (21.6).]

We have solved Maxwell's equations. Given the currents and charges in any circumstance, we can find the potential ϕ directly by a few integrals and then differentiate and get the fields. So we have finished off the Maxwell theory. At the moment we close the ring back to our theory of light, because to connect with our earlier work on light, we need only calculate the electric field from a

moving charge. All that remains is to take a moving charge, calculate the potential due to it, then integrate, and then differentiate to find E from $-\nabla\phi = \epsilon_0 E/\rho$. We would get Eq. (21.13). It turns out to be lots of work, but that's the principle.

So here is the center of the universe of electromagnetism—the complete theory of electricity and magnetism, and of light; a complete description of the fields produced by any moving charges; and more. It is all here. Here is the structure built by Maxwell, complete in all its power and beauty. It is probably one of the greatest accomplishments of physics. To remind you of its importance, we will put it all together in a nice frame.

Maxwell's equations:

$$\nabla \cdot E = \frac{\rho}{\epsilon_0} \quad \nabla \cdot B = 0$$

$$\nabla \times E = -\frac{\partial B}{\partial t} \quad \nabla \times B = \frac{J}{\epsilon_0} + \frac{\partial E}{\partial t}$$

Their solutions:

$$E = -\nabla\phi - \frac{\partial A}{\partial t}$$

$$B = \nabla \times A$$

$$\phi(r, t) = \int \frac{q(1, t - r_{12}/c)}{4\pi\epsilon_0 r_{12}} dV_1$$

$$A(r, t) = \int \frac{q(2, t - r_{12}/c)}{4\pi\epsilon_0 r_{12}} dV_2$$

21-4 The fields of an oscillating dipole

We have still not lived up to our promise to derive Eq. (21.1) for the electric field of a point charge in motion. Even with the results we already have, it is a relatively complicated thing to do. We have not found Eq. (21.1) anywhere in the influential literature except in Vol. I of these lectures.* So you can see that it is not easy to derive. (The fields of a moving charge have been written in many other forms that are equivalent, of course.) We will have to limit ourselves here just to showing that, in a few examples, Eqs. (21.15) and (21.16) give the same results as Eq. (21.1). First, we will show that Eq. (21.1) gives the correct fields with only the restriction that the motion of the charged particle is nonrelativistic. (This, the special case will take care of 99 percent, or more, of what we said about light.)

We consider a situation in which we have a blob of charge that is moving about in some way, in a small region, and we will find the fields far away. To put it another way, we are finding the field at any distance from a point charge that is shaking up and down in very small motion. Since light is usually emitted from neutral objects such as atoms, we will consider that our wiggling charge has greater near equal and opposite charges at rest. If the separation between the centers of the charges is a , the charges will have a dipole moment $\mathbf{p} = qa$, which we take to be a function of time. Now we should expect that if we look at the fields close to the charges, we won't have to worry about the delay: the electric field will be exactly the same as the one we have calculated earlier for an electro-dipole

* This formula was worked out by R. P. Feynman, in about 1990, and given in his lectures as a good way of thinking about synchrotron radiation.

—using, of course, the instantaneous dipole moment $\rho(t)$. But if we go very far out, we ought to find a term in the field that goes as $1/c$ and depends on the acceleration of the charge perpendicular to the line of sight. Let's see if we get such a result.

We begin by calculating the vector potential A , using Eq. (21.16). Suppose that our moving charge is in a small blob whose charge density is given by $\rho(x, y, z)$, and the wave function is harmonic at any time and with the velocity v . Then the current density $j(x, y, z, t)$ will be equal to $v \rho(x, y, z)$. It will be convenient to take our coordinate system so that the z -axis is in the direction of v ; then the geometry of our problem is as shown in Fig. 21-2. We want the integral

$$\int \frac{R^2(t) - r^2/3}{r^3} dV_2. \quad (21.17)$$

Now if the size of the charge blob is really very small compared with r_{12} , we can set the r_{12} term in the denominator equal to r , the distance to the center of the blob, and take it outside the integral. Next, we are also going to set $r_{12} = r$ in the numerator, although that is not really quite right. It is not right because we should take r at, say, the top of the blob and slightly different time than we used for just the bottom of the blob. When we set $r_{12} = r$ in $j(t) = v \rho(x, y, z)$, we are taking the current density for the whole blob at the same time ($t = \tau/v$). That is an approximation that will be good only if the velocity v of the charge is much less than c . So we are making a nonrelativistic calculation. Replacing r by $r\tau$, the integral (21.17) becomes

$$\frac{1}{r} \int \rho(t) (1 - r/\tau)^2 dV_2.$$

Since all the charge has the same velocity, this integral is just v/c times the total charge ρ . But ρ is just $d\rho/dt$, the rate of change of charge content, which is, of course, to be evaluated at the instant $t = \tau/v$. We will write it as $\rho(t - \tau/v)$. So we get for the vector potential

$$A(t, r) = \frac{1}{4\pi c r^2} \frac{\rho(t - \tau/v)}{v}. \quad (21.18)$$

Our result says that the current in a varying dipole produces a vector potential in the form of spherical waves whose source strength is $\rho/16\pi c^2 v^2$.

We can now get the magnetic field from $B = \nabla \times A$. Since ρ is really in the z -direction, A has only a z -component; there are only two directions perpendicular to the curl. So $B_x = i \partial A_y / \partial z$ and $B_z = -i \partial A_y / \partial x$. Let's first look at B_x ,

$$B_x = \frac{i A_y}{\partial z} = \frac{1}{4\pi c r^2} \frac{\partial \rho(t - \tau/v)}{\partial y}. \quad (21.19)$$

Every time on the calculation, we must remember that $x = \sqrt{r^2 + y^2 + z^2}$, so

$$B_x = \frac{1}{4\pi c r^2} \rho(t - \tau/v) \frac{\partial}{\partial y} \left(\frac{1}{\sqrt{r^2 + y^2}} \right) = \frac{1}{16\pi c^2 r^3} \frac{\partial \rho(t - \tau/v)}{\partial y}. \quad (21.20)$$

Remembering that $y/\partial y = -v/r$, the first term gives

$$\frac{1}{4\pi c r^2} \frac{\rho(t - \tau/v)}{r^3}, \quad (21.21)$$

which is proportional to $1/r^3$ like the fields of a static dipole (because ρ/t is constant for a given direction).

The second term in Eq. (21.20) gives us the new effect. Carrying out the differentiation, we get

$$= \frac{1}{4\pi c r^2} \frac{\partial}{\partial z} \rho(t - \tau/v), \quad (21.22)$$

where τ means, of course, the second derivative of ρ with respect to t . The term,

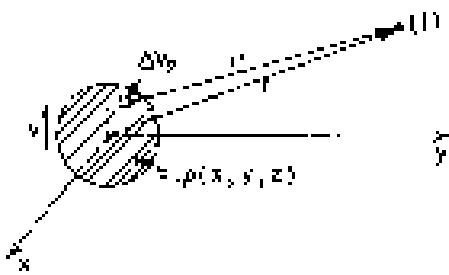

Fig. 21-2. The potentials at (1) are given by integrals over the charge density ρ .

which comes from differentiating the monopole, is responsible for radiation. First, it describes a field which decreases with distance only as $1/r$. Second, it depends on the acceleration \ddot{r} . That's why it's important to see how we're going to get a result like Eq. (21.1), which requires the radiation velocity.

Let's examine in a little more detail how this radiation term looks about—it is such an interesting and important result. We start with the expression (21.18), which has a $1/r$ dependence and is therefore like a Coulomb potential, except for the delay term in the numerator. Why is it true that, when we differentiate with respect to space around nodes to get the fields, we don't just get a $1/r^2$ field—well, of course, the source has loop time delays?

We can see why it is following way: Suppose that we let our dipole oscillate up and down in a sinusoidal motion. Then we would have

$$\vec{p} = \vec{p}_0 + p_0 \sin \omega t$$

and

$$J_r = \frac{1}{4\pi c r^2} \frac{\omega p_0 \cos \omega t - \dot{p}_0}{r}.$$

If we plot a graph of J_r as a function of r at a given instant, we get the curve shown in Fig. 21-5. The peak amplitude decreases as $1/r$, but there is, in addition, an oscillation in space, bounded by the $1/r$ envelope. When we take the spatial derivatives, they will be proportional to the slope of the curve. In fact the figure we see that there are slopes much steeper than the slope of the $1/r$ envelope itself. This, in fact, is clear, that for a given frequency the peak slopes are proportional to the amplitude of the wave, which varies as $1/r$. So that explains the drop-off rate of the radiation term.

It all comes about because the variations with time at the source are transformed into variations in space as the waves are propagated outward, and the magnetic fields depend on the spatial derivatives of the potential.

Let's go back and finish our calculation of the magnetic field. We have for B_r the two terms (21.21) and (21.22), so

$$B_r = \frac{1}{4\pi c \mu_0 r^2} \left[\frac{p_0 \theta(r - r_0)}{r^2} - \frac{p_0 \theta'(r - r_0)}{r^2} \right]$$

With the same kind of mathematics, we get

$$B_r = \frac{1}{4\pi c \mu_0 r^2} \left[\frac{\partial^2 \theta(r - r_0)}{r^2} - \frac{\partial \theta'(r - r_0)}{r^2} \right]$$

Or we can add it all together in a nice vector formula:

$$\vec{B} = \frac{1}{4\pi c \mu_0 r^2} \left[\vec{p} + (\vec{v}_0 c) \vec{s}_0 \cdot \hat{r} \hat{r} \times \vec{r} \right] \quad (21.23)$$

Now let's look at this formula. First of all, if we go very far out in r , only the \vec{p} term remains. The direction of \vec{B} is given by $\vec{p} \times \vec{r}$, which is at right angles to the radius \vec{r} and also at right angles to the acceleration, as in Fig. 21-4. Everything is at once at right; Let's take the result, we get from Eq. (21.17)

Now let's look at what we are not used to—at what happens closer in. In Section 14-9 we worked out the law of Biot and Savart for the magnetic field of an elemental current. We found that a current element $d\vec{l}$ contributes to the magnetic field the amount

$$d\vec{B} = \frac{1}{4\pi c \mu_0 r^2} \frac{\vec{l} \times \vec{r}}{r^3} dI. \quad (21.24)$$

You see that this formula looks very much like the first term of Eq. (21.23), if we remember that \vec{p} is the current. But there is one difference. In Eq. (21.23), the current is to be evaluated at the origin ($r = r_0$), which doesn't appear in Eq. (21.24). Actually, however, Eq. (21.24) is still very good for small r , because the second

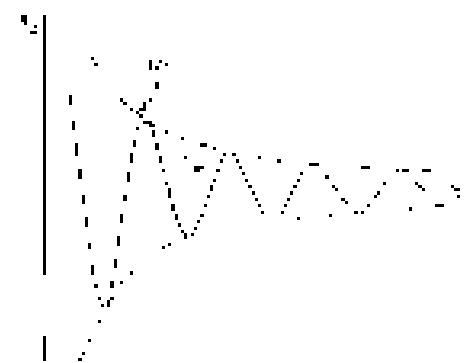

Fig. 21-5. The magnitude of A as a function of r at the instant t for the spherical wave from an oscillating dipole.

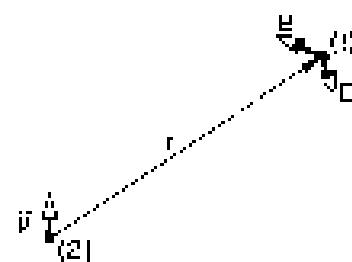

Fig. 21-4. The radiation fields B and E of an oscillating dipole.

term of Eq. (21.23) tends to cancel out the effect of the retardation in the first term. The two together give a result very near to Eq. (21.24) when r is small.

We can see that this way, when r is small, $(r - r_0c)$ is not very different from r_0 , so we can expand the bracket in Eq. (21.23) in a Taylor series. For the first term,

$$\rho(r - r_0c) = \rho(r) - \frac{1}{c} \dot{\rho}(r) + \text{etc.}$$

and to the same order in c/r ,

$$\rho(r - r_0c) = \bar{\rho}(r)$$

When we take the sum, the two terms in ρ cancel, and we are left with the zero-retarded current ρ ; that is, $\rho(r) = \rho_0(r)$ plus terms of order $(r/c)^2$ or higher (e.g., $\rho(r/c)^2 \ddot{\rho}$) which will be very small for r small enough that ρ does not alter markedly in the time c/r .

So Eq. (21.23) gives fields very much like the instantaneous theory—much closer than the instantaneous theory with a delay; the first-order effects of the delay are taken care of by the second term. The static formulas are very accurate, much more accurate than you might think. Of course, the compensation only works for points close in. For points far out the correction becomes very bad, because the terms of ρ_0 produce a very large effect, and we get the important $1/r^2$ term of the radiation.

We still have the problem of computing the electric field and current density that is the same as Eq. (21.1). For large distances we can see that the answer is going to come out all right. We know that far from the sources, where we have a propagating wave, it is perpendicular to E and also to B , as in Fig. 2.1-1, and that $eB = E$. So E is proportional to the acceleration p , as expected from Eq. (21.1).

To get the electric field completely for all distances, we need to solve for the electrostatic potential. When we compute the current integral for A to get Eq. (21.18), we make an approximation by disregarding the slight variation of r in the delay term. This will not work for the electrostatic potential, because we would then get A times the integral of the charge density, which is a constant. This approximation is too rough. We need to go to one higher order. Instead of being involved in that higher-order computation directly, we can do something else—we can determine the scalar potential from Eq. (21.6), using the vector potential we have already found. The divergence of A , in our case, is just $\partial A/\partial r$ —since A_r and A_θ are identically zero. (We're working in the same way that we did above to find B .)

$$\begin{aligned}\nabla \cdot A &= \frac{1}{4\pi\epsilon_0 c^2} \left[\rho(r - r_0c) \frac{\partial}{\partial r} \left(\frac{1}{r} \right) + \frac{1}{c} \frac{\partial}{\partial r} \rho(r - r_0c) \right] \\ &= \frac{1}{4\pi\epsilon_0 c^2} \left[-\frac{\rho_0(r)}{r^2} - \frac{\rho'(r)}{r} - \frac{\rho_0(r - r_0c)}{c r^2} \right].\end{aligned}$$

Or, in vector notation,

$$\nabla \cdot A = -\frac{1}{4\pi\epsilon_0 c^2} \frac{A_r - \rho(r)\hat{r}}{r^2}.$$

Using Eq. (21.6), we have an equation for ϕ :

$$\frac{\partial \phi}{\partial r} = \frac{1}{4\pi\epsilon_0 c^2} \frac{[p + (\rho/c)\hat{r}] - \rho(r)\hat{r}}{r^2}.$$

Integrating with respect to r just removes one \hat{r} from each of the $\rho\hat{r}$'s, so

$$\phi(r, t) = \frac{1}{4\pi\epsilon_0 c^2} \frac{[p + (\rho/c)\hat{r}] - \rho(r)\hat{r}}{r^2}. \quad (21.83)$$

(The constant of integration would correspond to some superposed static field which could, of course, exist. But the oscillating dipole we have taken, there is no static field.)

We are now able to find the electric field \mathbf{E} here:

$$\mathbf{E} = -\nabla \phi = \frac{d\phi}{dt}.$$

Since the steps are tedious but straightforward [provided you remember that $\rho(t) = r/c$ and its time derivatives depend on x , y , and z through the retardation r/c], we will just give the result:

$$\mathbf{E}(r, t) = \frac{1}{4\pi\epsilon_0 c^2 r^3} \left[-\rho^* + \frac{\rho'(t-r/c)}{r^2} \mathbf{r} + \frac{1}{c^2} (\rho(t-r/c) \times \mathbf{r}) \times \mathbf{r} \right] \quad (21.26)$$

with

$$\rho^* = \rho(t-r/c) + \frac{r}{c} \dot{\rho}(t-r/c). \quad (21.27)$$

Although it looks rather complicated, the result is easily interpreted. The vector ρ^* is the dipole moment retarded and then "corrected" for the retardation, so the two terms with ρ^* give just the static dipole field when r is small. (See Chapter 6, Eq. 16.14.) When r is large, the term in ρ dominates, and the electric field is proportional to the acceleration of the charges, at right angles to \mathbf{v} , and, in fact, directed along the projection of \mathbf{v} in a plane perpendicular to \mathbf{r} .

This result agrees with what we would have gotten using Eq. (21.1). Of course, Eq. (21.1) is more general; it works with any motion, while Eq. (21.26) is valid only for small motions for which we can take the retardation r/c as constant over the source. At any rate, we have now provided the underpinnings for our entire previous discussion of light (excepting some matters discussed in Chapter 26 of Vol. 1), for it all hangs on the last term of Eq. (21.26). We will discuss next how the fields can be obtained for more rapidly moving charges (concerning the relativistic effects of Chapter 16 of Vol. 1).

21.5 The potentials of a moving charge: the general solution of Trémaud and Whehere

In the last section we made a simplification in calculating our integral for ϕ by considering only y -axis motion. But in doing so we missed two important points and also one where it is easy to go wrong. We will therefore take up now a calculation of the potentials for a point charge moving in any way whatever— even with a relativistic velocity. Once we have this result, we will know the complete electromagnetism of electric charges. Even Eq. (21.1) can then be derived by taking derivatives. The story will be complete. So here we go.

Let's try to calculate the scalar potential $\phi(1, t)$ for the point (x_1, y_1, z_1) produced by a point charge such as an electron, moving in any manner whatsoever. By a "point" charge we mean a very small ball of charge, shrunk down as small as you like, with a charge density $\rho(x_1, y_1, z_1)$. We can find ϕ from Eq. (21.15):

$$\phi(1, t) = \frac{1}{4\pi\epsilon_0 c} \int \frac{\rho(2, t')}{r_{12}} dV_2. \quad (21.28)$$

The answer would seem to be—and almost everyone would, at first, think—but the integral of a ever-steady "point" charge is 0 , the total charge is so 0 !

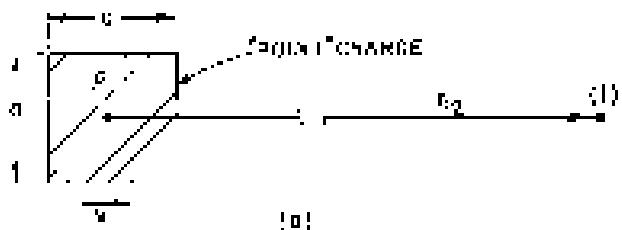

$$\phi(1, t) = \frac{1}{4\pi\epsilon_0 c} \frac{q}{r_{12}}. \quad (\text{wrong!})$$

By r_{12} we mean the radius vector from the charge at point (2) to point (1) at the retarded time $t' = r_{12}/c$. It is wrong.

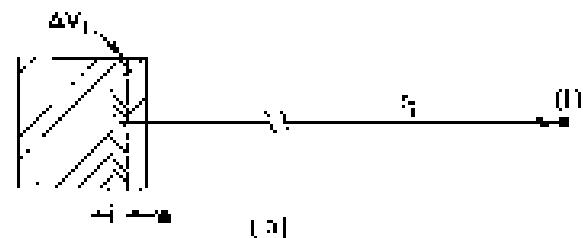

The correct answer is

$$\phi(1, t) = \frac{1}{4\pi\epsilon_0 c} \frac{q}{r_{12}} \cdot \frac{1}{1 + v_{12}/c}, \quad (21.29)$$

where v_{12} is the component of the velocity of the charge at retarded time r_{12} , namely, toward point (1). We will now show you why. To make the argument easier to

(a)

(b)

Fig. 21-5. (a) "Point" charge considered as a small cubical distribution of charge moving with the speed v toward point (1). (b) The volume element ΔV_1 used for calculating the potential.

follow, we will write the calculation first for a "point" charge which is in the form of a little cube of charge moving toward the point (1) with the speed v , as shown in Fig. 21-5(a). Let the length of a side of the cube be a , which we take to be much, much less than x_{10} , the distance from the center of the charge to the point (1).

Now to evaluate the integral of Eq. (21.28), we will return to basic principles; we will write it as the sum

$$\sum \frac{\rho_0}{r} \frac{e^2 k_e}{\epsilon_0}, \quad (2.30)$$

where a is the distance from point (1) to the s th volume element ΔV_s , and ρ_0 is the charge density $\rho_0 = \epsilon_0 E_0 / (v - c/v)$. Since $x_1 < a$, always, it will be convenient to take out ΔV_s in a form of thin, rectangular slices perpendicular to the x -axis, as shown in Fig. 21-5(b).

Suppose we start by using the volume elements ΔV_s with very thickness Δx_s much less than a . The individual elements will appear as shown in Fig. 21-6(a), where we have put in more than enough to cover the charge. But we have not shown the charge, and for a good reason. Where should we draw it? For each volume element ΔV_s , we are to take ρ at the time $t_s = (t - x_s/v)$, but since the charge is moving, it is in a different place for each volume element ΔV_s .

Let's say that we began with the volume element labeled "1" in Fig. 21-6(a), chosen so that at the time $t_1 = (t - x_1/v)$ the "back" edge of the charge occupies ΔV_1 , as shown in Fig. 21-6(b). Then when we evaluate $\rho_1/\Delta V_1$, we must use the position of the charge at the slightly later time $t_2 = (t - x_2/v)$, when the charge will be in the position shown in Fig. 21-6(c). And so on, for $\Delta V_2/\Delta V_2$, etc. Now we can evaluate the sum:

Since the thickness of each ΔV_s is Δx_s , its volume is $a^2 \Delta x_s$. Then each volume element just overlaps the charge distribution by an amount of charge Δq_s , where ρ is the density of charge within the cube, which we take to be uniform. When the distance from the charge to point (1) is large, we will make a negligible error by setting all the x 's in the denominators equal to some average value, say the retarded position t' of the center of the charge. Then the sum (21.30) is

$$\sum_s \frac{\rho a^2}{r'} \frac{\Delta x_s}{\epsilon_0},$$

where Δx_s is the Δx_s 's that overlaps the charge distribution and r' is as shown in Fig. 21-6(e). The sum is, already,

$$R \frac{\rho a^2}{r'} = \frac{a^2}{r'} \left(\frac{Mv}{\sigma} \right),$$

Note ρa^2 is the total charge per unit x and Mv is the length R shown in part (c) of the figure. So what's new?

$$e = \frac{q}{4\pi\epsilon_0 R} \left(\frac{R}{a} \right) \quad (2.31)$$

What is δt ? It is the length of the path of charge increased by the distance moved by the charge between $t_1 = (t - r_1/c)$ and $t_2 = (t - r_2/c)$ —which is the distance the charge moves in the time

$$\Delta t = t_2 - t_1 = (r_2 - r_1)/c = b/c.$$

Since the speed of the charge is v , the distance moved is $v\Delta t = v/b$. But the length b is this distance added to a :

$$b = a + \frac{v}{c}b.$$

Substituting b , we get

$$b = \frac{a}{1 - (v/c)}.$$

Of course, by v we mean the velocity at the retarded time $t' = (t - r'/c)$, which we can indicate by writing $t' = v/v_{rel}$, and Eq. (21.21) for the potential becomes

$$\phi(t, \vec{r}) = \frac{q}{4\pi\epsilon_0 c^2 t'} - \frac{1}{(v \cdot \vec{r})_{rel}}.$$

This result agrees with our assertion, Eq. (21.20). There is a correction term which comes from the fact that the charge moving as it moves “sweeps over the charge.” When the charge is moving toward the point C , its contribution to the integral is increased by the ratio b/a . It reduces the overall integral of q/r' multiplied by b/a , which is $1/(1 - v/c)^2$.

If the velocity of the charge is not directed toward the observation point C , you can see just what matters is the component of the velocity toward point C . Calling this velocity component v_{rel} , it is related to v by $v = v_{rel}/\cos\theta$. Also, the analysis we have made goes exactly the same way for $v < c$ (up to the condition of no source—it doesn’t have to be a cube). Finally, since the “size” of the charge q doesn’t enter into the final result, the same result holds when we let the charge shrink to any size—even to a point. The general result is that the scalar potential for a point charge moving with any velocity is

$$\phi(t) = \frac{q}{4\pi\epsilon_0 c^2 (1 - (\vec{v} \cdot \vec{r}))_{rel}}. \quad (21.22)$$

This equation is often written in the equivalent form

$$\phi(\vec{r}, t) = \frac{q}{4\pi\epsilon_0 c^2} \frac{1}{(\vec{v} \cdot \vec{r})_{rel}}, \quad (21.23)$$

where \vec{r} is the vector from the charge to the point (t) , where ϕ is being evaluated, and all the quantities in the bracket are to have their values at the retarded time $t' = t - r'/c$.

The same thing happens when we compute \vec{A} for a point charge, from Eq. (21.16). The retarded density is p_0 and the integral $\int d\tau$ is the same as we found for ϕ . The scalar potential is

$$A(t, \vec{r}) = \frac{q\vec{v}_0}{4\pi\epsilon_0 c^2 t'} - \frac{\vec{v}_0}{(v \cdot \vec{r})_{rel}}. \quad (21.24)$$

The potentials for a point charge were first deduced in this form by Lienard and Wiechert and are called the Lienard-Wiechert potentials.

To close the ring back to Eq. (21.1) it’s only necessary to compute E and B from these potentials (using $\vec{E} = \nabla \times \vec{A}$ and $\vec{B} = -\nabla \phi - (1/c)\partial \vec{A}/\partial t$). It is now only an exercise. The arithmetic, however, is fairly involved, so we will not write out the details. Perhaps you will trust our word for it that Eq. (21.1) is equivalent to the Lienard-Wiechert potentials we have derived.¹⁷

¹⁷ If you have a lot of paper and time you can try to work it through yourself. We would then make two suggestions. First, don’t forget that the derivatives of \vec{r} are complicated, since it is a function of t' . Second, don’t try to derive Eq. (21.1) but carry out the derivatives on it and then compare what you get with the \vec{E} obtained from the potentials (2.230) and (2.232).

21-6 The potentials for a charge moving with constant velocity: the Lorentz formula

We want next to use the Liénard-Wiechert potentials for a special case: to find the fields of a charge moving with uniform velocity in a straight line. We will do it again later, using the principle of relativity. We already know what the potentials are when we are standing in the rest frame of a charge. When the charge is moving, we can figure everything out by a relativistic transformation from one system to the other. But relativity had its origin in the theory of electricity and magnetism. The formulas of the Lorentz transformation (Chapter 15, Vol. I) were discoveries made by Lorentz when he was studying the equations of electricity and magnetism. So that you can appreciate where things have come from, we would like to show that the Maxwell equations do lead to the Lorentz transformation. We begin by calculating the potentials of a charge moving with uniform velocity, directly from the electrodynamics of Maxwell's equations. We have shown that Maxwell's equations lead to the potentials for a moving charge that we get in the last section. So when we get these potentials, we are up to Maxwell's theory.

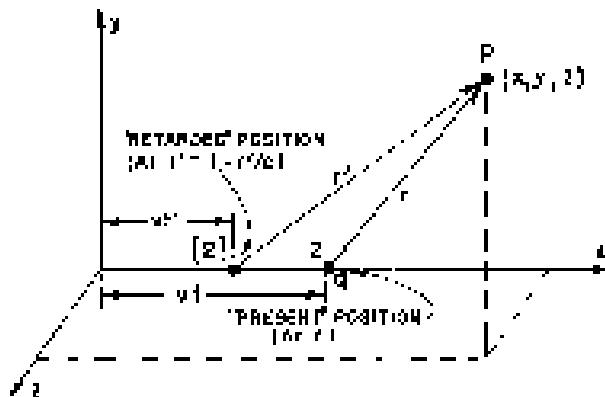

Fig. 21-7. Finding the potentials ϕ & ψ of a charge moving with uniform velocity v along the x -axis.

Suppose we have a charge moving along the x -axis with the speed v . We want the potentials at the point (x, y, z) , as shown in Fig. 21-7. If $t = 0$ is the instant when the charge is at the origin, at $(0, 0, 0)$, then the charge is at $(x - vt, y, z - 0)$. What we want to know, however, is its position at the retarded time

$$t'' = t - \frac{r'}{c}, \quad (21.35)$$

where r' is the distance from the point P to the x -axis, r , of the retarded time. At the retarded time t'' , the charge was at $(x - vt', y, 0)$.

$$r' = \sqrt{(x - vt')^2 + y^2} = \sqrt{x^2 + y^2}. \quad (21.36)$$

To find v' or r' we have to combine this equation with Eq. (21.35). First, we eliminate r' by solving Eq. (21.35) for t' and substituting in Eq. (21.36). Then, squaring both sides, we get

$$c^2(r - vt)^2 = (x - vt')^2 + y^2 + z^2,$$

which is a quadratic equation in t' . Expanding the squared binomials and collecting like terms in t' , we get

$$(c^2 - v^2)r^2 - 2vtv + c^2vt' + x^2 + v^2 - z^2 - (vt')^2 = 0$$

Solving for t' ,

$$\left(1 - \frac{v^2}{c^2}\right)t' = \frac{v^2}{c^2} - \frac{1}{c} \sqrt{(x^2 + y^2 + z^2) - \left(\frac{c^2 - v^2}{c^2}\right)(r^2 - x^2)}. \quad (21.37)$$

To get ψ we have to substitute this expression for r' into

$$r' = c(t - t').$$

Now we are ready to find ϕ from Eq. (21.33), which, since ρ is constant, becomes

$$\phi(x, y, z, t) = \frac{q}{4\pi\epsilon_0} \frac{1}{r^2 - (y^2 + z^2/c^2)}, \quad (21.38)$$

The component of v in the direction of r' is $c \propto (x - ct)/r'$, so $v \cdot r'$ is just $c \propto (x - ct)$, and the whole denominator is

$$r'(t - t') = \sqrt{(x - ct)^2 + v^2} = c \left[t - \frac{v^2}{c^2} - \left(1 - \frac{v^2}{c^2} \right) t' \right].$$

Substituting for $(1 - v^2/c^2)t'$ from Eq. (21.37), we get for ϕ

$$\phi(x, y, z, t) = \frac{q}{4\pi\epsilon_0} \frac{1}{\sqrt{(x - ct)^2 + \left(1 - \frac{v^2}{c^2} \right)(y^2 + z^2)}}$$

This equation is more understandable if we rewrite it as

$$\phi(x, y, z, t) = \frac{q}{4\pi\epsilon_0} \frac{1}{\sqrt{1 - \frac{v^2}{c^2}} \left[\sqrt{\frac{(x - ct)^2}{\left(\sqrt{1 - v^2/c^2} \right)^2 + y^2 + z^2}} \right]^{1/2}} \quad (21.39)$$

The vector potential A is the same expression with an additional factor of cv/c^2 :

$$A = \frac{v}{c^2} \phi.$$

In Eq. (21.39) you can easily see the beginning of the Lorentz transformation. If the charge were at the origin in its own rest frame, its potential would be

$$\phi(x, y, z) = \frac{q}{4\pi\epsilon_0} [x^2 + y^2 + z^2]^{-1/2}$$

We are seeing it in a moving coordinate system, and it appears that the coordinates should be transformed by

$$\begin{aligned} x &\rightarrow \frac{x - vt}{\sqrt{1 - v^2/c^2}}, \\ y &\rightarrow y, \\ z &\rightarrow z. \end{aligned}$$

That is, the Lorentz transformation, and what we have done is essentially the way Lorentz discovered it.

But what about that extra factor $1/\sqrt{1 - v^2/c^2}$ that appears at the front of Eq. (21.39)? Also, how does the vector potential A appear when it is everywhere zero in the rest frame of the particle? We will soon show that A and ϕ together constitute a four-vector, like the momentum p and the total energy E of a particle. The extra $1/\sqrt{1 - v^2/c^2}$ in Eq. (21.39) is the same factor that always comes in when one transforms the components of a four-vector—just as the charge density ρ transforms to $\rho/\sqrt{1 - v^2/c^2}$. In fact, it is almost apparent from Eqs. (21.1) and (21.3) that A and ϕ are components of a four-vector, because we have already shown in Chapter 13 that j and ρ are the components of a four-vector.

Later we will take up in more detail the relativity of electrodynamics; here we only wished to show how naturally the Maxwell equations lead to the Lorentz transformation. You will not, then, be surprised to find that the laws of electricity and magnetism are already correct for Einstein's relativity. We will not have to "fix them up," as we had to do for Newton's laws of mechanics.

22. Circuits

22-1 Impedances

Most of our work in this course has been aimed at rendering the complete equations of Maxwell. In the last two chapters we have been discussing the consequences of these equations. We have found that the equations contain all the static phenomena we had worked out earlier, as well as the phenomena of electromagnetic waves and light that we had gone over in some detail in Volume I. The Maxwell equations give both phenomena, depending upon whether one computes the fields close to the currents and charges, or very far from them. There is not much interesting to say about the intermediate region; no special phenomena appear there.

There still remain, however, several subjects in electromagnetism that we want to take up. We can start by discussing the question of causality and the Maxwell equations: what happens when one looks at the Maxwell equations with respect to moving coordinate systems. There is also the question of the conservation of energy in electromagnetic systems. Then there is the basic subject of the electromagnetic properties of materials: so far, except for the study of the properties of dielectrics, we have considered only the electromagnetic fields in free space. And although we covered the subject of light in some detail in Volume I, there are still a few things we would like to do again from the point of view of the field equations.

In particular, we want to take up again the subject of the index of refraction, particularly for dense materials. Finally, there are the phenomena associated with waves confined in a limited region of space. We touched on this kind of problem briefly when we were studying sound waves. Maxwell's equations lead also to solutions which represent confined waves of the electric and magnetic fields. We will take up this subject, which has important technical applications, in some of the following chapters. In order to lead up to that subject, we will begin by considering the properties of electrical circuits at low frequencies. We will then be able to make a comparison between those situations in which the almost static approximations of Maxwell's equations are applicable and those situations in which high frequency effects are dominant.

So we descend from the great and esoteric heights of the last few chapters and turn to the relatively low-level subject of electrical circuits. We will see, however, that even such a mundane subject, when looked at in sufficient detail, can contain great complexities.

We have already discussed some of the properties of electrical circuits in Chapters 23 and 25 of Vol. I. Now we will cover some of the same material again, but in greater detail. Again we are going to consider only *ac* linear systems and with voltages and currents which all vary sinusoidally; we can then represent all voltages and currents by complex numbers, using the exponential notation described in Chapter 22 of Vol. I. Thus a time-varying voltage $V(t)$ will be written

$$V(t) = V e^{i\omega t}, \quad (22.1)$$

where V represents a complex number that is independent of t . It is, of course, understood that the actual time-varying voltage $V(t)$ is given by the real part of the complex function on the right-hand side of the equation.

22-6 A ladder network

22-7 Filters

22-8 Other circuit elements

Review: Chapter 22, Vol. I, Appendix
Chapter 21, Vol. I, Resonance
Chapter 18, Vol. I, Linear
Systems and Review

Similarly, all of our other time-varying quantities will be taken to vary sinusoidally at the same frequency ω . So we write

$$\begin{aligned} I &= \hat{I} e^{i\omega t} \quad (\text{current}), \\ \Phi &= \hat{\Phi} e^{i\omega t} \quad (\text{flux}), \\ E &= \hat{E} e^{i\omega t} \quad (\text{electric field}), \end{aligned} \quad (22.2)$$

and so on.

Most of the time we will write our equations in terms of V, I, Φ, \dots instead of in terms of $\hat{V}, \hat{I}, \hat{\Phi}, \dots$, remembering though that the time variations are as given in (22.2).

In our earlier discussion of circuits we assumed that such things as inductances, capacitances, and resistances were familiar to you. We will now look in a little more detail at what is meant by these idealized circuit elements. We begin with the inductance.

An inductance is made by winding many turns of wire in the form of a coil and bringing the two ends out to terminals a and b some distance from the coil, as shown in Fig. 22.1. We want to assume that the magnetic field produced by current I in the coil does not spread out strongly all over space and instead is in other parts of the circuit. This is usually arranged by winding the coil in a doughnut-shaped form, or by confining the magnetic field by winding the coil on a suitable iron core, or by placing the coil in some suitable metal box, as indicated schematically in Fig. 22.1. In any case, we assume that there is a negligible magnetic field in the external region near the terminals a and b . We are also going to assume that we can neglect any electrical resistance in the wire of the coil. Finally, we will assume that we can neglect the amount of electrical charge that appears on the surface of a wire in building up the electric fields.

With all these approximations we have what we call the "ideal" inductance. (We will see what happens when things are not as simple.) For our ideal inductance we say that the voltage across the terminals is equal to $L(dI/dt)$. Let's see why that is so. When there is a current flowing through the inductor, a magnetic field proportional to the current is built up inside the coil. If the current changes with time, the magnetic field also changes. In general, the sum of it is equal to

$\partial B / \partial t$ at a , just like every, the line integral of E all the way around any closed path is equal to $-i$ times ∂ of the total magnetic flux Φ through the loop. Now suppose we consider the following path: Begin at terminal a and go along the coil (going always inside the wire) to terminal b , the current then goes back to terminal a through the air in the space outside the inductor. The line integral of E around this closed path can be written as the sum of two parts:

$$\int E \cdot ds = \int_{\text{coil}}^a E \cdot ds + \int_b^a E \cdot ds. \quad (22.3)$$

As we have seen before, there can be no electric fields inside a perfect conductor. (The smallest fields would produce infinite currents.) Therefore the integral from a to b via the coil is zero. The whole contribution to the line integral of E comes from the path outside the inductor from terminal b to terminal a . Since we have assumed that there are no magnetic fields in the space outside of the "box," this part of the integral is independent of the path chosen and we can define the potential's of the two terminals. The difference of these two potentials is what we call the voltage difference, or simply the voltage V , so we have

$$V = \int_a^b E \cdot ds = - \int_b^a E \cdot ds$$

The complete line integral is what we have before called the electromotive force ϵ and is, of course, equal to the rate of change of the magnetic flux in the coil. We have seen earlier that this ϵ is equal to the negative rate of change of Φ :

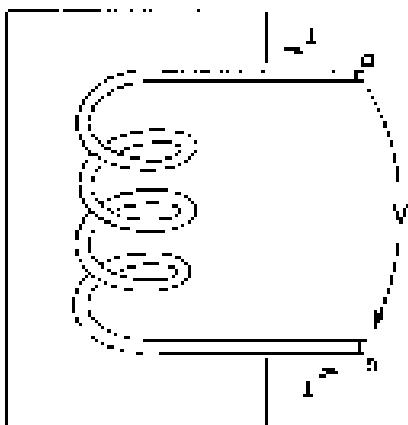

Fig. 22.1. An inductance.

the current, so we have

$$V = -i = L \frac{di}{dt},$$

where L is the inductance of the coil. Since $di/dt = idL$, we have

$$V = idL. \quad (22.4)$$

The way we have described the ideal inductor illustrates the general approach to other real circuit elements usually called "lumped" elements. The properties of the element are described completely in terms of currents and voltages that appear at the terminals. By making suitable approximations, it is possible to ignore the great complexities of the fields that appear inside the object. A separation is made between what happens inside and what happens outside.

For all the circuit elements we will find a relation like the one in Eq. (22.1), in which the voltage is proportional to the current, with a proportionality constant that is, in general, a complex number. This complex coefficient of proportionality is called the *impedance* and is usually written as z (not to be confused with the z -coordinate). It is, in general, a function of the frequency ω . So for any lumped element we write

$$\frac{V}{I} = \frac{\dot{V}}{\dot{I}} = z. \quad (22.5)$$

For an inductor, we have

$$\text{inductance} = z_L = idL. \quad (22.6)$$

Now let's look at a capacitor from the same point of view.* A capacitor consists of a pair of conducting plates from which two wires are brought out to suitable terminals. The plates may be of any shape whatsoever, and are often separated by some dielectric material. We'll draw such a situation schematically in Fig. 22-2. Again we make several simplifying assumptions. We assume that the plates and the wires are perfect conductors. We also assume that the insulation between the plates is perfect, so that no charges can flow across the insulation from one plate to the other. Next, we assume that the two conductors are close to each other but far from all others, so that all field lines which leave one plate end up on the other. Then there are always equal and opposite charges on the two plates and the charges on the plates are much larger than the charges on the surfaces of the lead-in wires. Finally, we assume that there are no magnetic fields close to the capacitor.

Suppose now we consider the line integral of E around a closed loop which starts at terminal a , goes along inside the wires to the top plate of the capacitor, jumps across the space between the plates, passes from the lower plate to terminal b through the wire, and returns to terminal a in the space outside the capacitor. Since there is no magnetic field, the line integral of E around this closed path is zero. The integral can be broken down into three parts:

$$\oint E \cdot d\ell = \int_{\text{wires}} E \cdot d\ell + \int_{\text{space}} E \cdot d\ell + \int_{\text{plates}} E \cdot d\ell. \quad (22.7)$$

The integral along the wires is zero, because there are no electric fields inside perfect conductors. The integral from b to a outside the capacitor is equal to the negative of the potential difference between the terminals. Since we imagined that the two plates are in some way isolated from the rest of the world, the total charge on

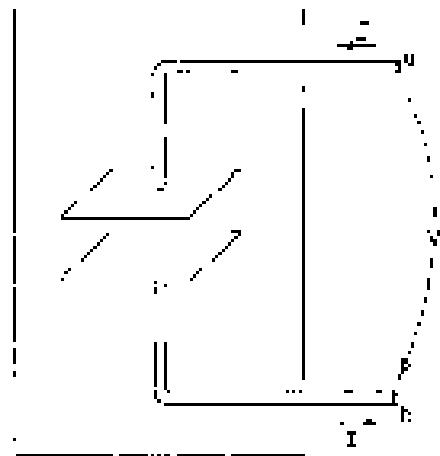

Fig. 22-2. A capacitor (or condenser).

* There are people who say we should call the objects by the names "inductor" and "capacitor" and call the properties "inductance" and "capacitance" (by analogy with "resistor" and "resistance"). We would rather let the words you will hear in the laboratory. Most people will say "inductance" for both the physical entity and its definition. If the word "capacitor" seems to have caught on, though, you will still hear "capacitance" fairly often, and vice versa still pretty frequently if "inductance" is "capacitance."

the two plates must be zero; if there is a charge Q on the upper plate, there is an equal, opposite charge $-Q$ on the lower plate. We have seen earlier that if two conductors have equal and opposite charges plus and minus Q , the potential difference between the plates is equal to Q/C , where C is called the capacity of the two conductors. From Eq. (22.7) the potential difference between the terminals a and b is equal to the potential difference between the plates. We have, therefore, that:

$$V = \frac{Q}{C}.$$

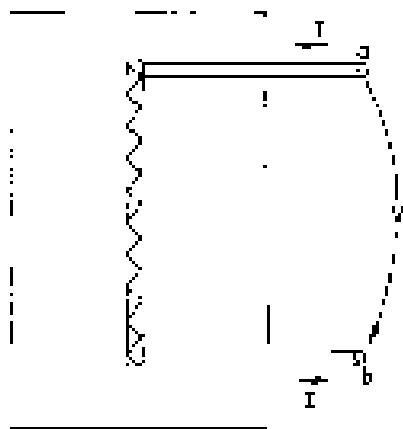

Fig. 22-3. A resistor.

The electric current I entering the capacitor through terminal a (and leaving through terminal b) is equal to dQ/dt , the rate of change of the electric charge on the plates. Writing dQ/dt as i_C , we can put the voltage equation V in analogy for a capacitor in the following way:

$$\text{for } C = \frac{Q}{V},$$

$$V = \frac{Q}{i_C C}. \quad (22.5)$$

The impedance z of a capacitor is then

$$z(\text{capacitor}) = z_C = \frac{1}{i_C C}. \quad (22.6)$$

The third element we want to consider is a resistor. However, since we have not yet discussed the electrical properties of real materials, we are not yet ready to talk about what happens inside a real conductor. We will just have to accept as fact that electric fields can exist inside real materials, that these electric fields give rise to a flow of electric charge—that is, to a current—and that this current is proportional to the integral of the electric field from one end of the conductor to the other. We then imagine a ideal resistor symbolized as in the diagram of Fig. 22-3. Two wires which we assume to be perfect conductors go from the terminals a and b to the two ends of a bar of resistive material. Following our usual line of argument, the potential difference between the terminals a and b is equal to the line integral of the external electric field, which is also equal to the line integral of the electric field through the bar of resistive material. It then follows that the current I through the resistor is proportional to the terminal voltage V :

$$I = \frac{V}{R},$$

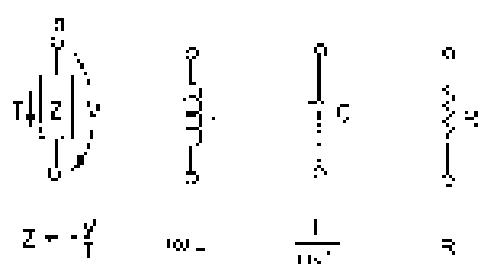

Fig. 22-4. The four lumped circuit elements (passive).

where R is called the resistance. We will see later that the relation between the current and the voltage for real conducting materials is only approximately linear. We will also see that the approximate proportionality is expected to be independent of the frequency of variation of the current and voltage only if the frequency is not too high. For alternating currents, then, the voltage across a resistor is proportional to the current, which means that the impedance is a real number:

$$z(\text{resistor}) = z_R = R. \quad (22.7)$$

Our results for the three lumped circuit elements—the inductor, the capacitor and the resistor—are summarized in Fig. 22-4. In the inductor as well as in the presenting case, we have indicated the voltage by an arrow that is directed from terminal a to terminal b . If the voltage is "positive"—that is, if the terminal a is the higher potential than the terminal b —the arrow indicates the direction of a positive "voltage drop."

Although we are talking about alternating currents, we can of course include the special case of circuits with steady currents by taking ω to be the frequency $\omega = 0$. At zero frequency—that is, for DC—the impedance of an inductor goes to zero, there is a short circuit, but of course the impedance of a capacitor

goes to infinity it becomes an open circuit. Since the impedance of a resistor is independent of frequency, it is the only element left when we analyze a circuit for us.

In the circuit elements we have described so far, the current and voltage are proportional to each other. If one is zero, so also is the other. We usually think in terms like these: An applied voltage is "responsible" for the current, or a current "gives rise to" a voltage across the terminals; so in a sense the elements "respond" to the "applied" external conditions. For this reason these elements are called *passive* elements. They can thus be contrasted with the active elements, such as the generator, we will consider in the next section, which are the *source*s of the oscillating currents or voltages in a circuit.

22-2 Generators

Now we want to talk about one active circuit element—one that is a source of the currents and voltage in addition to, recently, a passive one.

Suppose that we have a coil fixed in an inductor except that it has very low losses so that we may neglect the resistive loss of its own current. This coil, however, lies in a changing magnetic field which might be produced by a rotating magnet, as sketched in Fig. 22-5. (We have seen earlier that such a rotating magnetic field could also be produced by a suitable set of coils with alternating currents.) Again we must make several simplifying assumptions. The assumptions we will make are all the ones that we discussed for the case of the inductance. In particular, we assume that the varying magnetic field is restricted to a definite region in the vicinity of the coil and does not appear outside the generator in the space between the terminals.

Following closely the analysis we made for the inductance, we consider the line integral of \mathbf{B} around a complete loop that starts at terminal *a*, goes through the coil to terminal *b* and returns to its starting point in the space between the two terminals. Again we conclude that the potential difference between the terminals is equal to the total line integral of \mathbf{B} around the loop:

$$V_{ab} = \oint \mathbf{B} \cdot d\mathbf{l}$$

This line integral is equal to the emf in the system, so the potential difference V across the terminals of the generator is also equal to the rate of change of the magnetic flux linking the coil:

$$V = \dot{\phi}_m = \frac{d}{dt} (\text{flux}). \quad (22-1)$$

For an ideal generator we assume that the magnetic flux linking the coil is determined by external conditions such as the angular velocity of a rotating magnetic field and is not influenced in any way by the currents through the generator. Thus a "generator," at least the ideal generator we are considering, is not an impedance. The potential difference across its terminals is determined by the chirality assigned to the coil terminals *a* and *b*. Such an ideal generator is represented by the symbol shown in Fig. 22-6. The little arrow represents the direction of the emf when it is positive. A positive emf in the generator of Fig. 22-6 will produce a voltage $V = \dot{\phi}_m$ with the terminal *a* at a higher potential than the terminal *b*.

There is another way to make a generator which is quite different in the inside but which is indistinguishable from the one we have just described because what happens beyond its terminals. Suppose we have a coil of wire which is rotated in a fixed magnetic field, as indicated in Fig. 22-7. We can now let magnet to indicate the presence of a magnetic field; it could, of course, be replaced by any other source of a steady magnetic field, such as an alternating coil carrying a steady current. As shown in the figure, suppose we let the rotating coil *not* move in the outside world by means of strong contacts or "slip rings." At first we are interested in the potential difference that appears across the two terminals

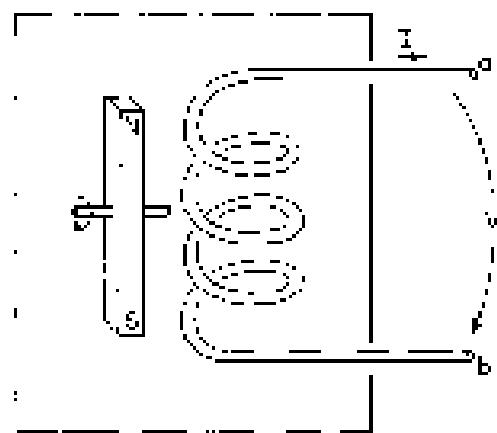

Fig. 22-5. A generator consisting of a fixed coil and a rotating magnetic field.

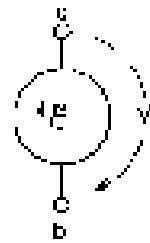

Fig. 22-6. Symbol for an ideal generator.

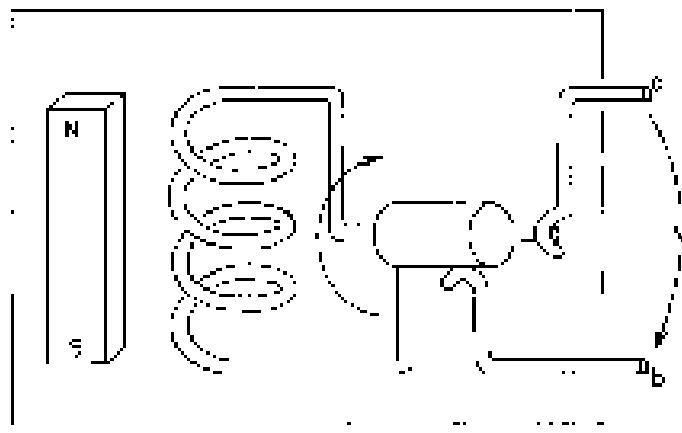

Fig. 22-7. A generator consisting of a coil rotating in a fixed magnetic field.

a and b, which is of course the integral of the electric field from terminal a to terminal b along a path outside the generator.

Now in the system of Fig. 22-7 there are no changing magnetic fields, so we might at first wonder how any voltage could appear at the generator terminals. In fact, there are no electric fields anywhere inside the generator. We are, as usual, assuming for our ideal element is that the wires inside are made of a perfectly conducting material, and as we have said many times, the electric field inside a perfect conductor is equal to zero. But that is not true. It is not true when a conductor is moving in a magnetic field. The true statement is that the total force on any charge inside a perfect conductor must be zero. Otherwise there would be an infinite flow of the free charges. So what is always true is that the sum of the electric field E and the cross product of the velocity of the conductor and the magnetic field B —which is the total force on a unit charge—must have the value zero inside the conductor:

$$\nabla \cdot E + v \times B = 0 \quad (\text{in a perfect conductor}). \quad (22.12)$$

where v represents the velocity of the conductor. (By another statement that I say is no electric field it is a perfect conductor, it will mean if the velocity v of the conductor is zero, or if even the current statement is given by Eq. (22.12).

Returning to our generator of Fig. 22-7, we know now that the line integral of the electric field E from terminal a to terminal b through the connecting path of the generator must be equal to the total force of $v \times B$ on the same path:

$$\int_{\text{path}}^b E \cdot dr = - \int_a^b (v \times B) \cdot dr. \quad (22.13)$$

It is still true, however, that the line integral of E around a complete loop, including the return from b to a outside the generator, must be zero, because there are no changing magnetic fields. So the first integral in Eq. (22.13) is also equal to V , the voltage between the two terminals. It turns out that the right-hand integral in Eq. (22.13) is just the rate of change of the flux linkage through the coil and is therefore—by the flux rule—equal to the emf in the coil. So we have again that the potential difference across the terminals is equal to the electromotive force in the circuit, in agreement with Eq. (22.11). So whether we have a generator in which a magnetic field changes near a fixed coil, or one in which a coil moves in a fixed magnetic field, the external properties of the generators are the same. There is a voltage difference V across the terminals, which is independent of the current in the circuit but depends only on the arbitrarily assigned conditions inside the generator.

So long as we are trying to understand the operation of generators from the point of view of Maxwells' equations, we might also consider the ordinary chemical cell, like a flashlight battery. It is also a generator, i.e., a voltage source, although it will of course only appear in the circuit. This simplest kind of cell is represented in Fig. 22-8. We imagine two small objects immersed in space

chemical solution. We suppose that the solution contains positive and negative ions. We suppose also that one kind of ion, say the negative, is much heavier than the rest of opposite polarity, so that its motion through the solution by the process of diffusion is much slower. We suppose next that by some means or other it is arranged that the concentration of the solution is made to vary from one part of the fluid to the other, so that the number of ions of both polarities near, say, the lower plate is much larger than the concentration of ions near the upper plate. Because of their rapid mobility the positive ions will drift more readily into the region of lower concentration, so that there will be a slight excess of positive charge arriving at the upper plate. The upper plate will become positively charged and the lower plate will have a net negative charge.

As more and more charges diffuse to the upper plate, the potential of this plate will rise until the resulting electric field between the plates produces forces on the ions which just compensate for their excess mobility, so the two plates of the cell finally reach a potential difference which is characteristic of the internal construction.

Arguing just as we did for the ideal capacitor, we see that the potential difference between the terminals *a* and *b* is just equal to the line integral of the electric field between the two plates when there is no longer any net diffusion of the ions. There is, of course, an essential difference between a capacitor and such a chemical cell. If we short-circuit the terminals of a condenser for a moment, the capacitor is discharged and there is no longer any potential difference across the terminals. In the case of the chemical cell a current can be drawn from the terminals continuously without any change in the emf—until, of course, the chemicals inside the cell have been used up. In a real cell it is found that the potential difference across the terminals decreases as the current drawn from the cell increases. In keeping with the abstractions we have been making, however, we may imagine an ideal cell in which the voltage across the terminals is independent of the current. A real cell can then be looked at as an ideal cell in series with a resistor.

22-5 Networks of ideal elements; Kirchhoff's rules

As we have seen in the last section, the description of an ideal circuit element in terms of what happens outside the element is quite simple. The current and the voltage are linearly related. But what is actually happening inside the element is quite complicated, and it is quite difficult to give a precise description in terms of Maxwell's equations. Imagine trying to give a precise description of the electric and magnetic fields of the inside of a radio which contains hundreds of resistors, capacitors, and inductors. It would be an impossible task to analyze such a thing by using Maxwell's equations. But, by making the many approximations we have discussed in Section 22-2 and summarizing the essential features of the real circuit elements in terms of idealizations, it becomes possible to analyze an electrical circuit in a relatively straightforward way. We will now show how that is done.

Suppose we have a circuit consisting of a generator and several impedances connected together, as shown in Fig. 22-9. According to our approximations there is no magnetic field in the region outside the individual circuit elements. Therefore the line integral of E around any curve which does not pass through any of the elements is zero. Consider then the curve Γ shown by the broken line which goes all the way around the circuit in Fig. 22-9. The line integral of E around this curve is made up of several pieces. Each piece is the line integral from one terminal of a circuit element to the other. This line integral we have called the voltage drop across the circuit element. The complete line integral is then just the sum of the voltage drops across all of the elements in the circuit:

$$\oint E \cdot d\tau = \sum V_L$$

Since the line integral is zero, we have that the sum of the potential differences

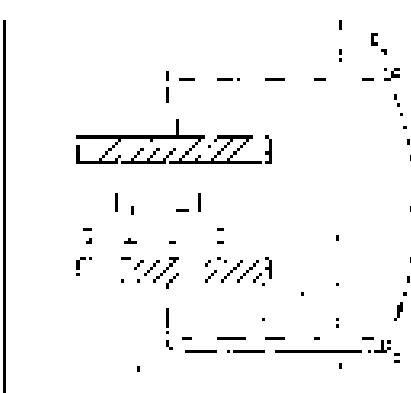

Fig. 22-8. A chemical cell.

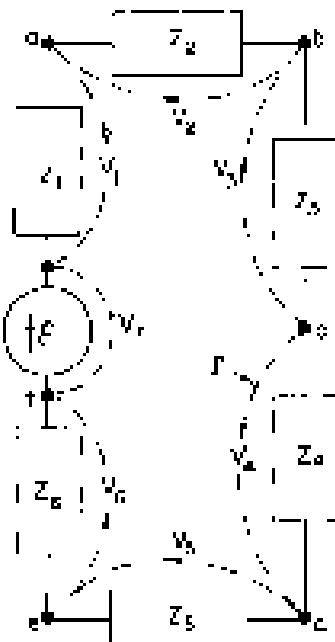

Fig. 22-9. The sum of the voltage drops around any closed path is zero.

around a complete loop of a circuit is equal to zero:

$$\sum_{\text{around}} V_i = 0. \quad (22.14)$$

This result follows from one of Maxwell's equations—that in a region where there are no magnetic fields the line integral of \mathbf{B} around any complete loop is zero.

Suppose we consider now a circuit like that shown in Fig. 22-10. The horizontal line joining the terminals a , b , c , and d is intended to show that these terminals are all connected, or that they are joined by wires of negligible resistance. In any case, this drawing means that terminals a , b , c , and d are all at the same potential V_0 and, similarly, that the terminals e , f , g , and h are also at the common potential V_1 . Then the voltage drop V across each of the four elements is the same.

Now one of our idealizations has been that negligible electrical charges accumulate on the terminals of the impedances. We now assume further that any electrical charges on the wires joining terminals can also be neglected. Then the conservation of charge requires that any charge which leaves one circuit element immediately enters some other circuit element. Or, what is the same thing, we require that the algebraic sum of the currents which enter any given junction must be zero. By a junction, of course, we mean any set of terminals a , b , c , d , e , f , g , and h which are connected. Such a set of connected terminals is usually called a "node." The conservation of charge then requires that for the network of Fig. 22-10,

$$I_1 + I_2 + I_3 + I_4 = 0. \quad (22.15)$$

The sum of the current entering the node which consists of the four terminals e , f , g , and h must also be zero:

$$I_5 + I_6 - I_7 - I_8 = 0. \quad (22.16)$$

This is, of course, the same as Eq. (22.15). The two equations are not independent. The general rule is that the sum of the currents into any node must be zero.

$$\sum_{\text{into node}} I_i = 0. \quad (22.17)$$

Our earlier conclusion that the sum of the voltage drops around a closed loop is zero must apply to any loop in a complicated circuit. Also, our result that the sum of the currents into a node is zero must be true for any node. These two equations are known as Kirchhoff's rules. With these two rules it is possible to solve for the currents and voltages in any network whatever.

Suppose we consider the more complicated circuit of Fig. 22-11. How shall we find the currents and voltages in this circuit? We can find them in the following straightforward way. We consider separately each of the four subsidiary closed loops which appear in the circuit. (For instance, one loop goes from terminal a to terminal b to terminal c to terminal d and back to terminal a .) For each of the loops we write the equation (as the first of Kirchhoff's rules) that the sum of the voltages around each loop is equal to zero. We must remember to count the voltage drop as positive if we are going in the direction of the current and negative if we are going across an element in the direction opposite to the current; and we must remember that the voltage drop across a generator is the negative of the emf in that direction. Thus if we consider the small loop that starts and ends at terminal a we have the equation

$$z_1 I_1 + z_2 I_2 + z_3 I_3 + A_1 = 0.$$

Applying the same rule to the remaining loops, we would get three more equations of the same kind.

Next, we can't write the current equation for each of the nodes in the circuit. For example, consider the currents into the node at terminal b gives the equation

$$I_1 - I_2 - I_3 = 0.$$

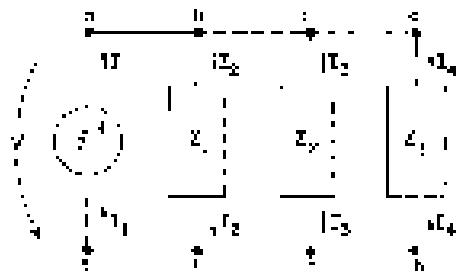

Fig. 22-10. The sum of the currents into any node is zero.

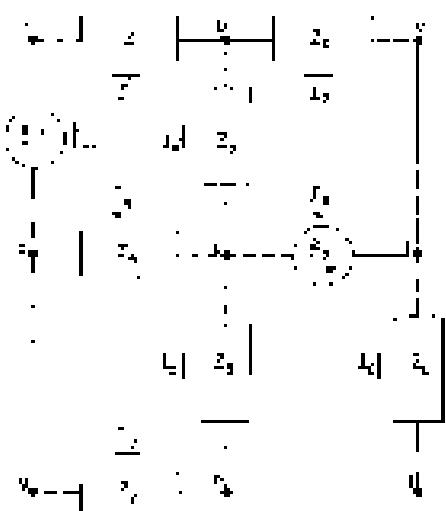

Fig. 22-11. Analyzing a circuit with Kirchhoff's rules.

Similarly, for the node between c we would have the current equation

$$I_1 + I_4 + I_5 - I_6 = 0.$$

For the circuit shown there are five such current equations. It turns out, however, that any one of these equations can be derived from the other four; there are, therefore, only four independent current equations. We thus have a total of eight independent linear equations: the four voltage equations and the four current equations. With these eight equations we can solve for the eight unknown currents. Once the currents are known the circuit is solved. The voltage drop across any element is given by the sum of those that element times its impedance (or, in the case of the voltage sources, it is already known).

We have seen that when we write the current equations, we get one equation which is not independent of the others. Generally, it is also possible to write down too many voltage equations. For example, in the circuit of Fig. 22-11, although we have considered only the four small loops, there are a large number of other loops for which we can also write the voltage equation. There is, for example, the loop along the path $a-b-f-d-a$. There is another loop which follows the path $a-b-f-e$. You can see that there are many loops. In analyzing complicated circuits it is very easy to get too many equations. There are rules which tell us how to proceed so that only the minimum number of equations is written down. But, already with a little thought it is possible to see how to get the right number of equations in the simplest form. Besides, writing an extra equation or two doesn't carry a burden. They will not lead to any wrong answers, only perhaps a little unnecessary algebra.

In Chapter 21 of Vol. I we showed that if the two impedances z_1 and z_2 are in series, they are equivalent to a single impedance z_s , given by

$$z_s = z_1 + z_2. \quad (22.8)$$

We also showed that if the two impedances are connected in parallel, they are equivalent to the single impedance z_p , given by

$$z_p = \frac{1}{(1/z_1) + (1/z_2)} = \frac{z_1 z_2}{z_1 + z_2}. \quad (22.9)$$

If you look back you will see that, in deriving these results we were in effect making use of Kirchhoff's rule. It is often possible to analyze a complicated circuit by repeated application of the formulas for series and parallel impedances. For instance, the circuit of Fig. 22-12 can be analyzed that way. First, the impedances z_1 and z_2 can be replaced by their parallel equivalent, and we also can z_3 and z_4 . Then the impedance z_5 can be combined with the parallel equivalent of z_6 and z_7 by the series rule. Proceeding in this way, the whole circuit can be reduced to a generator in series with a single impedance Z . The current through the generator is then $\mu = \mathcal{E}/Z$. Then by working backward one can solve for the currents in each of the impedances.

There are, however, quite simple circuits which cannot be analyzed by this method, as for example the circuit of Fig. 22-13. To analyze this circuit we must

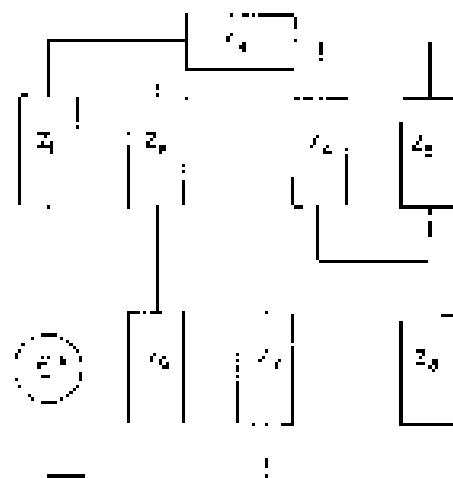

Fig. 22-12. A circuit which can be analyzed in terms of series and parallel combinations.

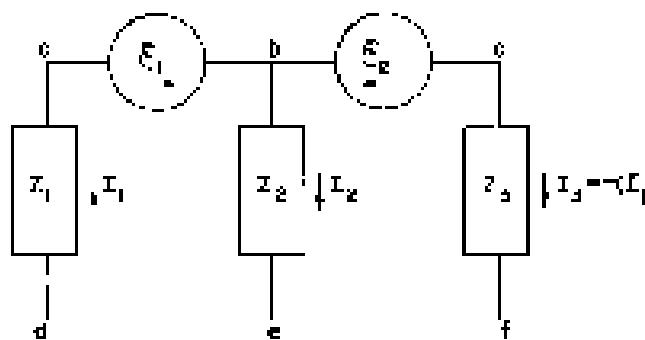

Fig. 22-13. A circuit that cannot be analyzed in terms of series and parallel combinations.

write down the current and voltage equations from Kirchhoff's rules. Let's do it. There is just one current equation:

$$I_1 + I_2 + I_3 = 0,$$

so we know immediately that

$$I_3 = -(I_1 + I_2).$$

We can save ourselves some trouble if we simply take note of this result in writing the voltage equations. But let's avoid that; there are two independent voltage equations; they are

$$-e_1 + I_2 z_2 - I_1 z_1 = 0$$

and

$$e_2 - I_1 z_1 + I_2 z_2 - I_3 z_3 = 0.$$

There are two equations and two unknown currents. Solving these equations for I_1 and I_2 , we get

$$I_1 = \frac{-z_2 e_2 - (z_2 + z_3) e_1}{z_1 z_2 - z_2 z_3 + z_1 z_3} \quad (22.20)$$

and

$$I_2 = \frac{z_1 e_2 - z_3 e_1}{z_1 z_2 - z_2 z_3 + z_1 z_3} \quad (22.21)$$

The third current is obtained from the sum of these two.

Another example of a circuit that cannot be analyzed by using the rules for series and parallel impedance is shown in Fig. 22-14. Such a circuit is called a "bridge." It appears in many instruments used for measuring impedances. With such a circuit one is usually interested in the question: How must the various impedances be related if the current through the impedance z_4 is to be zero? We leave it for you to find the conditions for which this is so.

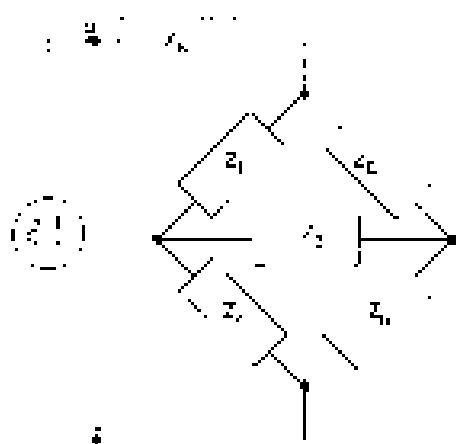

Fig. 22-14. A bridge circuit.

22-4 Equivalent elements

Suppose we connect a generator \mathcal{E} to a circuit containing some complicated interconnection of impedances, as indicated schematically in Fig. 22-15(a). All of the equations we get from Kirchhoff's rules are linear, so when we solve them for the current I through the generator, we will get that I is proportional to \mathcal{E} . We can write

$$I = \frac{\mathcal{E}}{Z_{eq}}$$

where Z_{eq} is an equivalent impedance, an algebraic function of all the elements in the circuit. If we connect another generator \mathcal{E}' after \mathcal{E} (as shown), there is no additional impedance of \mathcal{E}' . But this equation is just what we would write in the circuit of Fig. 22-15(b). So long as we are interested only in what happens to the left of the two terminals a and b , the networks of Fig. 22-15 are equivalent. We can, therefore, make the general statement that any two-terminal network of two elements can be replaced by a single impedance Z_{eq} , without changing the currents or voltages in the rest of the circuit. This statement is, of course, just a compact way of stating out of Kirchhoff's rules, and it is surely better than memory of Maxwell's equations.

The idea of a general Z is so simple that it includes generators as well as impedances. Suppose we look at such a circuit "in the point of view" of one of the terminals, which we will call a , as in Fig. 22-16(a). If we were to solve the equation for the whole circuit, we would find that the voltage V_a between the two terminals a and b is a linear function of I , which we can write

$$V_a = A - BI_{eq} \quad (22.22)$$

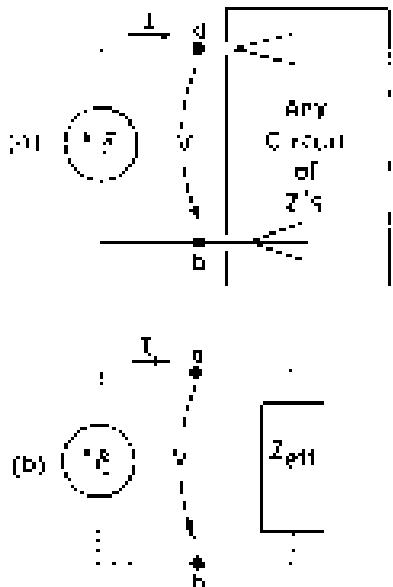

Fig. 22-15. Any two-terminal network of passive elements is equivalent to an effective impedance.

where A and B depend on the generators and impedances in the circuit to the left of a .

of the terminals. For instance, for the circuit of Fig. 22-13, we find $V_1 = I_1 z_1$. This can be written (by rearranging Eq. (22-20)) as

$$V_1 = \left[\left(\frac{z_1}{z_1 + z_2} \right) V_{\text{in}} - \frac{1}{2} \frac{z_1 z_2}{z_1 + z_2} I_1 \right]. \quad (22-23)$$

The complete solution is then obtained by combining this equation with the one for the impedance z_2 , namely, $V_2 = I_2 z_2$. As in the general case, by combining Eq. (22-22) with

$$V_2 = I_2 z_2,$$

If now we consider that z_1 is attached to a simple series circuit of a generator and a current, as in Fig. 22-15(b), the equation corresponding to Eq. (22-22) is

$$V_{\text{in}} = E_{\text{gen}} + I_{\text{gen}} z_{\text{gen}}$$

which is identical to Eq. (22-22) provided we set $E_{\text{gen}} = A$ and $I_{\text{gen}} = B$. So if we are interested only in what happens to the right of the terminals a and b , the arbitrary circuit of Fig. 22-16 can always be replaced by an equivalent circuit consisting of a generator in series with an inductance.

22-4 Energy

We have seen that to build up the current I in an inductance, the energy $G = \frac{1}{2} I^2 L$ must be provided by the external circuit. When the current falls back to zero, this energy is delivered back to the external circuit. There is no energy loss mechanism in an ideal inductance. When there is an alternating current through an inductance, energy flows back and forth between it and the rest of the circuit, but the average rate at which energy is delivered to the circuit is zero. We say that an inductance is a nondissipative element; no electrical energy is dissipated—that is, “lost”—in it.

Similarly, the energy of a condenser, $G = \frac{1}{2} C V^2$, is returned to the external circuit when a condenser is discharged. When a condenser is in an ac circuit energy flows in and out of it, but the net energy flow in each cycle is zero. An ideal condenser is also a nondissipative element.

We know that an emf is a source of energy. When a current I flows in the direction of the emf, energy is delivered to the external circuit at the rate $dG/dt = SI$. If current is driven against the emf by other generators in the circuit, the emf will absorb energy at the rate $-SI$; since I is negative, dG/dt will also be negative.

If a generator is connected to a resistor R , the current through the resistor is $I = E/R$. The energy being supplied by the generator at the rate SI is being absorbed by the resistor. This energy goes into heat in the resistor and is lost from the electrical energy of the circuit. We say that electrical energy is dissipated in a resistor. The rate at which energy is dissipated in a resistor is $dG/dt = RI^2$.

In an ac circuit the average rate of energy loss to a resistor is the average of dG/dt over one cycle. Since $I = I_0 \sin \omega t$, by which we really mean that I varies as $\sin \omega t$, the average of I^2 over one cycle is $|I|^2/2$, since the peak current is $|I|$ and the average of $\cos^2 \omega t$ is $1/2$.

What about the energy loss when a generator is connected to an arbitrary impedance z ? (By “loss” we mean, of course, conversion of electrical energy into thermal energy.) Any impedance z can be written as the sum of its real and imaginary parts. That is,

$$z = R + jX, \quad (22-24)$$

where R and X are real numbers. From the point of view of equivalent circuits we can say that any impedance z is equivalent to a resistance in series with a pure inductance or pure capacitance—called a generator—as shown in Fig. 22-17.

We have seen earlier that any circuit that contains only J 's and C 's has no dissipative loss if J is a pure inductive member. Since there is no energy loss in any of the J 's and C 's out in a source, a pure resistance containing only R 's and C 's will have no energy loss. We can see that this must be true in general for a resistance.

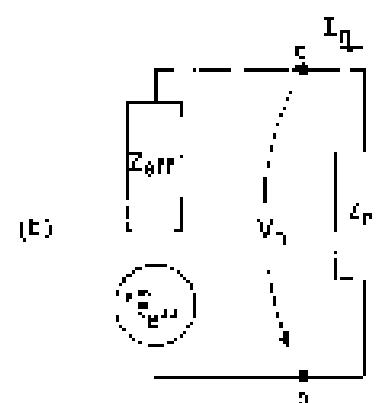

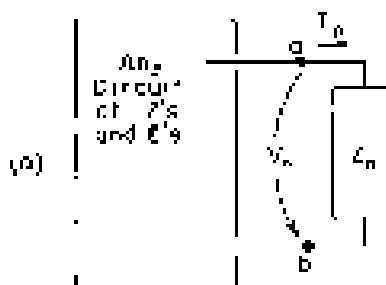

Fig. 22-16. Any a - b -terminal network can be replaced by a generator-series with an inductor.

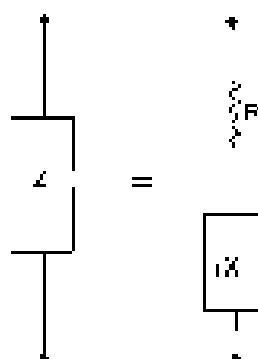

Fig. 22-17. Any impedance z is equivalent to a series combination of a pure resistance and a pure reactance.

If a generator with the emf E is connected to the impedance z of Fig. 22-17, the emf must be related to the current I from the generator by

$$E = IR = (I)z. \quad (22.25)$$

To find the average rate at which energy is delivered, we take the average of the product IR . Now we must be careful. When dealing with such products, we must deal with the real quantities $E(t)$ and $I(t)$. (The real parts of the complex quantities will represent the actual physical quantities only when we have linear equations; here we are concerned with products, which are certainly not linear.)

Suppose we choose our origin of t so that the amplitude I is a real number, let's say I_0 , then the total time variation I is given by

$$I = I_0 \cos \omega t.$$

The emf of Eq. (22.25) is the real part of

$$E_0 \cos(\omega t + \phi) (R + jX)$$

or

$$E = I_0 R \cos \omega t - I_0 X \sin \omega t. \quad (22.26)$$

The two terms in Eq. (22.26) represent the voltage drops across R and X in Fig. 22-17. We see first, the voltage drop across the resistance is in phase with the emf E , while the voltage drop across the purely reactive part is out of phase with the emf.

The average rate of energy loss, $\langle P \rangle_{av}$, from the generator is the integral of the product of over one cycle divided by the period T , in other words,

$$\langle P \rangle_{av} = \frac{1}{T} \int_0^T E I dt = \frac{1}{T} \int_0^T I_0 R \cos^2 \omega t dt = \frac{1}{T} \int_0^T P X \cos \omega t \sin \omega t dt.$$

The first integral is $\langle I_0^2 R \rangle$, and the second integral is zero. So the average energy loss in an impedance $z = R + jX$ depends only on the real part of z , and is $E_0^2 R / 2$, which is in agreement with our earlier result for the energy loss in a resistor. There is no energy loss in the reactive part.

22-6 A ladder network

We would like now to consider an interesting circuit which can be analyzed in terms of series and parallel combinations. Suppose we start with the circuit of Fig. 22-18(a). We can see right away that the impedance from terminal a to terminal b is simply $z_a - z_b$. Now let's take a little ladder circuit, the one shown in Fig. 22-18(b). We could analyze this circuit using Kirchhoff's rules, but it is also easy to handle with series and parallel combinations. We can replace the two impedances on the right hand end by a single impedance $z_3 = z_1 + z_2$, as in part (c) of the figure. Then the two impedances z_1 and z_2 can be reduced by their equivalent parallel impedance z_p , as shown in part (d) of the figure. Finally, z_1 and z_2 are equivalent to a single impedance z_{av} , as shown in part (e).

Now we may ask an amusing question: What would happen if in the network of Fig. 22-18(b) we kept on adding more sections forever—so we indicate by the dashed lines in Fig. 22-19(a)? Can we solve such an infinite network? Well, that's

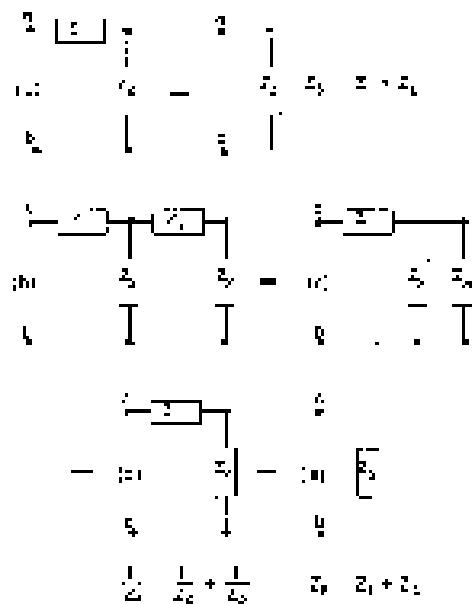

Fig. 22-18. The effective impedance of a ladder.

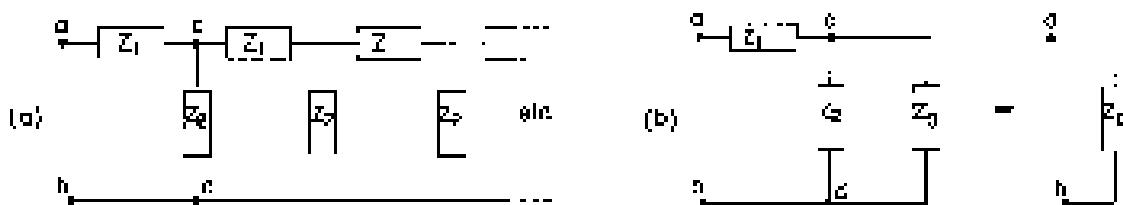

Fig. 22-19. The effective impedance of an infinite ladder.

not so hard. First, we notice that such an infinite network is unchanged if we add one more section at the "front" end. Secondly, if we add one more section to an infinite network it is still the same infinite network. Suppose we call the impedance between the two terminals a and b of the infinite network z_0 ; then the impedance of all the stuff to the right of the two terminals a and b is also z_0 . Therefore, so far as Eq. (22-19) and its consequences are concerned, we can represent the network as shown in Fig. 22-19(b). Combining the parallel combinations z_0-z_1 and adding the result in series with z_1 , we can immediately write down the impedance of this combination:

$$z_1 + z_0 = \frac{1}{(1/z_1) + (1/z_0)} \quad (22-20)$$

But this impedance is also equal to z_0 , so we have the equation

$$z_0 = z_1 + \frac{z_1 z_0}{z_0 - z_1}$$

We can solve for z_0 to get

$$z_0 = \frac{1}{\frac{1}{z_1} + \sqrt{(\frac{1}{z_1})^2 + z_1/z_0}} \quad (22-21)$$

So we have found the solution for the impedance of an infinite ladder of resistor units and parallel impedances. The impedance z_0 is called the *characteristic impedance* of such an infinite network.

Let's now consider a specific example in which the series element is an inductance L and the shunt element is a capacitance C , as shown in Fig. 22-20(a). In this case we find the impedance of the infinite network by setting $z_1 = j\omega L$ and $z_0 = j\omega C$. Notice that the first term, z_1/z_0 , in Eq. (22-21) is just equal to the impedance of the first element. It would therefore seem more natural, in at least somewhat simpler, if we were to draw our infinite network as shown in Fig. 22-20(b). Looking at the infinite network from the terminal a we would fix the characteristic impedance

$$z_0 = \sqrt{j\omega LC} = (\omega^2 LC)^{1/4}. \quad (22-22)$$

Now there are two interesting cases, depending on the frequency ω . If $\omega^2 L^2$ is less than $1/4C$, the second term in the radicand will be smaller than the first, and the impedance z_0 will be a real number. On the other hand, if ω^2 is greater than $4/LC$ the impedance z_0 will be a pure imaginary number which we can write as

$$z_0 = \pm \sqrt{j\omega LC/4} = j(\omega L^2)^{1/4}.$$

We have said earlier that $j\omega L^2$ which represents only inductive inductances, such as inductances and capacitors, will have an impedance which is purely imaginary. How can it be then that for the circuit we are now studying—which has only L 's and C 's—the impedance is a pure resistance for frequencies below $\sqrt{4/LC}$? For higher frequencies the impedance is surely being noisy, in agreement with our earlier statement. But lower frequencies the impedance is a pure resistance and will therefore absorb energy. But how can the circuit continue to absorb energy, if it is made only of inductances and capacitors? Answer: Because this is an infinite number of inductances and capacitors, so that when a source is connected to the circuit it supplies energy to the last inductance and capacitor, then to the second, to the third, and so on. In a circuit of this kind, energy is continually absorbed from the generator at a constant rate and flows continually out of the network, supplying energy which is stored in the inductive inductances close to the line.

This is a very strange situation, and about what is happening in the circuit. We would expect that, for example, a source to the front end, the effects of this source will be propagated through the network toward the infinite end. The propagation of the waves toward the line is much like the radiation from an antenna which loses energy from its driving source; that is, we expect such a propagation to occur, when the impedance is real, which occurs if ω is less than $\sqrt{4/LC}$. But since the impedance is purely imaginary, which happens for ω greater than $\sqrt{4/LC}$, we would not expect to see any such propagation.

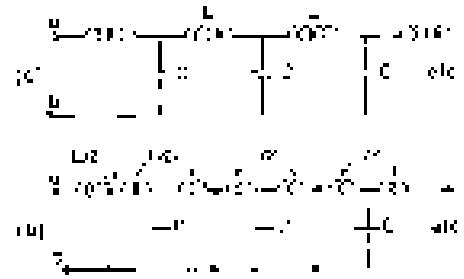

Fig. 22-20. An L-C ladder, shown in two equivalent ways.

22-7 Ladders

We saw in (Lecture 20) that the infinite ladder network of Fig. 22-20 above can carry energy continuously if it is driven at a frequency below a certain critical frequency $\sqrt{A/LC}$, which we will call the "cutoff frequency" ω_0 . We suggested that this effect could be understood in terms of a continuous transport of energy down the line. On the other hand, at high frequencies, for $\omega > \omega_0$, there is no continuous absorption of energy; we should then expect that perhaps the currents don't "propagate" very far down the line. Let's see whether these ideas are right.

Suppose we have the input end of the ladder connected to some AC generator and we ask what the voltage looks like at, say, the 75th section of the ladder. Since the network is infinite, whatever happens to the voltage from one section to the next is always the same; so let's just look at what happens when we go from some section, say the n th to the next. We will define the currents I_n and voltages V_n as shown in Fig. 22-21(a).

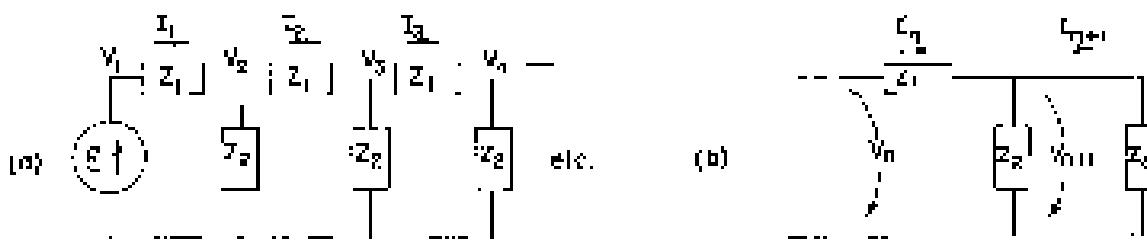

Fig. 22-21. Finding the propagation factor of a ladder.

We can get the voltage V_{n+1} from V_n by remembering that we can always replace the rest of the ladder after the n th section by its characteristic impedance γ_n ; then we need only analyze the circuit of Fig. 22-21(b). First, we notice that any V_{n+1} since I_n is across Z_n , must again I_{n+1} . Also, the difference between V_n and V_{n+1} is just $I_n Z_n$:

$$V_n - V_{n+1} = I_n Z_n \approx V_n \frac{\gamma_n}{\gamma_n}$$

So we get the ratio

$$\frac{V_{n+1}}{V_n} = -\frac{Z_n}{Z_{n+1}} \approx \frac{\gamma_n}{\gamma_{n+1}}$$

We can call this ratio the *propagation factor* for one section of the ladder; we'll call it α . It is, of course, the same for all sections:

$$\alpha = \frac{\gamma_n}{\gamma_{n+1}} \quad (22.29)$$

The voltage after the n th section is then

$$V_n = \alpha^n V_0 \quad (22.30)$$

You can now link the voltage after 254 sections, V_{254} , just to the initial power times α .

Suppose we set up a circuit for the $L-C$ ladder of Fig. 22-20(p) (using π_0 from Eq. (22.23)), and $\omega = \omega_0$; we get

$$\alpha = \frac{\sqrt{A/C} + (\omega C/4)}{\sqrt{A/C} - (\omega C/4)} = (\omega d/2) \quad (22.31)$$

If the driving frequency is below the cutoff frequency $\omega_0 = \sqrt{A/LC}$, the radical is a real number, and the magnitudes of the complex numbers in the numerator and denominator are equal. Therefore, the magnitude $|\alpha|$ is one; we can write

$$\alpha = e^{j\phi}$$

which means that the magnitude of the voltage is the same at every section, only

dephase phase. The phase change ϕ , is, in fact, a negative number and represents the "delay" of the voltage as it passes through the network.

For frequencies above the cutoff frequency ω_0 , it is useful to factor out ω/ω_0 from the numerator and denominator of Eq. (22-31) and rewrite it as

$$\alpha = \frac{\sqrt{L/C}(\omega/4)}{\sqrt{(4\omega^2/4) - (L/C)} - (L/C)} = \frac{1}{\omega\omega_0}. \quad (22-32)$$

The propagation factor α is now a real number, and a number less than one. That means that the voltage at any section is always less than the voltage at the preceding section by the factor α . For any frequency above ω_0 , the voltage decreases rapidly as we go along the network. A plot of the absolute value of α as a function of frequency looks like the graph in Fig. 22-22.

We see that the behavior of α , both above and below ω_0 , agrees with our interpretation that the network propagates, stores energy, and blocks it for $\omega > \omega_0$. We say that the network "passes" low frequencies and "rejects" or "blocks" the high frequencies. Any network designed to have these characteristics says in a prescribed way with frequency is called a "filter." We have been analyzing a "low-pass filter."

You may be wondering why all this discussion of an infinite network which obviously cannot actually occur. The point is that the same characteristics are found in a finite network if we finish it off at the end with an impedance equal to the characteristic impedance ω_0 . Now in practice it is not possible to exactly reproduce the characteristic impedance with a few simple elements like resistors, inductors, and capacitors. But it is often possible to do so with a fair approximation for a certain range of frequencies. In this way one can make a finite filter network whose properties are very nearly the same as those for the infinite case. For instance, the L-C ladder behavior which we have described in (c) is contained in the pure resistance $R = \sqrt{L/C}$.

If in our L-C ladder we interchange the positions of the L's and C's, to make the ladder shown in Fig. 22-23(a), we can have a filter that propagates high frequencies and rejects low frequencies. It's easy to see what happens with this network by using the results we already have. You will notice first whenever we change an L to a C and vice versa, we also change every ω to $1/\omega_0$. So whatever happens at ω before will now happen at $1/\omega$. In particular, we can see how α will vary with frequency by using Fig. 22-22 and changing the label on the axis to $1/\omega_0$, as we have done in Fig. 22-23(b).

The low-pass and high-pass filters we have described have various technical applications. An L-C low-pass filter is often used as a "smoothing" filter in a power supply. If we want to manufacture \propto power from an ac source, we begin with a rectifier which permits current to flow only in one direction. From the rectifier we get a series of pulses that looks like the function $V(t)$ shown in Fig. 22-24, which is noisy ω , because it wobbles up and down. Suppose we would like a nice pure \propto , such as a battery provides. We can come close to that by putting a low-pass filter between the rectifier and the load.

We know from Chapter 8 of Vol. I that the time function in Fig. 22-24 can be represented as a superposition of a constant voltage plus a sine wave, plus a higher frequency sine wave, plus a still higher frequency sine wave, etc.—by a Fourier series. If our filter is linear (i.e., as we have been assuming, the L's and C's don't vary with the currents or voltages), then what comes out of the filter is the superposition of the outputs for each component of the input. If we arrange that the cutoff frequency ω_0 of our filter is well below the lower frequency in the function $V(t)$, the $\omega = 0$ (for which $\omega = 0$) goes through fine, but the amplitude of the first harmonic will be cut down a lot. And amplitudes of the higher harmonics will be cut down even more. So we can get the output as smooth as we wish, depending only on how many filter sections we are willing to buy.

A high-pass filter is used in one way to reject certain low frequencies. For instance, in a phonograph amplifier a high-pass filter may be used to let the music

(b) A simple resonant filter.

through, while keeping out the low-passed sounding from the music of the turntable.

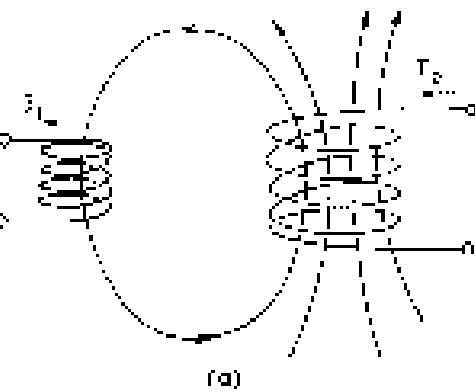

It is also possible to make "band-pass" filters that, to cut frequencies below some frequency ω_1 and above another frequency ω_2 (greater than ω_1), but pass the frequencies between ω_1 and ω_2 . This can be done simply by putting together a high-pass and a low-pass filter, but it is more usually done by making a "filter in which the impedances ω_1 and ω_2 is more complicated—here, and a combination of ω_1 's and ω_2 's. Such a band-pass filter might have a propagation constant like that shown in Fig. 22-25(a). It might be used, for example, in separating signals that occupy only an interval of frequencies, such as most of the music wave channels in a high-frequency telephone system, or the modulated carrier of a radio transmission.

We have seen in Chapter 25 of Vol. I that such filtering can also be done using the selectivity of an ordinary resonator curve, which we have shown in comparison in Fig. 22-25(b). But the resonator filter is not as good for some purposes as the band-pass filter. You will remember (Chapter 25, Vol. I) that when a carrier of frequency ω_1 is modulated with a "signal" frequency ω_2 , the total signal contains not only the carrier frequency but also the two side-band frequencies $\omega_1 + \omega_2$ and $\omega_1 - \omega_2$. With a resonator filter, these side-bands are always attenuated somewhat, and the attenuation is more, the higher the signal frequency, as you see from the figure. So there is a poor "frequency response." The higher musical tones don't get through. But if the filtering is done with a band-pass filter, designed so that the width $\omega_2 - \omega_1$ is at least twice the highest signal frequency, the frequency response will be "flat" for the signals wanted.

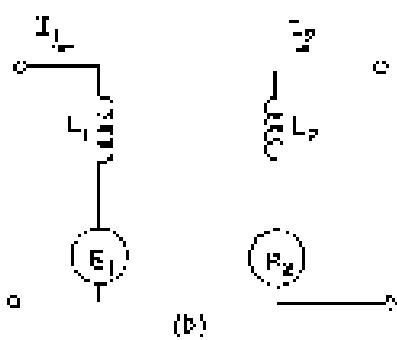

We want to make one more point about the ladder filter: the *L-C* ladder of Fig. 22-20 is often an approximate representation of a transmission line. If we have a long conductor that runs parallel to another conductor—such as a wire in a coaxial cable, or a wire suspended above the earth—there will be some capacitance between the two conductors and also some inductances due to the magnetic field between them. If we imagine the line as broken up into small lengths Δz , each length will look like one section of the *L-C* ladder with a series inductance ΔL and a shunt capacitance ΔC . We can then use our results for the ladder filter. If we take the limit as Δz goes to zero, we have a good description of the transmission line. Notice that as Δz is made smaller and smaller, both ΔL and ΔC decrease but in the same proportion, so that the ratio $\Delta L/\Delta C$ remains constant. So if we take the circuit of Eq. (22-28) as Δz and ΔC go to zero, we find that the characteristic impedance ω_0 is a pure resistance whose magnitude is $\sqrt{\Delta L/\Delta C}$. We can also write the ratio $\Delta L/\Delta C$ as L_0/C_0 , where L_0 and C_0 are the inductance and capacitance of a unit length of the line; then we have

$$\omega_0 = \sqrt{L_0/C_0} \quad (22-39)$$

You will also notice that as ΔL and ΔC go to zero, the cutoff frequency $\omega_c = \sqrt{4/LC}$ goes to infinity. There is no cutoff frequency for an ideal transmission line.

(a)

(b)

Fig. 22-26. Equivalent circuit of a valve inductor.

22-8 Other circuit elements

We have so far defined only the ideal circuit impedances—the inductance, the capacitance, and the resistance—as well as the ideal voltage generator. We would now be able to show that other elements, such as mutual inductances or varactors diodes, can be described by using only the same three elements. Suppose that we have two coils and that on purpose, or otherwise, some flux from one of the coils links the other, as shown in Fig. 22-28(a). Then the two coils will have a mutual inductance M such that when the current varies in one of the coils, there will be a voltage generated in the other. Can we take account of such a effect in our equivalent circuits? We can in the following way. We have seen that the

induced emf's in each of two inexciting coils can be written as the sum of two parts:

$$\begin{aligned}\delta_1 &= -L_1 \frac{dI}{dt} + M \frac{dI_2}{dt}, \\ \delta_2 &= -L_2 \frac{dI_2}{dt} + M \frac{dI_1}{dt}.\end{aligned}\quad (22.34)$$

The first term comes from the self-inductance of the coil, and the second term comes from its mutual inductance with the other coil. The sign of the second term can be plus or minus, depending on the way the flux from one coil links the other. Making the same approximations we used in describing an ideal inductance, we would say that the potential difference across the terminals of each coil is equal to the electromotive force in the coil. Then the two equations of (22.34) are the same as the ones we would get from the circuit of Fig. 22-26(b), provided the electromotive force in each of the two circuits shown depends on the current in the opposite circuit according to the relations

$$E_1 = -2\pi M I_2, \quad E_2 = -2\pi M I_1. \quad (22.35)$$

So what we can do is represent the effect of the self-inductance in a normal way and replace the effect of the mutual inductance by an auxiliary ideal voltage generator. We must, in addition, of course, have the equation that relates this emf to the current in some other part of the circuit; but so long as this equation is linear, we have just added more linear equations to our circuit equations, and all of our earlier conclusions about equivalent circuits and so forth are still correct.

In addition to mutual inductances there may also be mutual capacitances. So far, when we have talked about condensers we have always imagined that there were only two electrodes, but, in many situations, for example in a vacuum tube, there may be many electrodes close to each other. If we put an electric charge on any one of the electrodes, its electric field will induce charges on each of the other electrodes and affect its potential. As an example, consider the arrangement of four plates shown in Fig. 22-27(a). Suppose these four plates are connected to external circuits by means of the wires A, B, C, and D. So long as we are only worried about electrostatic effects, the equivalent circuit of such an arrangement of electrodes is as shown in part (b) of the figure. The electrostatic interaction of any electrode with each of the others is equivalent to a capacity between the two electrodes.

Finally, let's consider how we should represent such complicated devices as transistors and radio tubes in an ac circuit. We should point out at this stage that such devices are often operated in such a way that the relationship between the currents and voltages is not at all linear. In such cases, those statements we have made which depend on the linearity of equations are, of course, no longer correct. On the other hand, in many applications the operating characteristics are sufficiently linear that we may consider the transistors and tubes to be linear devices. By this we mean that the alternating currents in, say, the plate of a vacuum tube are linearly proportional to the voltages that appear on the other electrodes, say the grid voltage and the plate voltage. When we have such linear relationships, we can incorporate the device into our equivalent circuit representation.

As in the case of the mutual inductance, our representation will have to include auxiliary voltage generators which describe the influence of the voltages or currents in one part of the device on the currents or voltages in another part. For example, the plate circuit of a tube can usually be represented by a resistance in series with an ideal voltage generator whose strength is proportional to the grid voltage. We get the equivalent circuit shown in Fig. 22-28(c). Similarly, the collector circuit

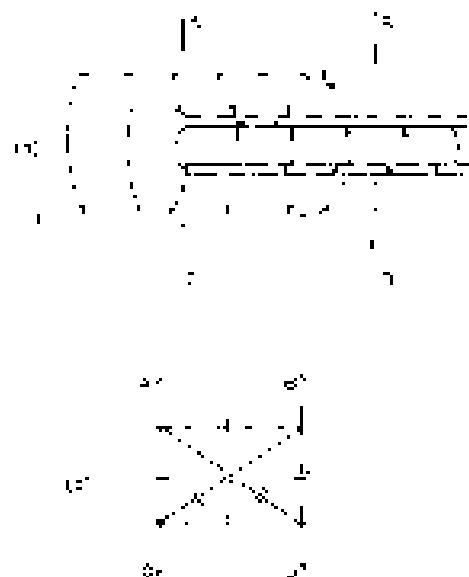

Fig. 22-27. Equivalent circuit of mutual capacitance.

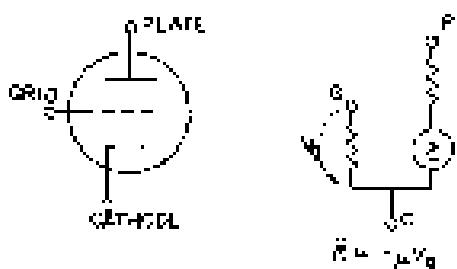

Fig. 22-28. A low-frequency equivalent circuit of a vacuum tube.

* The equivalent circuit, shown here is only for low frequencies. For high frequencies the equivalent circuit gets much more complicated and will include various so-called "parasitic" capacitances and inductances.

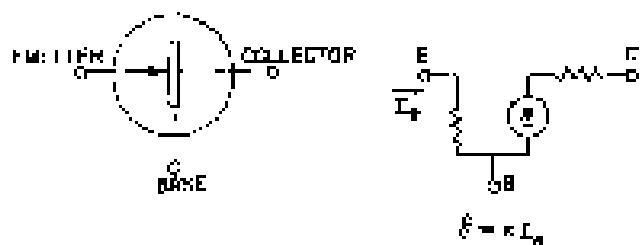

Fig. 22-29. A low-frequency equivalent circuit of a transistor.

of a capacitor is conveniently represented as a resistor in series with an ideal voltage generator whose output voltage is proportional to the current from the emitter to the base of the transistor. The equivalent circuit is then like that in Fig. 22-29. So long as the resistances which describe the elements are linear, we can use such representations for tubes or transistors. (Note, when tubes are incorporated in a complicated network, our general conclusion about the equivalent representation of any arbitrary connection of elements is still valid.)

There is one remarkable thing about transistors and radio tube circuits which is different from circuits containing only impedances: the real part of the effective impedance γ_{AB} can be truly negative. We have seen that the real part of γ represents the loss of energy. But, it is the characteristic of transistors and tubes that they *supply* energy to the circuit. (Of course they don't just "pass" energy; they also convert from the DC currents of the power supplies into currents at high AC voltage.) So it is possible to have a circuit with a negative real-term. Such a circuit has the property that if you connect it to an input with a positive real part, i.e., a positive resistance, and accept emitters as the sign of the two real parts is exactly *opp*, then there is no dissipation in the connected circuit. If there is no loss of energy, any alternating voltage once started will continue forever! This is the basic idea behind the operation of an oscillator or signal generator which can be used as a source of alternating voltage at any desired frequency.

Circuit Resonance

23-1 Real circuit elements

When looked at from any one point in a circuit, any arbitrary circuit will look up to an impedance and admittance as, at any given frequency, equivalent to a generator & load in series with an impedance. This makes sense because if we put a voltage V across the terminals and solve all the equations to find the current I , we must get a linear relation between the current and the voltage. Since all the equations are linear, the result for I must also depend on V linearly or $I = KV$. The most general linear form can be expressed as

$$I = \frac{1}{Z} (V - R) \quad (23.1)$$

In general, both Z and R may depend in some complicated way on the frequency ω . Equation (23.1), however, is the relation we would get if below the two terminals there was just a generator "in series with its impedance Z ".

There is also the opposite kind of question. If we have any electronic circuit device at which we know the impedances and we measure the voltage between two points to determine certain functions of frequency, can we find a equivalent circuit of real elements that is equivalent to the stated impedances? The answer is that for any reasonably simple & physically reasonable circuit it is impossible to approximate the situation to as high a degree of accuracy as you wish with a finite number of real elements. We can't want to consider the general problem now, but only look at what might be expected from physical arguments for a few cases.

If we think of a real resistor, we know that the current through it will produce a magnetic field. At any rate, resistors almost always have some inductance. After all, when a resistor has a potential difference across it, there must be charges on the ends of the resistor to produce the necessary electric field. As the voltage changes, the charges will change in proportion, so the resistor will also have some capacitance. We expect that a real resistor *in the form* the equivalent circuit shown in Fig. 23-1. In a well designed resistor, the so called "parasitic" elements A and C are small, so that at the frequencies for which it's intended, ω_A is much less than ω , and ω_C is much greater than ω . It may therefore be possible to neglect them. As the frequency is raised, however, they will eventually become important, and a resistor begins to look like a resonant circuit.

A real inductor is also not equal to the idealized inductor, whose impedance is ωL . A real coil of wire will have some resistance, so at low frequencies the coil is really equivalent to an inductor in series with some resistance, as shown in Fig. 23-2(a). But, you are thinking, the resistance and inductance are *together* in a real coil—the resistance is spread all along the wire so it's mixed in with the inductance. We should probably use a circuit more like the one in Fig. 23-2(b), which has several little R 's and L 's in series. But the total impedance of such a circuit is just $\sum R + \sum L\omega$. That's what is equivalent to the simpler diagram of part (a).

As we go up in frequency ω , in a real coil the representation of an inductor as a pure inductor is no longer very good. The charges that must build up on the wires to make the voltage will become non-linear. It's as if there were little resistors across the turns of the n_1 and n_2 sketched in Fig. 23-2(a). We might try to approximate the real coil by the circuit of Fig. 23-2(b), but in fact, this circuit can be converted fairly easily to the simpler form of part (a) of the figure (which is again the only reasonable circuit we could find for the high-frequency theory of a resistor). For higher frequencies, however, the more complexer circuit of

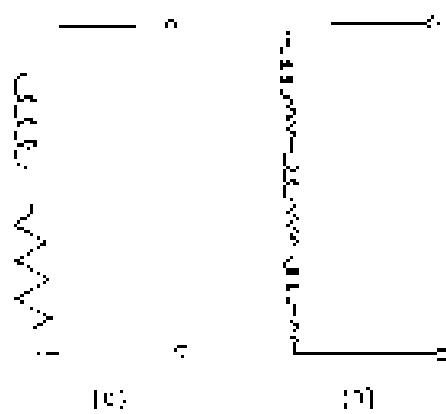

Fig. 23-2. The equivalent circuit of a real inductor at low frequencies.

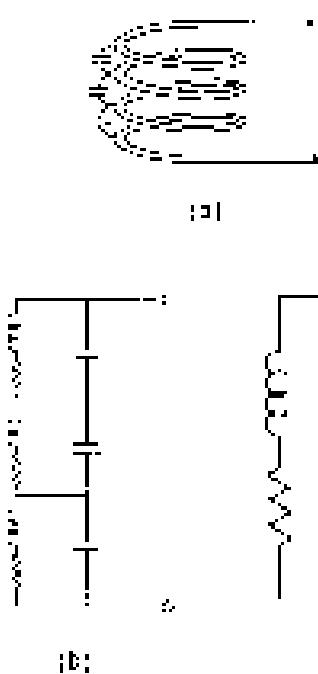

Fig. 23-3. The negative ωL circuit of a real inductance at higher frequencies.

Fig. 24. (a) As you learn, to build the more accurately you wish to approach the actual impedance of a real physical inductor, the more ideal elements you will have to use in the artificial model at it.

Let's look a little more closely at what goes on in a real coil. The impedance of an inductor depends on what it is wound around. For example, if it is wound around a thin wire, the reactance of the wire is small. As we go up in frequency, ω , one becomes much larger than R , and the coil looks mostly like a real inductor. At very low frequencies, the inductor becomes unimportant. At very high frequencies, a resistor is in "series" across the coil, and when it is in parallel with something else, it allows no current. But at high frequencies, the current prefers to flow into the capacitance between the turns, rather than through the inductor. So the current in the coil jumps from one turn to the other and doesn't have to go around and around where it has to stick the ear! So although we may have imagined that the current should go around the loop, it will take the easier path—the path of least impedance.

If the subject had been one of popular interest, this effect would have been called "the high frequency barrier," or some such name. The same kind of thing happens in all subjects. In aerodynamics, if you try to make things go faster than the speed of sound when they were designed for lower speeds, they don't work. It doesn't mean that there is a great "barrier" there; it just means that the object should be redesigned. So this coil which we designed as an "inductance" is not going to work as a good inductance, but as some other kind of thing at very high frequencies. For high frequencies, we have to find a new design.

23-2. A capacitor at high frequencies

Now we want to discuss in detail the behavior of a capacitor—a geometrically ideal capacitor—as the frequency gets larger and larger, so we can see the transition off its properties. (We prefer to use a capacitor instead of an inductance, because the geometry of a pair of plates is much less complicated than the geometry of a coil.) We consider the capacitor shown in Fig. 23-4(a), which consists of two parallel circular plates connected to an external generator by a pair of wires. If we charge the capacitor well DC, there will be a positive charge on one plate and a negative charge on the other, and there will be a uniform electric field between the plates.

Now suppose that instead of DC, we put in $V_0 \cos \omega t$ of low frequency on the plates. (We will find out later what is "low" and what is "high.") Say we repeat the capacitor as a lower-frequency generator. As the voltage alternates, the positive charge on the top plate is taken off and moves to the bottom plate. While that is happening, the electric field disappears and then, in due time, it appears in reverse.

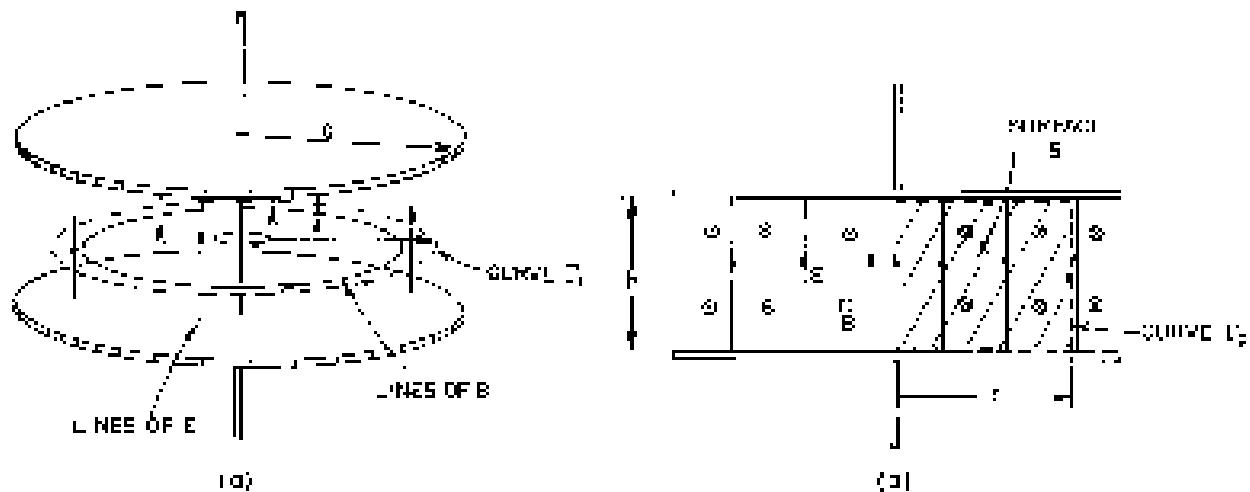

Fig. 23-4. The electric and magnetic fields between the plates of a capacitor.

As the charge shuffles back and forth slowly, the electric field follows. At each instant the electric field is uniform as shown in Fig. 22-1(b), except for some edge effects which we are going to disregard. We can write the magnitude of the electric field as

$$E = E_0 e^{i\omega t}, \quad (22.2)$$

where E_0 is a constant.

Now will that continue to be right as the frequency goes up? No, because as the electric field is going up and down, there is a flux of electric field through any loop like "1" in Fig. 22-4(a). And as you know, a changing electric field sets up a magnetic field. One of Maxwell's equations says that when there is a varying electric field, as there is here, the \mathbf{E} has got to be a line integral of the magnetic field. (Or integrals of the magnetic field are on a closed loop, and induced by \mathbf{E} , so if you go around the loop twice, the change in \mathbf{E} there are no net work.)

$$\epsilon^2 \oint_{C_1} \mathbf{B} \cdot d\mathbf{s} = \frac{\partial}{\partial t} \int_{\text{inside } C_1} \mathbf{E} \cdot d\mathbf{s}. \quad (22.3)$$

So now what magnetic field is there? That's not very hard. Suppose that we take the loop C_1 , which is a circle of radius r . We can see from symmetry that the magnetic field goes around as shown in the figure. Then the line integral of \mathbf{B} is $2\pi r B$. And, since the electric field is uniform, the flux of the electric field is simply E multiplied by πr^2 , the area of the circle:

$$r' B \cdot 2\pi r = \frac{\partial}{\partial t} (E \cdot \pi r^2). \quad (22.4)$$

The derivative of E with respect to time is, for our alternating field, simply $i\omega E_0 e^{i\omega t}$. So we find that our capacitor has the magnetic field

$$B = \frac{\mu_0}{2\pi r} E_0 e^{i\omega t}. \quad (22.5)$$

In other words, the magnetic field also oscillates and with a strength proportional to r .

What is Earth's law of that? When there is a magnetic field that is varying, there will be an induced electric field, or the capacitor will begin to act a little bit like an inductor. As the frequency goes up, the magnetic field gets stronger; it is proportional to the rate of change of E , and so to $i\omega$. The resistance of the capacitor will no longer be simply R/r .

Let's continue to raise the frequency and to analyze what happens more carefully. We have a magnetic field that goes shushing back and forth. But then the electric field cannot be uniform, as we have assumed! When there is a varying magnetic field, there must be a line integral of the electric field—because of Faraday's law. So if there is an appreciable magnetic field, as begins to happen at higher frequencies, the electric field cannot be the same at all distances from the center. The electric field must change with r so that the line integral of the electric field can equal the changing flux of the magnetic field.

Let's see if we can figure out the correct electric field. We can do that by computing a "correction" to the uniform field we originally assumed for low frequencies. Let's call the uniform field E_0 , which will still be $E_0 e^{i\omega t}$, and we'll call the correct field as

$$E = E_0 + E_1,$$

where E_1 is the correction due to the changing magnetic field. The way we will write the field at the center of the capacitor as $E_0 e^{i\omega t}$ (barely defining E_0), so that we have no correction at the center: $E_1 = 0$ at $r = 0$.

To find E_1 we can use the integrated form of Faraday's law

$$\oint_C \mathbf{E} \cdot d\mathbf{s} = - \frac{\partial}{\partial t} (\text{flux of } \mathbf{B}).$$

For simplicity, consider if we take the path for the curve Γ shown in Fig. 23-4(b), which goes up along the left edge, outwards by the distance a , then down the right edge to the vertical dashed line to the axis. The line integral of B around this curve is $\oint \mathbf{B} \cdot d\mathbf{l}$, equal to zero, as only B_x contributes, and its integral is just $B_x a$, where a is the separation between the plates. (We will *C* points if it points against \mathbf{dl} ; Γ is oriented to the rate of change of the flux of B , which we have to get by an integration over the shaded area S inside Γ , in Fig. 23-4(a).) The flux through a vertical strip of width dx is $B_x dx$, so the total flux is

$$B_x \int_0^a B_x(x) dx.$$

Setting $-i\omega t$ of the flux equal to the line integral of E_x , we have

$$E_x(x) = -\frac{i}{a} \int_0^x B_x(z) dz. \quad (23.6)$$

Note that $i\omega t$ has been added to the line integral because of the separation of the plates.

Using Eq. (23.5) for $B_x(x)$, we have

$$E_x(x) = \frac{c}{m} \frac{\omega^{1/2}}{4\pi^2} E_0 e^{i\omega t}.$$

The time derivative just brings down another factor $i\omega$, so we get

$$E_x(x) = -\frac{\omega^{1/2}}{2\pi^2} B_0 e^{i\omega t}. \quad (23.7)$$

As we expect, the induced field wants to reduce the electric field, otherwise, the corrected field $E = E_0 + B_0$ is zero.

$$E = E_0 + B_0 = \left(1 - \frac{\omega^{1/2}}{4\pi^2}\right) E_0 e^{i\omega t}. \quad (23.8)$$

The electric field in the capacitor is no longer uniform; it has the parabolic shape shown by the broken line in Fig. 23-5. You see that a simple capacitor is becoming slightly complicated!

We could now use our results to calculate the impedance of the capacitor at high frequencies. Knowing the electric field, we could compute the charges on the plates and then on how the current through the capacitor depends on the frequency ω , but we are not interested in that problem for the moment. We are more interested in seeing what happens as we continue to go up with the frequency ω to see what happens at even higher frequencies. Again, we already find "no". No, because we have corrected the electric field, which means that the magnetic field we have calculated is no longer right. The magnetic field of Eq. (23.5) is approximately right, but it is only a first approximation. So let's call it B_1 . We should then rewrite Eq. (23.5) as

$$B_1 = \frac{i\omega}{2\pi} B_0 e^{i\omega t}. \quad (23.9)$$

You will remember that this field was produced by the variation of E_0 . Now the correct magnetic field will be that produced by the total electric field $E = E_0 + E_1$. If we write the magnetic field as $B = B_1 + B_0$, the second term is just the additional field produced by E_0 . To find B_0 , we can go through the same arguments we have used to find B_1 , the line integral of B_0 around the curve Γ , is equal to the rate of change of the flux of B , through Γ . We will just use Eq. (23.4) again with B replaced by B_0 and A replaced by ΔA :

$$\omega^2 \Delta A / \Delta t = \frac{1}{g} (\text{flux of } B_0 \text{ through } \Gamma).$$

surface inside Γ_1 . Using $2\pi dr$ as the element of area, this integral is

$$\int_{r_0}^r E_2(r') \cdot 2\pi r' dr'$$

So we get for B_{21} :

$$B_{21}(r) = \frac{1}{r_0^2} \frac{\partial}{\partial r} \int_{r_0}^r E_2(r') r' dr'. \quad (23.13)$$

Using $E_2(r)$ from Eq. (23.9), we need the integral of $r^3 dr$, which is, of course, $r^4/4$. The result of the magnetic field becomes

$$B_{21}(r) = -\frac{i\omega^{3/2}}{16\pi^2} E_0 r'^{1/2}. \quad (23.14)$$

But we are still not finished! If the magnetic field B is not the same as we first thought, then we have incorrectly computed E_2 . We must make a further correction to E , which comes from the extra magnetic field B_2 . Let's call this additional correction to the electric field E_3 . It is related to the magnetic field B_2 in the same way that E_2 was related to B_1 . We can use Eq. (23.8) all over again, just by changing the subscripts:

$$E_3(r) = \frac{1}{ir} \int B_2(r') dr'. \quad (23.15)$$

Using our result, Eq. (23.14), for B_2 , the new correction to the electric field is

$$E_3(r) = \pm \frac{i\omega^{1/2}}{64\pi^2} E_0 r'^{1/2}. \quad (23.16)$$

Writing our finally corrected electric field as $E = E_1 + E_2 + E_3$, we get

$$E = E_0 r'^{1/2} \left[1 + \frac{1}{2} \left(\frac{\omega r}{c} \right)^2 + \frac{1}{2} + \frac{1}{48} \left(\frac{\omega r}{c} \right)^4 \right]. \quad (23.17)$$

The variation of the electric field with radius is no longer the simple parabola we drew in Fig. 23-5, but at large radii lies slightly above the curve ($E_1 = E_0$).

We are not quite through yet. The new electric field produces a new correction to the magnetic field, and the newly corrected magnetic field will produce a further correction to the electric field, and on and on. However, we already have all the formulas that we need. For B , we can use Eq. (23.10), changing the subscripts of B and E from 2 to 3.

The next correction to the electric field is

$$E_4 = -\frac{1}{2^2 \cdot 12 \cdot 6^2} \left(\frac{\omega r}{c} \right)^6 E_0 r'^{1/2}.$$

So to this order we have that the complete electric field is given by

$$E = E_0 r'^{1/2} \left[1 + \frac{1}{2} \left(\frac{\omega r}{c} \right)^2 + \frac{1}{2} + \frac{1}{48} \left(\frac{\omega r}{c} \right)^4 - \frac{1}{2^2 \cdot 12 \cdot 6^2} \left(\frac{\omega r}{c} \right)^6 + \dots \right], \quad (23.18)$$

where we have written the corrected coefficients in a way that it is obvious how the series is to be continued.

Our final result is that the starting field between the plates of the capacitor, for any frequency, is given by $E_0 r'^{1/2}$ times the infinite series which contains only the even terms. If we wish, we can define a special function, which we will call $J_0(x)$, as follows (which is precisely in the manner of Eq. (23.18)):

$$J_0(x) = 1 + \frac{1}{(1)^2} \left(\frac{x}{2} \right)^2 + \frac{1}{(2)^2} \left(\frac{x}{2} \right)^4 - \frac{1}{(3)^2} \left(\frac{x}{2} \right)^6 + \dots \quad (23.19)$$

Then we can write our solution as $E_0 e^{i\omega t}$ times this function, with $x = \omega/c$:

$$E = E_0 e^{i\omega t} J_0 \left(\frac{\omega c}{v} \right) \quad (23.17)$$

The reason we have called our special function J_0 is thus, naturally, this is not the first time anyone has ever worked out a problem with oscillations in a cylinder. The function has come up before and is usually called J_0 . It always comes up whenever you solve a problem about waves in a cylindrical geometry. The function J_0 is to cylindrical waves what the cosine function is to waves on a straight line. So it is an important function, invented a long time ago. Then a man named Bessel got his name attached to it. The subscript zero means that Bessel invented a whole lot of different functions and this is just the first of them.

The other functions of Bessel— J_1 , J_2 , and so on—have to do with cylindrical waves which have a variation of their strength with the angle around the axis of the cylinder.

The completely corrected electric field between the plates of our circular capacitor, given by Eq. (23.17), is plotted as the solid line in Fig. 23-5. For frequencies that are not too high, our second approximation was already quite good. The third approximation was even better—so good, in fact, that if we had plotted it, you would not have been able to see the difference between it and the solid curve. You will see in the next section, however, that the complete series is needed to get an accurate description for large radii, or for high frequencies.

23-3 A resonant cavity

We want to look now at what our solution gives for the electric field between the plates of the capacitor as we continue to go to higher and higher frequencies. For large x , the parameter $x = \omega/c$ also gets large, and the first few terms in the series for J_0 of x will increase rapidly. That means that the parabola we have drawn in Fig. 23-3 curves downward more steeply at higher frequencies. In fact, it looks as though the field would fall all the way to zero at some high frequency, perhaps when $c\omega$ is approximately one-half of σ . Let's see whether J_0 does indeed go through zero and become negative. We begin by trying $x = 2$:

$$J_0(2) \approx -1.14 \quad \text{at } \omega = 10^3$$

This value is still not zero, so let's try a higher value of x , say, $x = 2.5$. Putting in our numbers, we write

$$J_0(2.5) \approx -1 - 1.65 - 0.61 - 0.09 \approx -3.04.$$

The function J_0 has already gone through zero by the time we get to $x = 2.5$. Comparing the results for $x = 2$ and $x = 2.5$, it looks as though J_0 goes through zero about half of the way from 2.3 to 2. We would guess that the zero occurs for x approximately equal to 2.3. Let's see what that value of x gives:

$$J_0(2.3) \approx -1 - 1.44 - 0.52 - 0.08 = 3.00$$

We get zero in the same way as our two previous attempts. If we triple the frequency instead of double (or since J_0 is a well-known function, if we took it up a third), we find that it goes through zero at $x = 3.205$. We leave you to try out by hand to show you how you can't have discovered these things without doing some numerical work.

As long as we are looking up J_0 on a table, it is interesting to notice how it goes for large values of x , such as the graph in Fig. 23-6. As longer and longer distances between positive and negative values of x the oscillations damp out of oscillation.

We have given the following interesting test. If we go high enough in frequency, the electric field in the center of our condenser will be negative and the electric field near the edge will point in the opposite direction. For example,

suppose that we take an ω high enough so that $r = \omega/c$ at the outer edge of the capacitor is equal to 4; then the edge of the capacitor corresponds to the a radius $x = 4$ in Fig. 23-6b. This means that our capacitor is being operated at the frequency $\omega = 2\pi c/4$. At the edge of the plates, the electric field will have a rather high magnitude opposite the direction we would expect. That's the terrible thing that can happen to a capacitor at high frequencies. If we go to very high frequencies, the direction of the electric field oscillates back and forth many times as we go out from the center of the capacitor. Also there are the magnetic fields associated with these electric fields. It is not surprising that our capacitor doesn't look like the ideal capacitance for high frequencies. We may even start to wonder whether it looks more like a capacitor or an inductance. We should emphasize that there are even more complicated effects that we have neglected which happen at the edges of the capacitor. For instance, there will be a radiation of waves out past the edges, so the fields are even more complicated than the ones we have computed, but we will not worry about these effects now.

We could try to build an equivalent circuit for the capacitor, but perhaps it is better if we just admit that the capacitor we have designed for low-frequency below is just a lumped element, very much so if the frequency is too high. If we want to treat the equivalent of such an object at high frequencies, we should remember the important features of Maxwell's equations that we have used for creating circuits and return to the complete set of equations which describe completely the fields in space. Instead of dealing with idealized circuit elements, we have to deal with the real conductors as they are, taking into account all the fields in the spaces in between. For instance, if we want a resonant circuit at high frequencies we will not try to design one using a model for a parallel-plate capacitor.

We have already mentioned that the parallel-plate capacitor we have been analyzing has some of the aspects of both a capacitor and an inductance. With the electric field there are charges on the surfaces of the plates, and with the magnetic fields there are rock emfs. Is it possible that we already have a resonant circuit? We do indeed. Suppose we pick a frequency for which the electric field pattern falls to zero at some radius inside the edge of the disc; that is, we choose ω/c greater than 2.405. Everywhere on a circle coaxial with the plates the electric field is to be zero. Now suppose we take a thin metal sheet and cut a strip just wide enough to fit between the plates of the capacitor. Then we bend it into a cylinder that will go around at the radius where the electric field is zero. Since there are no electric fields there, when we put this conducting cylinder in place, no currents will flow in it and there will be no changes in the electric and magnetic fields. We have been able to put a direct short circuit across the capacitor without changing anything. And look what we have: we have a complete cylindrical can with electrical and magnetic fields inside and no connection at all to the outside world. The fields inside won't change even if we turn over the edges of the plates outside our can, and also the capacitor loses. All we have left is a closed can with electric and magnetic fields inside, as shown in Fig. 23-7(a). The electric fields oscillate back and forth at the frequency ω —which, don't forget, determined the diameter of the can. The amplitude of the oscillating E field varies with the distance from the axis of the can, as shown in the graph of Fig. 23-7(b). This curve is just the first arch of the Bessel function of zero order. There is also a magnetic field which goes in circles around the axis and oscillates in time $\sin \omega t$ out of phase $\pi/2$ to the electric field.

We can also write out a series for the magnetic field and plot it, as shown in the graph of Fig. 23-7(c).

How is it that we can have an electric and magnetic field inside a can with no alternating currents? It is because the electric and magnetic fields maintain them selves. In short, if E moves in B and the changing B makes an E , all according to the equations of Maxwell, the magnetic field has its own wave aspect, and the electric field is supported by B ; together they make something like a resonant circuit. Notice that the conditions we have described would only happen if the radius of the can is exactly 2.405 cm. For a can of a given radius, the oscillating electric and magnetic fields will remain in themselves. In the way we have described

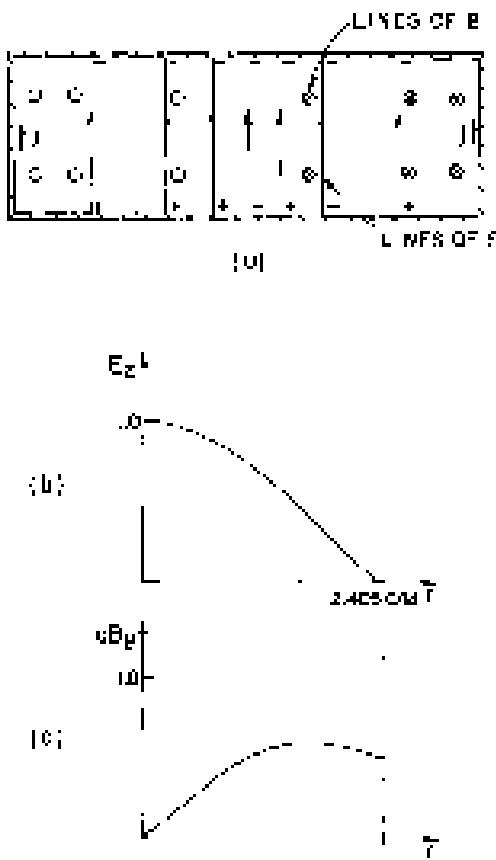

Fig. 23-7. The electric and magnetic fields in an enclosed cylindrical can.

only at that particular frequency. So a cylindrical can of radius a is resonant at the frequency

$$\omega_0 = 2\pi f_0 = \frac{c}{a} \quad (23-18)$$

We have said that the fields continue to oscillate in the same way after the can is completely closed. That is not exactly right. It would be possible if the walls of the can were perfect conductors. For a real can, however, the oscillating currents which exist on the inside walls of the can lose energy because of losses stored in the material. The oscillations of the fields will gradually die away. We can see from Fig. 23-7 that there must be standing waves associated with electric and magnetic field amplitudes in cavity. Because there is real absorption of energy, evidently at the top and bottom plates of the can, it is a logical consequence that there must be positive and negative standing charges on the inner surfaces of the can, as shown in Fig. 23-8(a). When the exterior field reverses, the charges under reversal also reverse, causing an induced dipole moment between the top and bottom plates of the can. These charges will flow in the sides of the can, as shown in the figure. We can also see that an alternating voltage is built up across the cavity by considering what happens to the magnetic field. In a typical Fig. 23-6 it is clear that the magnetic field suddenly drops to zero at the end of the can. Such a sudden change in the magnetic field can happen only if there is a current in the wall. This current is what gives the alternating electric charges on the top and bottom plates of the can.

You may be wondering about that history of currents in the vertical sides of the can. What about our earlier statement that nothing would be changed when we introduce these vertical sides in a region where the electric field was zero? Remember, however, that when we first put in the sides of the can, the top and bottom plates extended out beyond them, so that there were also magnetic fields on the outside of our can. It was only when we threw away the parts of the top/bottom plates beyond the edges of the can that no currents had to appear on the insides of the vertical walls.

Although the electric and magnetic fields in the completely enclosed can will gradually die away because of the energy losses, we can stop this from happening if we make a little hole in the can and put in a little bit of electrical energy to make up the losses. We take a small wire loop through the hole in the side of the can, and fasten it to the inside wall so that it makes a small loop, as shown in Fig. 23-8. If we now connect this wire to a source of high frequency alternating current, this current will couple energy into the electric and magnetic fields of the cavity and keep the oscillations going. This will happen, of course, only if the frequency ω of the drive source is at the resonant frequency of the can. If the source is at the wrong frequency, the electric and magnetic fields will not resonate, and the fields in the can will be very weak.

The resonant behavior can easily be seen by making another small hole in the can and blocking it another coupling loop, as we have also drawn in Fig. 23-8. The changing magnetic field through this loop will generate an induced electromotive force in the loop. If this loop is now connected to some external inductor circuit, the current will be proportional to the strength of the fields in the cavity. Suppose we now connect the input loop of our cavity to an R.F. signal generator, as shown in Fig. 23-9. The signal generator contains a varactor diode, meaning whose frequency can be varied by varying the bias on the diode of the generator. Then we connect the output loop of the cavity to a "detector," which is an instrument that measures the current through the cavity loop. It gives an output signal proportional to this current. If we now increase the current, as a function of the frequency of the signal generator, we find a curve like that shown in Fig. 23-10. The output signal is small for all frequencies except those very near the frequency ω_0 , which is the resonant frequency of the cavity. The resonant frequency ω_0 in fact these we described in Chapter 23 is MHz . The width of the resonance is, however, much narrower than we usually find for resonators, circuits made of resistances and capacitors; that is, the Q of the cavity is very high. It is not unusual to find Q 's as high as 100,000 or more if the inside walls of the cavity are made of some material with a very good constant ϵ_r , such as alumina.

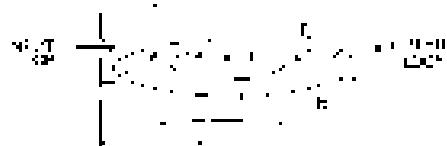

Fig. 23-6. Coupling into and out of a resonant cavity.

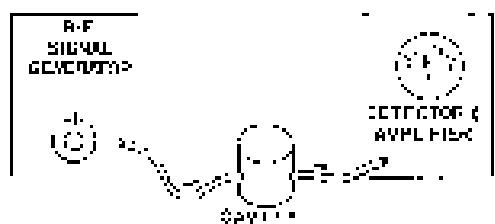

Fig. 23-9. A setup for measuring the cavity resonance.

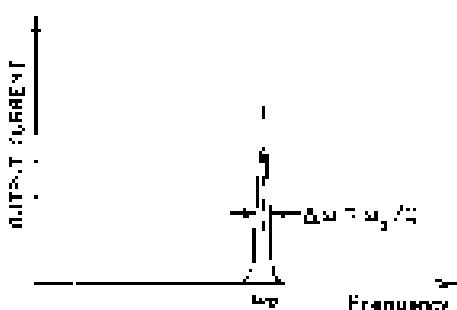

Fig. 23-10. The frequency response curve of a resonant cavity.

Suppose we now try to check our theory by making measurements with an oscilloscope. We take a can which has a diameter of 2.0 inches and a height of about 3.5 inches. The can is filled with an input signal at a frequency as shown in Fig. 23-11. If we take note of the resonant frequency expected for this can according to Eq. 23-10, we get $100\pi f_0 = \omega_0/2\pi = 3016$ megacycles. With the set of ω_0 /frequency of the signal generator at near 3000 megacycles, and vary it slightly up and down the resonance, we observe that the maximum output current occurs for a frequency of 3050 megacycles, which is quite close to the predicted resonant frequency, but not exactly the same. There are several possible reasons for this discrepancy. Perhaps the resonant frequency is changing as a result of some of the voltage or current due to our in the coupling loops. A little thought, however, shows that this does sound likely. The resonant frequency varies a little bit, so that ω_0 and ω the mean. Perhaps there some slight change in frequency of the train of the signal generator or perhaps an expansion of the diameter of the cavity, and oscillatory energy. Any way, the agreement is fairly close.

What more important is something that happens if we vary the frequency of our signal generator somewhat higher than 3000 megacycles. When we do just what we did in Fig. 23-11, we find that, in addition to the resonance we expected near 3000 megacycles, there is another one at 3400 megacycles and one near 3750 megacycles. Why are there two others than one? We might think that from Fig. 23-6, although we have been assuming that the horizontal axis of the Bessel function remains at the edge of the can, it could change due to the second zero of the Bessel function occurring at the edge of the can as the amplitude decreases in the electric field as we move from the center of the can out to the edge as shown in Fig. 23-12. This is another possible cause for this oscillating field. We should again expect the zero to resonate in such a mode. But notice, the second zero of the Bessel function occurs very near which is over 2π in length or over $1/2$ of the radius. The resonant frequency of this mode should therefore be higher than 3000 megacycles. We would not expect this to do, but it does not explain the two more we observe at 3400.

Another possibility is that there may be other boundary conditions or edge which we have considered using only a single parameter, or a portion of the electric field amplitude. We have assumed that the electric fields are vertical and that the magnetic fields remain transverse to the electric field components. The only requirements are that the fields should satisfy Maxwell's equations inside the can, and that the electric field should be zero at the outer right angles. We have considered the case in which the top and bottom of the can are straight, but it is possible that the field boundary conditions at the top and bottom, and which is the case. It is at least possible to show that there is a mode of oscillation of the field's inside the can, in which the electric field is given by the curve of diameter of the can as shown in Fig. 23-13.

It is not too hard to calculate with the natural frequency of this mode should be not very different from the natural frequencies of the first mode we have considered. Suppose the boundary condition along the entire width of the can is that the electric field is zero at the top and bottom. In a mode with the electric field going up and down with constant frequency, the natural frequency is the note in which the electric field was excited right and left. If we now excite the electric field in a mode, we will change the frequency of the note. We would still expect the same. In fact, if we do such, provided we keep the RF boundary of the cavity intact or the top edge, the frequency of the mode of Fig. 23-13 should not be too different from the mode of Fig. 23-4. We could make a rough estimate of the natural frequency of the mode shown in Fig. 23-13, but we do not do that now. When the oscillating amplitude is enough, it is found that for the dimensions we have assumed, the resonant frequency comes out very close to the natural resonance at 3000 megacycles.

By similar reasoning it is possible to show that there should be still another mode at the order $n = 2$. Frequency we found near 3400 megacycles. The ad-

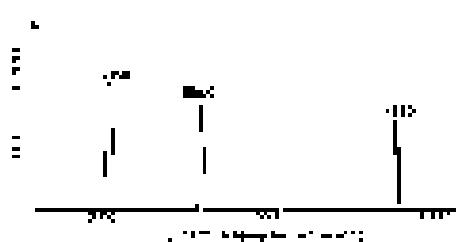

Fig. 23-11. Oscilloscope record for a cavity of cavity 23-1.

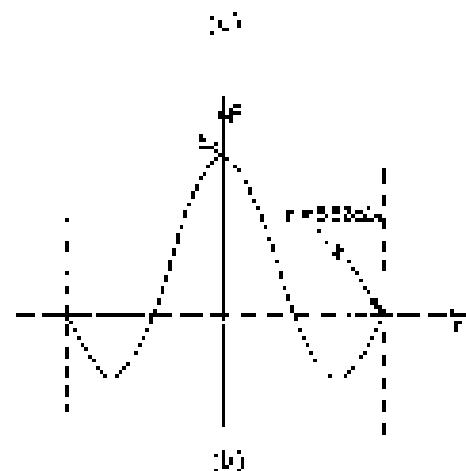

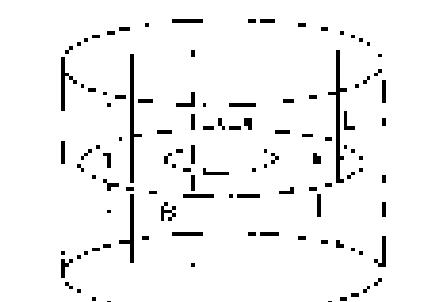

Fig. 23-13. A transverse mode of the cavity 23-1.

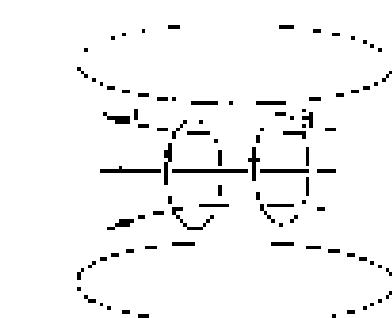

Fig. 23-14. A higher-order mode of the cavity 23-1.

of course, the electric and magnetic fields are as shown in Fig. 23-4. The electric field is zero and Faraday's law gives the tangential flux density. It goes from the axes to the end walls, as shown.

As you will probably know better, if we go higher and higher in frequency we should expect to find more and more resonances. There are many different modes and at a high enough frequency there is a resonance corresponding to some particular spatial placement arrangement of the electric and magnetic fields. Each of these different arrangements is called a resonant mode. The resonance frequency of each mode can be calculated by solving Maxwell's equations for the electric and magnetic fields in the cavity.

When we have a resonance at some particular frequency, how can we know which mode is being excited? One way is to poke a little wire into the cavity through a small hole. If the electric field is along the wire, as in Fig. 23-15(a), there will be relatively large currents in the wire, sapping energy from the field, and the resonance will be suppressed. If the electric field is as shown in Fig. 23-15(b) the wire will have a much smaller effect. We could find which way the field points in this mode by bending the end of the wire, as shown in Fig. 23-15(c). Then, as we move to the wire, there will be a big effect when the end of the wire is parallel to E and a small effect when it is rotated so as to be at 90° to E .

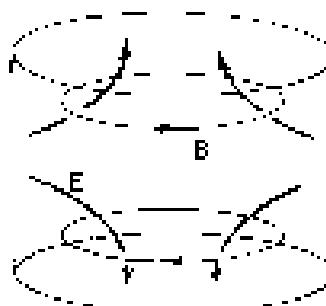

Fig. 23-4. Another view of a cylindrical cavity.

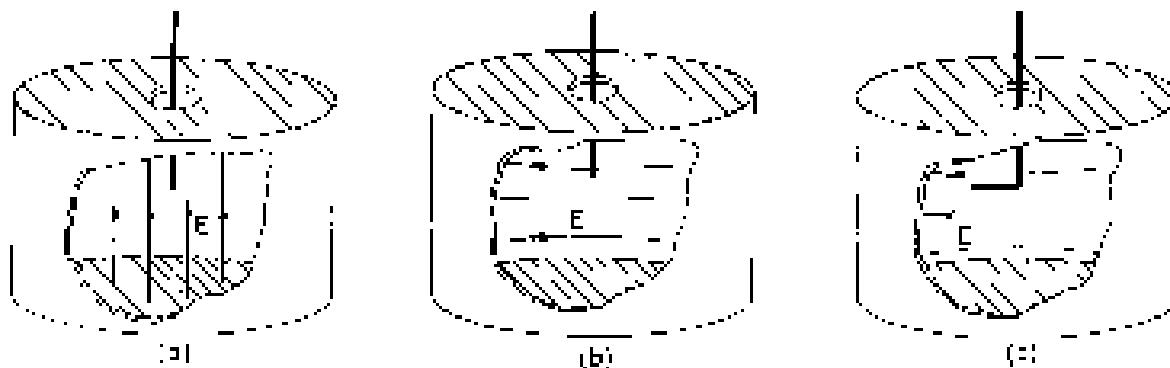

Fig. 23-15. A thin metal wire inserted into a cavity will scrub more power when it is parallel to E than when it is at right angles.

23-5 Cavities and resonant circuits

Although the resonant cavity we have been discussing seems to be quite different from the ordinary resonant circuit consisting of an inductor and a capacitor, the two resonant systems are, of course, closely related. They are both members of the same family; they are just two extreme cases of electromagnetic oscillation—and there are many intermediate cases between these two extremes. Suppose we start by considering the resonant circuit in question in parallel with a capacitor, as shown in Fig. 23-16(a). This circuit will resonate at the frequency $\omega_0 = 1/\sqrt{LC}$. If we want to make the resonant frequency ω_0 this much larger, we can do so by increasing the inductance L . One way is to increase the number of turns in the coil. We can, however, probably see that in the first place. Essentially we will go down to the last term and we will have just a piece of wire, namely, the top and bottom edges of the condenser. We could increase the resonant frequency still further by making the capacitor even smaller; however, we can also continue to increase the inductance by putting several inductances in parallel. Two inductors and another one parallel will triple only half the inductance of each alone. So when we add one we have been reduced to a single turn, but we can add in two more to restore the original inductance by adding other single loops from the top plate to the bottom plate of the condenser. For instance, Fig. 23-16(b) shows the condenser plates separated by six such "single turn inductances"; if we continue to add many more pieces of wire, we can make the transition to the completely enclosed resonant system shown in part (c) of the figure, which is a drawing of the cross section of a cylindrically symmetrical cavity.

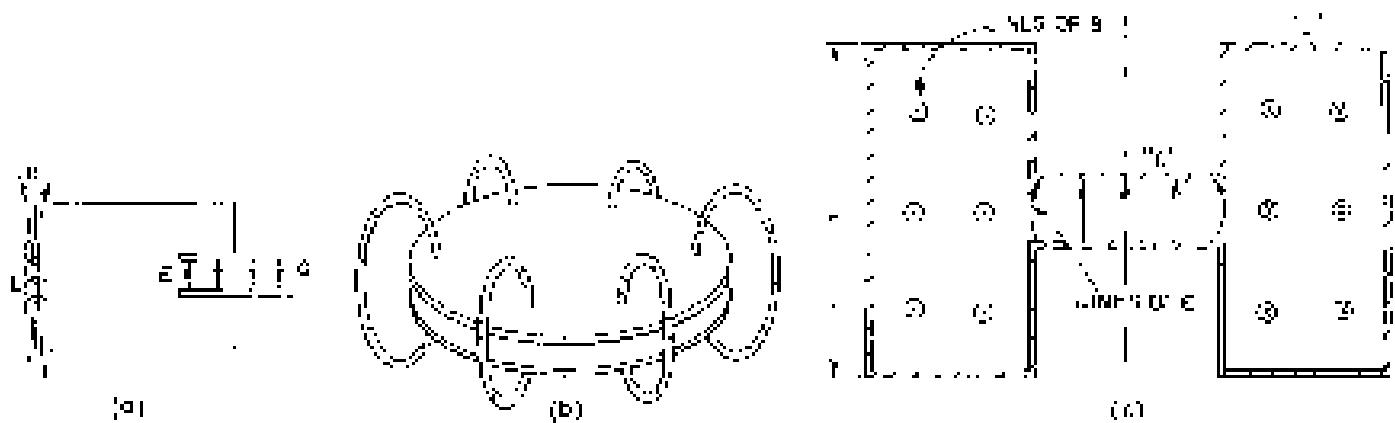

Fig. 23-16. Resonators of progress: (a) higher wave and frequency.

object. Our inductance is now a cylindrical hollow can attached to the edges of the condenser plates. The electric and magnetic fields will be as shown in the figure. Such an object, of course, is resonant. It is called a "hoisted" cavity. But we can still think of it as an $L-C$ circuit in which the capacity section is the region where we find most of the electric field and the inductance section is that region where we find most of the magnetic field.

If we want to make the frequency of the resonator in Fig. 23-16 still higher, we can do so by decreasing its inductance L . To do that, we must decrease the geometric dimensions of the inductance section. For example, by decreasing the dimension a in the drawing. As a is decreased, the resonant frequency will be increased. Eventually, as a comes down to the value a_0 in which the bend B is just equal to the separation between the condenser plates, we shall have just a cylinder or pipe that is resonant at low frequency (resonator of Fig. 24).

You will notice that in the simple $L-C$ circuit of Fig. 13-19, the electric and magnetic fields are quite separate. As we have gradually modified the resonator system by making higher and higher frequencies, the magnetic field has been brought closer and closer to the electric field until, in the cavity resonator, the two are quite intermixed.

Although the cavity resonators we have talked about in this chapter have been cylindrical cans, there is nothing magic about the cylindrical shape. A can of any shape will have resonant frequencies corresponding to various possible modes of oscillations of the electric and magnetic fields. For example, the "cavity" shown in Fig. 23-17 will have its own particular set of resonant frequencies—although they would be rather difficult to calculate.

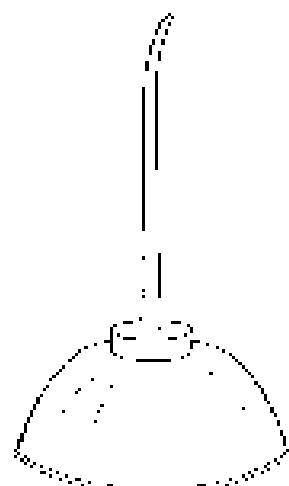

Fig. 23-17. Another resonant cavity.

Waveguides

24-1 The transmission line

In the last chapter we studied what happened to the turned elements of certain resonant circuits when they were operated at very high frequencies, and we were led to see that a resonant circuit could be replaced by a cavity with the fields resonating inside. Another interesting technical problem is the connection of one object to another, so that electromagnetic energy can be transferred between them. At low frequency circuits the connection is made with wires, but this method doesn't work very well at high frequencies because the circuits would radiate energy into all the space around them, and it is hard to control where the energy will go. The fields spread out, are and die away; the currents and voltages are not "guided" very well by the wires. In this chapter we want to look into the ways that objects can be interconnected at high frequencies. At least, that's one way of presenting our subject.

Another way is to say that we have been discussing the behavior of waves in free space. Now it is time to see what happens when oscillating fields are confined in one or more dimensions. We will discover the fascinating new phenomena when the fields are confined in only two dimensions and allowed to go free in the third dimension, they propagate in waves. These are "guided waves"—the subject of this chapter.

We begin by discussing only the general theory of the transmission line. The arbitrary power transmission line that runs from tower to tower over the countryside radiates away some of its power, but the power requirements (50–60 cycles/sec) are so low that this loss is not serious. The radiation could be stopped by surrounding the line with a metal pipe, but this method would not be practical for power lines because the voltage and current used would require a very large, expensive, and heavy pipe. So simple "open lines" are used.

For somewhat higher frequencies—say, a few kilocycles—radiation can already be serious. However, it can be reduced by using "twisted pair" transmission lines, as in telephone transmission. At high frequencies, however, the radiation soon becomes unacceptable, either as a loss of power losses or because the energy appears in other directions where it isn't wanted. Far frequencies from a few kilocycles to some hundreds of megacycles, electronic guitar signals and power are usually transmitted via coaxial lines consisting of a wire inside a cylindrical "outer conductor" or "shield." Although the following treatment will apply to a transmission line of two parallel conductors of any shape, we will carry it out referring to a coaxial line.

We take the simplest coaxial line that has a central conductor, whose top pole is at the top of the long cylinder, and an outer conductor which is another thin cylinder on the same axis as the inner conductor, as in Fig. 24-1. We begin by figuring out approximately how the line behaves at relatively low frequencies. We have already described some of the low-frequency behavior when we said earlier that two such conductors had a certain amount of inductance per unit length and a certain capacity per unit length. We can, in fact, describe the low-frequency behavior of any transmission line by giving its inductance per unit length, L_0 , and its capacity per unit length, C_0 . Then we can analyze the line as the lumped-case of the $L-C$ filter as discussed in Section 22-6. We can make a filter which simulates the line by taking small series elements $L_0 \Delta x$ and small shunt capacities $C_0 \Delta x$, where Δx is an element of length of the line. Using our results for the infinite filter, we see that there would be a propagation of electric

24-8 Another way of looking at the guided waves

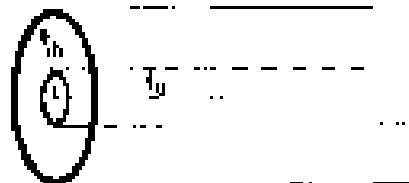

Fig. 24-1. A coaxial transmission line.

signals along the line. Rather than following that approach, however, we would now rather look at the line from the point of view of a differential equation.

Suppose that we see what happens at two neighbouring points along the transmission line, say at the distances x and $x + \Delta x$ from the beginning of the line. Let's call the voltage difference between the two conductors $V(x)$, and the current along the "hot" conductor $I(x)$ (see Fig. 24.2). If the current in the line is varying, the inductance will give us a voltage drop across the small section of line from x to $x + \Delta x$ in the amount

$$\Delta V = V(x + \Delta x) - V(x) = -L_0 \Delta x \frac{dI}{dx}.$$

Or, taking the limit as $\Delta x \rightarrow 0$, we get

$$\frac{dV}{dx} = -L_0 \frac{dI}{dx}. \quad (24.1)$$

The changing current gives a gradient of the voltage.

Referring again to the figure, if the voltage at x is changing, there must be some charge supplied to the capacitor in that region. If we take the small piece of line between x and $x + \Delta x$, the charge on it is $q = C_0 \Delta x V$. The total electric charge of this element is $C_0 \Delta x dV/dx$, but the charge changes only if the current $I(x)$ goes through it, different from the current $I(x + \Delta x)$ just. Calling the difference ΔI , we have

$$\Delta I = -C_0 \Delta x \frac{dV}{dx}.$$

Taking the limit as $\Delta x \rightarrow 0$, we get

$$\frac{dI}{dx} = -C_0 \frac{dV}{dx}. \quad (24.2)$$

So the conservation of charge implies that the gradient of the current is proportional to the time rate-of-change of the voltage.

Equations (24.1) and (24.2) are then the basic equations of a transmission line. If we wish, we could neatly do a to discuss the effects of resistance in the conductors or of leakage of charge through the insulation between the conductors, but for our present discussion we will just stay with the simple example.

The two transmission-line equations can be combined by differentiating one with respect to x and the other with respect to x and differentiating either V or I . Then we have either

$$\frac{\partial^2 V}{\partial x^2} = C_0 L_0 \frac{\partial^2 I}{\partial x^2}, \quad (24.3)$$

or

$$\frac{\partial^2 I}{\partial x^2} = C_0 L_0 \frac{\partial^2 V}{\partial x^2}. \quad (24.4)$$

Once more we recognize the wave equation in x . For a finite transmission line, the voltage (and current) propagates along the line as a wave. The voltage along the line is then of the form $V(x, t) = f(z - vt)$ or $V(x, t) = f(z + vt)$, or a sum of both. Now what is the velocity v ? We know that the coefficient a^2 in the $\partial^2/\partial x^2$ term is just $1/c^2$, so

$$v = \frac{1}{\sqrt{L_0 C_0}}. \quad (24.5)$$

We will leave it for you to show that the voltage for each wave in a line is proportional to the current of that wave and that the constant of proportionality is just the characteristic impedance z_0 . Calling V_0 and I_0 the voltage and current for a wave going in the plus x -direction, you should get

$$V_0 = z_0 I_0. \quad (24.6)$$

Similarly, for the wave going toward minus x the relation is

$$V_{-} = -z_0 f_{-}$$

The characteristic impedance z_0 we found out from our other equations—is given by

$$z_0 = \sqrt{\frac{L_0}{C_0}}, \quad (24.7)$$

and is, therefore, a pure resistance.

To find the propagation speed v and the characteristic impedance z_0 of a transmission line, we have to know the inductance and capacity per unit length. We can calculate them easily for a coaxial cable, so we will see how that goes. For the inductance we follow the ideas of Section 17-8, and set $\oint B \cdot d\ell$ equal to the magnetic energy which we get by integrating $\epsilon_0 r^2 B^2 / 2$ over the volume. Suppose that a coaxial conductor carries the current I . Then we know that $B = I/2\pi r \mu_0$, where r is the distance from the axis. Taking as a volume element a cylindrical shell of thickness dr and of length l , we have for the magnetic energy

$$U = \frac{\mu_0 l^2}{2} \int_{a/2}^{b/2} \left(\frac{I}{2\pi r \mu_0 c^2} \right)^2 / 2 \pi r dr,$$

where a and b are the radii of the inner and outer conductors, respectively. Carrying out the integral, we get

$$U = \frac{l^2}{4\pi \epsilon_0 c^2} \ln \frac{b}{a}. \quad (24.8)$$

Setting the energy equal to $\frac{1}{2} I^2 / R$, we find

$$L = \frac{l}{2\pi \epsilon_0 c^2} \ln \frac{b}{a}. \quad (24.9)$$

It is, as it should be, proportional to the length l of the line, so the inductance per unit length L_0 is

$$L_0 = \frac{\ln(b/a)}{2\pi \epsilon_0 c^2}. \quad (24.10)$$

We have worked out the charge on a cylindrical conductor (see Section 12-2). Now, dividing the charge by the potential difference, we get

$$C_0 = \frac{2\pi \epsilon_0 l}{\ln(b/a)}.$$

The capacity per unit length C_0 is $1/l$. Combining this result with Eq. (24.10), we see that the product $L_0 C_0$ is just equal to $1/c^2$, so $c = \sqrt{L_0 C_0}$ is equal to v . The wave travels down the line with the speed of light. We point out that this result depends on our assumptions: (a) that there are no dielectrics or magnetic materials in the space between the conductors, and (b) that the currents flow all on the surfaces of the conductors (as they would in the perfect conductors). We will see later that for good conductors at high frequencies, and currents distributed themselves on the surfaces as they would form a perfect conductor, so this assumption is then valid.

Now it is interesting that so long as assumptions (a) and (b) are correct, the product $L_0 C_0$ is equal to $1/c^2$ for any parallel pair of conductors—even, say, for a hexagonal inner conductor anywhere inside an elliptical outer conductor. So long as the cross section is constant and the space between has no material, waves are propagated at the velocity of light.

No such general statement can be made about the characteristic impedance. For the coaxial line, it is

$$z_0 = \frac{\pi (b/a)}{2\pi \epsilon_0}, \quad (24.11)$$

The Dielectric Line has the dimensions of a resistance and is equal to Ω ohms. The conductive Factor (I_{conduct}) depends only logarithmically on the dimensions, so for the coaxial line—a $\lambda/2$ waveguide—the characteristic impedance has typical values of the $\pi/2$ ohms up to a few hundred ohms.

24-2 The rectangular waveguide

The next thing we want to talk about seems at first sight to be a striking pleasure memoir: if the central conductor is removed from the waveguide, it can still carry electromagnetic waves. In other words, at high enough frequencies a hollow tube will work just as well as one with wires. It is related to the mysterious way in which a resonator circuit or a condenser and voltage pole replaced by nothing but a string at high frequencies.

A thought may seem to be a reasonable thing when one has been thinking in terms of a transmission line or a distributed inductor and capacitor, we all know that electromagnetic waves can travel along inside a hollow metal pipe. If the pipe is straight, we can see through it. So certainly electromagnetic waves go through a pipe. But we also know that it is not possible to transmit low-frequency waves (power or telephone) through the inside of a single metal pipe. So it must be that high-frequency waves will go through it over a wavelength so short enough. Therefore we want to discuss the limiting case of the longest wavelength for the lowest frequency that can get through a pipe of a given size. Since the pipe is then being used to carry waves, it is called a *waveguide*.

We will begin with a rectangular pipe, because it is the simplest case to analyze. We will first give a mathematical treatment and come back later to look at the problem in a much more elementary way. The more elementary approach, however, can be applied easily only to a rectangular guide. The basic phenomena are the same for a general guide of arbitrary shape, so the mathematical argument is fundamentally more sound.

The problem then is to find what kind of waves can exist inside a rectangular pipe. Let's first choose some convenient coordinates: we take the x -axis along the length of the pipe, and the y - and z -axes parallel to the two sides, as shown in Fig. 24-3.

We know that when light waves go down the pipe, they have a transverse electric field; so suppose we look first for solutions in which E is perpendicular to z , say with only a y -component, E_y . This electric field will have some variation across the guide; in fact, it must go to zero at the sides parallel to the y -axis, because the currents and charges in a conductor always adjust themselves so that there is no tangential component of the electric field at the surface of a conductor. So E_y will vary with y in some such way shown in Fig. 24-4. Perhaps it is the Bessel function we found for a cavity? No, because the Bessel function has to do with cylindrical geometries. For a rectangular geometry, waves are usually simple harmonic functions, so we should try something like $\sin k_y y$.

Since we want waves that propagate down the guide, we expect the field to alternate between positive and negative values as we go along in x , as in Fig. 24-5, and these oscillations will travel along the guide with some velocity v . If we have oscillations at some definite frequency ω , we would guess that the wave might vary with x like $\cos(\omega t - k_x x)$, or to use the more convenient mathematical form, like $\sin(k_x x - \omega t)$. Thus x -dependence represents a wave travelling with the speed $v = \omega/k_x$ (see Chapter 29, Vol. I).

So we might guess that the wave in the guide would have the following mathematical form:

$$E_y = E_0 \sin(k_x x) e^{j(k_y y - \omega t)} \quad (24.12)$$

Let's see whether this guess satisfies the relevant requirements. First, the electric field should have no tangential components at the conductors. Our field satisfies this requirement; it is perpendicular to the top and bottom faces and is zero at the two side faces. Well, it is if we choose k_y so that one-half a cycle of 24-4

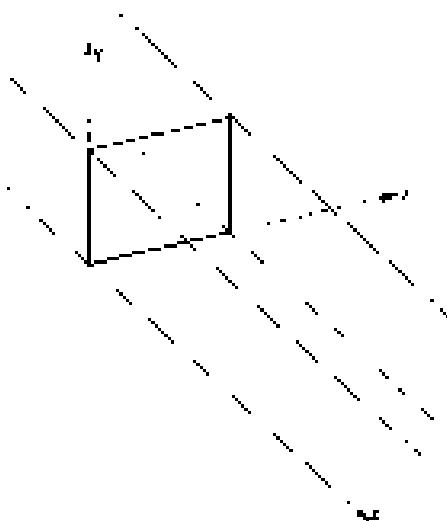

Fig. 24-3. Coordinate system for the rectangular waveguide.

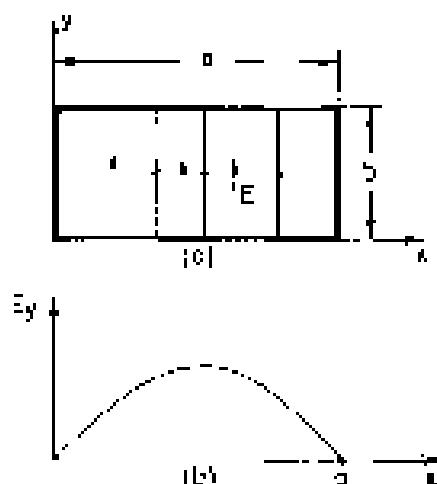

Fig. 24-4. The electric field in the waveguide at some value of z .

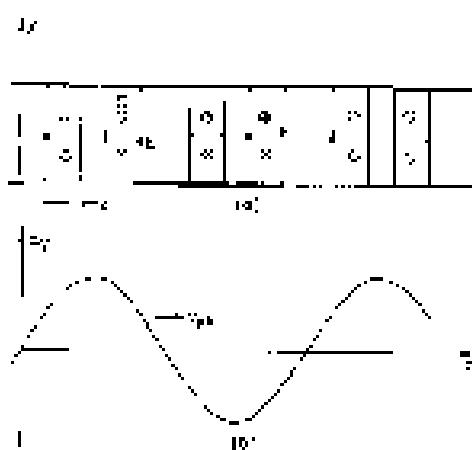

Fig. 24-5. The x -dependence of the field in the waveguide.

sin $k_x z$ just fits in the width of the guide—that is, a^2

$$k_{x0} = \pi/a. \quad (24.15)$$

There are other possibilities, like $k_{x0} = 2\pi, 3\pi, \dots$, or, in general

$$k_{x0} = n\pi, \quad (24.16)$$

where n is any integer. These represent various complicated arrangements of the field, but for now let's take only the smallest one, where $k_x = \pi/a$, where a is the width of the inside of the guide.

Next, the divergence of \mathbf{B} must be zero in the free space inside the guide, since there are no charges there. Our \mathbf{E} has only a y component, and it doesn't change with x , so we do have that $\nabla \cdot \mathbf{E} = 0$.

Finally, our electric field must agree with the rest of Maxwell's equations in the free space inside the guide. That is the same thing as saying that it must satisfy the wave equation:

$$\frac{\partial^2 E_y}{\partial x^2} = \frac{\partial^2 E_y}{\partial y^2} = \frac{\partial^2 E_y}{\partial z^2} = \frac{1}{c^2} \frac{\partial^2 E_y}{\partial t^2} = 0. \quad (24.17)$$

We have to see whether our guess, Eq. (24.12), will work. The second derivative of E_y with respect to x is just $-k_x^2 E_y$. The second derivative with respect to y is zero, since nothing depends on y . The second derivative with respect to z is $-k_z^2 E_y$, and the second derivative with respect to t is $-\omega^2 E_y$. Equation (24.17) then says that

$$k_x^2 E_y + k_z^2 E_y - \frac{\omega^2}{c^2} E_y = 0.$$

Unless E_y is zero everywhere (which is not very interesting), this equation is correct if

$$k_x^2 + k_z^2 - \frac{\omega^2}{c^2} = 0. \quad (24.18)$$

We previously fixed k_x , so this equation tells us that there can be waves of the type we have assumed if k_z is related to the frequency ω so that Eq. (24.18) is satisfied. In other words, if

$$k_z = \sqrt{(\omega^2/c^2) - (\pi^2/a^2)}, \quad (24.19)$$

the waves we have described are propagated in the z direction with this value of k_z .

The wave number k_z we get from Eq. (24.17) tells us, for a given frequency ω , the speed with which the nodes of the wave propagate down the guide. The phase velocity is

$$v = \frac{\omega}{k_z}. \quad (24.20)$$

You will remember that the wavelength λ_0 of a traveling wave is given by $\lambda = 2\pi/v$, so k_z is also equal to $2\pi/\lambda_0$, where λ_0 is the wavelength of the oscillations along the z direction—the guide wavelength. The wavelength in the guide is different, of course, from the free-space wavelength λ_0 of electromagnetic waves of the same frequency. If we call the free-space wavelength λ_0 , which is equal to $2\pi/\omega$, we can write Eq. (24.17) as

$$k_z = \frac{\lambda_0}{\sqrt{1 - (\lambda_0/2a)^2}}. \quad (24.21)$$

Besides the electric fields there are magnetic fields that will travel with the wave, but we will not bother to work out an expression for them right now. Since $c^2 \mathbf{E} \times \mathbf{B} = \mu_0 \mathbf{J}_0$, the lines of \mathbf{B} will circulate around the regions in which $\mu_0 \mathbf{J}_0$ is largest, that is, halfway between the maximum and minimum of \mathbf{E} . The loops of \mathbf{B} will be parallel to the xy plane and between the crests and troughs of \mathbf{E} , as shown in Fig. 24-6.

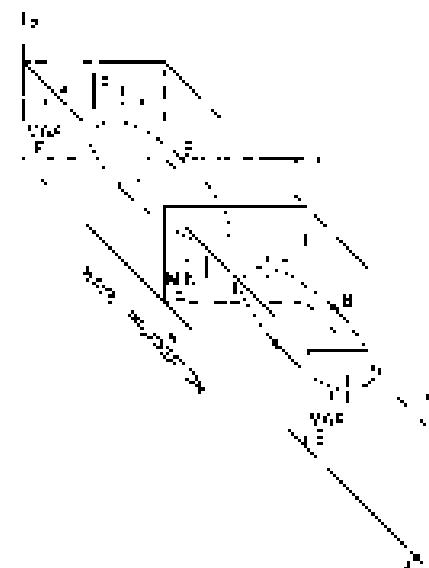

Fig. 24-6. The magnetic field in the waveguide.

24.3 The cutoff frequency

In solving Eq. (24.16) for k_x , there should really be two roots—one plus and one minus. We should write

$$k_x = -\sqrt{(\omega^2/c^2) - (\epsilon_0 \omega^2)} \quad (24.20)$$

The two signs simply mean that there can be waves which propagate with a negative phase velocity (backward $-v$) as well as waves which propagate in the plus v direction in the guide. Naturally, it would be possible for waves to go in either direction. Since both types of waves can be present at the same time, there will be the possibility of standing-wave oscillations.

Our equation for k_x also tells us that higher frequencies give larger values of k_x , and therefore smaller wavelengths. But, in the limit of large ω , k becomes equal to ω/c , which is the value we would expect for waves in free space. The light we "see" through a pipe still travels at the speed c . But now notice that if we go toward low frequencies, something strange happens. At first the wavelength gets longer and longer, but if ω gets too small the quantity inside the square root of Eq. (24.20) suddenly becomes negative. This will happen, as soon as ω gets no less than ω_{c} —that is, when k_x becomes greater than ω/c . In other words, when the frequency gets smaller than a certain critical frequency $\omega_{\text{c}} = \omega_{\text{c}}/\epsilon_0$, the wave number k_x (and also k_y) becomes imaginary and we haven't got a solution any more. Oh dear! Who's it that k has to be real? What if it does come out imaginary? Our field equations are still satisfied. Perhaps an imaginary k also represents a wave?

Suppose ω is less than ω_{c} ; then we can write

$$k_x = \pm ik' \quad (24.21)$$

where k' is a positive real number.

$$k' = \sqrt{\epsilon_0^2/c^2} = (\omega^2/c^2)^{1/2} \quad (24.22)$$

If we now go back to our expression, Eq. (24.13), for E_y , we have

$$E_y = E_0 \sin k_{y0} e^{ik' z_0} e^{-k' z}, \quad (24.23)$$

which we can write as

$$E_y = E_0 \sin k_{y0} e^{ik' z_0} e^{-k' z}. \quad (24.24)$$

This expression gives an E -field that oscillates with time as $e^{i\omega t}$ but which varies with z as $e^{-k' z}$. It decreases or increases with z smoothly as a real exponential. In our derivation we didn't worry about the source that started the waves, but there must, of course, be a source somewhere in the guide. The sign that goes with k' must be the one that makes the field decrease with increasing z away from the source of the waves.

So for frequencies below $\omega = \omega_{\text{c}}$, waves do not propagate down the pipe; the oscillating fields penetrate into the guide only a distance of the order of $1/k'$. For this reason, the frequency ω_{c} is called the "cutoff frequency" of the guide. Looking at Eq. (24.22), we see that for frequencies just a little below ω_{c} , the number k' is small and the fields can penetrate a long distance into the guide. But if ω is much less than ω_{c} , the exponential coefficient, k' , is equal to π/a so the field dies off extremely rapidly, as is shown in Fig. 24-7. The field decreases by 1/e in the distance a/k' , or in only about one-third of the guide width. The fields penetrate very little farther than this distance.

We want to emphasize an interesting feature of our analysis of the guided waves—the appearance of an imaginary wave number k_x . Normally, if we solve an equation in physics and get an imaginary number, it doesn't mean anything physical. For waves, however, an imaginary wave number does mean something. The wave equation is still satisfied; it only means that the solution gives exponentially decaying fields instead of propagating waves. So in any wave problem where k becomes imaginary for some frequency, it means that the form of the wave changes—the sine wave changes into an exponential.

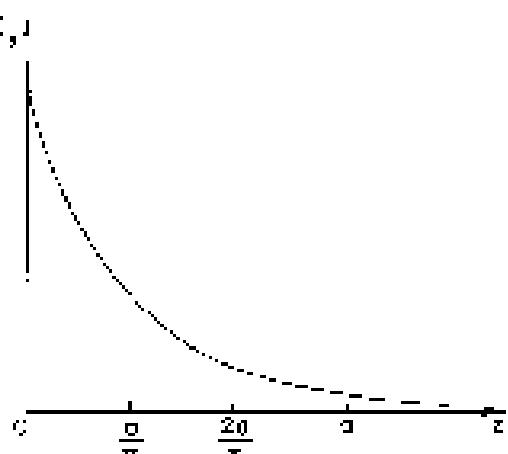

Fig. 24-7. The variation of E_y with z for $\omega < \omega_{\text{c}}$.

24-4 The speed of the guided waves

The wave velocity we have used above is the phase velocity, which is the speed of a mode of the wave; it is a function of frequency. If we combine Eqs. (24.17) and (24.18), we can write

$$v_{\text{phase}} = \frac{c}{\sqrt{1 - (\omega_0/\omega)^2}}. \quad (24.25)$$

For frequencies above cutoff—where travelling waves exist— ω/ω_0 is less than one, and v_{phase} is real and greater than the speed of light. We have already seen in Chapter 25 of Vol. I that phase velocities greater than light are possible, because it is just the locus of the wave, which are moving and not energy or information. In order to know how fast signals will travel, we have to calculate the speed of pulses or modulations made by the interference of a wave of one frequency with one or more waves of slightly different frequencies (see Chapter 18, Vol. II). We have called the speed of the envelope of such a group of waves the group velocity; it is not with our *disks*!

$$v_{\text{group}} = \frac{d\omega}{dk}. \quad (24.26)$$

Taking the derivative of Eq. (24.17) with respect to ω and inverting to $k = \omega/c$, we find that

$$v_{\text{group}} = c \sqrt{1 - (\omega_0/\omega)^2}, \quad (24.27)$$

which is less than the speed of light.

The geometric mean of v_{phase} and v_{group} is just c , the speed of light:

$$\text{geometric mean} = c^{\frac{1}{2}}. \quad (24.28)$$

This is curious, because we have seen a similar relation in quantum mechanics. For a particle with any velocity— even relativistic—the momentum p and energy E are related by

$$E^2 = p^2c^2 + m^2c^4. \quad (24.29)$$

Now, in quantum mechanics the energy is $\hbar\omega$, and the momentum is \hbar/k , which is equal to $\hbar k$; so Eq. (24.29) can be written

$$\frac{\omega^2}{c^2} - k^2 = \frac{m^2c^2}{\hbar^2}. \quad (24.30)$$

$$k = \sqrt{(\omega^2/c^2) - (m^2c^2/\hbar^2)}, \quad (24.31)$$

which looks very much like Eq. (24.17). . . interesting!

The group velocity of the waves is c as the speed at which energy is transported along the guide. If we want to find the energy flow down the guide, we can get it from the energy density times the group velocity. If the root-mean-square electric field is E_0 , then the average density of electric energy is $\epsilon_0 E_0^2/2$. There is also some energy associated with the magnetic field. We will not prove it here, but in any cavity or guide the magnetic and electric energies are equal, so the total electromagnetic energy density is $\epsilon_0 E_0^2$. The power *down* a section of the guide is then

$$\frac{dU}{dx} = \epsilon_0 E_0^2 v_{\text{group}}. \quad (24.32)$$

(We will see later another, more general way of stating the *conservation law*.)

24-5 Observing guided waves

Energy can be coupled into a waveguide by some kind of an "antenna." For example, a little vertical wire or "stub" will do. The presence of the guided waves can be observed by picking up some of the electromagnetic energy with a little receiving "antenna," which again can be a little stub of wire or a small loop.

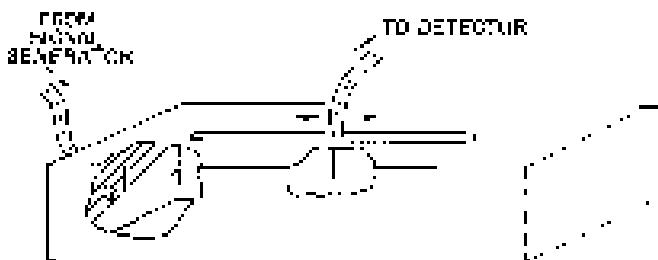

Fig. 24-8. A waveguide with a driving stub and a pickup probe.

In Fig. 24-8, we show a guide with some arrows to show a driving stub and a pickup "probe". The driving stub can be connected to a signal generator via a coaxial cable, and the pickup probe can be connected by a similar cable to a detector. It is usually convenient to insert the pickup probe via a long thin slot in the guide, as shown in Fig. 24-8. Then the probe can be moved back and forth along the guide to sample the fields at various positions.

If the signal generator is set at some frequency ω greater than the cutoff frequency ω_c , there will be waves propagated down the guide from the driving stub. There will be the only waves present if the guide is infinitely long, which can effectively be arranged by terminating the guide with a carefully designed absorber in such a way that there are no reflections from the far end. Then, since the detector measures the time average of the fields near the probe, it will pick up a signal which is independent of the position along the guide; its output will be proportional to the power being transmitted.

If now the far end of the guide is terminated off in some way that produces a reflected wave—say, an extreme example, if we close it off with a metal plate—there will be a reflected wave in addition to the original forward wave. These two waves will interfere and produce a standing wave in the guide similar to the standing waves on a string which we discussed in Chapter 9 of Vol. 2. Each as the pickup probe is moved along the line, the detector reading will rise and fall periodically, showing a maximum in the field at each node of the standing wave and a minimum at each anti-node. The distance between two successive nodes (or crests) is just $\lambda/2$. This gives a convenient way of measuring the guide wavelength. If the frequency is now moved closer to ω_c , the distances between nodes increase, showing that the guide wavelength increases as predicted by Eq. (24-19).

Suppose now the signal generator is set at a frequency just a little below ω_c . Then the detector output will decrease gradually as the pickup probe is moved down the guide. If the frequency is set somewhat lower, the field strength will fall rapidly, following the curve of Fig. 24-7, one showing that waves are not propagated.

24-6 Waveguide plumbing

An important practical use of waveguides is for the transmission of high-frequency power, e.g., for example, in coupling the high-frequency oscillator or output amplifier of a radar to an antenna. In fact, the antenna itself usually consists of a parabolic reflector fed at its focus by a waveguide. Part of it at the end is made a "horn," that radiates the waves coming down the guide. Although high frequencies can be transmitted along a coaxial cable, a waveguide is better for transmitting large amounts of power, first, the maximum power that can be transmitted along a line is limited by the breakdown of the insulation between the conductors. For a given amount of power, the field strengths in a guide are usually less than they are in a coaxial cable, so higher powers can be transmitted before breakdown occurs. Second, the power losses in the coaxial cable are usually greater than in a waveguide. In a coaxial cable there must be insulating material to support the central conductor, and there is an energy loss in this material—particularly at high frequencies. Also, the current densities on the central conductor are quite high, and since the losses go as the square of the current density, the lower currents that appear on the walls of the guide result in lower

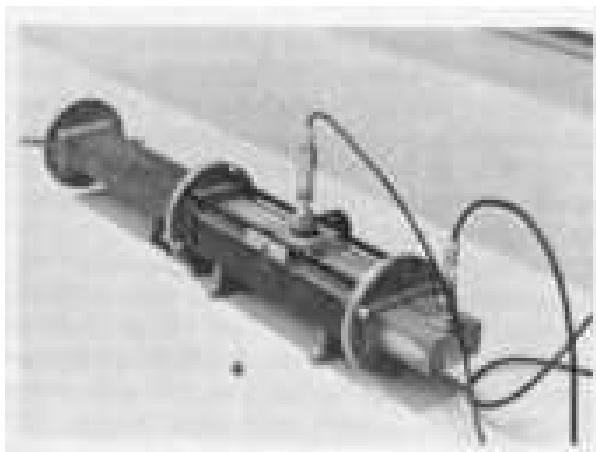

Fig. 24-9. Section of waveguide connected with flanges.

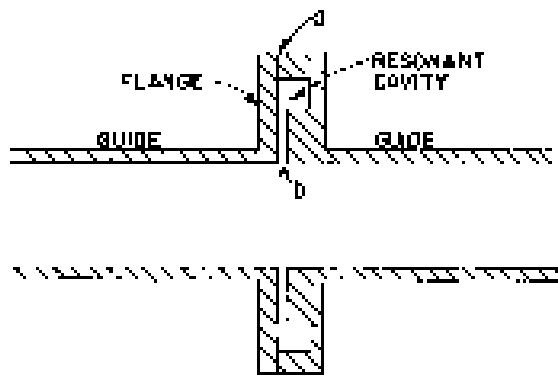

Fig. 24-10. A low-loss connection between two sections of waveguide.

energy losses. To keep these losses as minimum, the inner surfaces of the guide are often plated with a material of high resistivity, such as silver.

The problem of connecting a "circuit" with waveguides is quite different from the corresponding circuit problem at low frequencies, and is usually called *waveguide "ply along"*. Many special devices have been developed for this purpose. For instance, two sections of waveguide are usually connected together by means of flanges, as can be seen in Fig. 24-9. Such connections can, however, cause serious energy losses, because the surface currents must flow across the joint which may have a relatively high resistance. One way to avoid such losses is to make the flanges as shown in the cross-section chart in Fig. 24-10. A small gap is left between the adjacent sections of the guide, and a groove is cut in the face of one of the flanges to make a small cavity of the type shown in Fig. 24-10(a). The dimensions are chosen so that this cavity is resonant at the frequency being used. This resonant cavity presents a high "impedance" to the currents, so no relatively little current flows across the metallic joints (as is in Fig. 24-10). The high guide currents simply charge and discharge the "capacitance" of the gap (or *d* in the figure), where there is little dissipation of energy.

Suppose you want to stop a waveguide in a way that won't result in reflected waves. Then you must put something at the end that imitates an infinite length of guide. You need a *terminator*, i.e., something that absorbs the arriving waves without making reflections. Then the guide will act as though it went on forever. Such terminations are made by putting inside the guide some wedges of resistance material carefully designed to absorb the wave energy while generating almost no reflected waves.

If you want to connect three things together—for instance, one source to two different antennas—then you can use a "T" like the one shown in Fig. 24-11. Power fed into the center section of the "T" will be split and go into the two side arms (and there may also be some reflected waves). You can see qualitatively from the sketches in Fig. 24-12 that the fields would spread out when they get to the end of the input section and make electric fields that will start waves going out the two arms. Depending on whether electric fields in the guides are parallel or perpendicular to the "top" of the "T," the fields at the junction would be roughly as shown in (a) or (b) of Fig. 24-12.

Finally, we would like to measure how much energy "leaks out" of a waveguide, which is very useful for telling what is going on after you have connected a complicated arrangement of waveguides. Suppose you want to know which way the waves are going in a particular section of guide; you might be wondering, for instance, whether or not there is a strong reflected wave. The total reflected power is taken as a small fraction of the power of a guide if there is a wave going one way, but none of the wave is going the other way. By connecting the output of the coupler to a detector, you can measure the "one-way" power in the guide.

Fig. 24-11. A waveguide "T". [The flanges have plastic end caps to keep the inside clean while the "T" is not being used.]

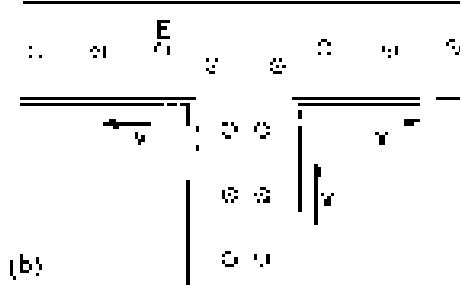

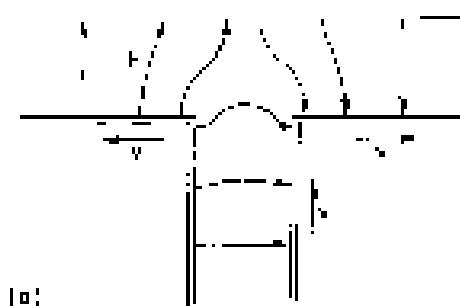

Fig. 24-12. The electric fields in a waveguide "T" for two parallel field orientations.

Figure 24-12 is a drawing of a unidirectional coupler. A piece of waveguide AB has another piece of waveguide CD soldered to it along one face. The guides CD is moved away so that there is room for the connecting flanges. Before the guides can solder together, two (or more) holes have been drilled in each guide (not let up) and then so that some of the fields in the main guide AB can be coupled out to the secondary guide CD. Each of the holes acts like a little antenna that generates a wave in the secondary guide. If there were only one hole, waves would be sent in both directions and would be the same no matter which way the wave was going in the primary guide. But when there are two holes with a separation equal to one-quarter of the guide wavelength, they will make two sources *out of phase*. Do you remember that we considered in Chapter 29 of vol. I the interference of the waves from two antennas spaced $\lambda/4$ apart and excited 90° out of phase at time? We found that the waves interfere in one direction and add in the opposite direction. The same thing will happen here. The wave produced in the guide CD will be going in the same direction as the wave in AB.

If the wave in the primary guide is travelling from A toward B, there will be a wave at the output D of the secondary guide. If the wave in the primary guide goes from B toward A, there will be a wave going toward the end C of the secondary guide. This end is equipped with a terminal or, so that this wave is absorbed and there is no wave at the output of the coupler.

24-7 Waveguide modes

The wave we have chosen to analyze is a special solution of the field equations. There are many more. Each solution is called a waveguide "mode." For example, if the dependence of the field was just one-half a cycle of a sine wave, then a $\pi/2$ equally good solution with a full cycle, then the variation of E_y with x is as shown in Fig. 24-14. The k_x for such a mode is twice as large, so the cutoff frequency is much higher. Also, in the wave we studied, E has only a y -component, but there are other modes with more complicated electric fields. If the electric field has components only in y and z , so that the total electric field is always at right angles to the x -direction, the mode is called a "transverse electric" (TE) mode. The magnetic field of such modes will always have a z -component. If I look at that if E has a component in the x -direction (along the direction of propagation), then the magnetic field will always have only transverse components. So such fields are called transverse magnetic (TM) modes. For a rectangular guide, all the other modes have a single cutoff frequency, but in the simple TE mode we were described, it is, therefore, possible—and usual—to use a guide with a frequency just above the cutoff for the lowest mode but below the cutoff frequency for all the others, so that just the one mode is propagated. Of course, the behavior gets complicated and difficult to control.

24-8 Another way of looking at the guided waves

We want now to show you another way of understanding why a waveguide attenuates its signals rapidly for frequencies below the cutoff frequency ω_c . Then you will have a more "physical" idea of why the behavior changes so drastically between low and high frequencies. We can do this for the rectangular guide by visualizing the fields in terms of cylindrical harmonics in the walls of the guide. This approach only works for rectangular guides, however, that's why we started with the round, rather than flat, cylinders which works, in principle, for guides of any shape.

In the mode we have described, longitudinal charges are moving but no x -field, so we can ignore the top and bottom of the guide and imagine that the guide is extended indefinitely in the vertical direction. We may then set the guide just as easily in two vertical parts with no separation.

Let's say that the current in the field is a vertical wire placed in the middle of the guide, with the wire carrying a current that oscillates at the frequency ω . In the absence of the guide walls such a wave would produce cylindrical waves.

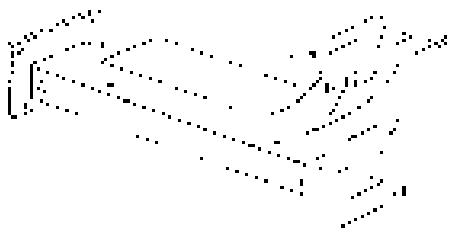

Fig. 24-12. A unidirectional coupler.

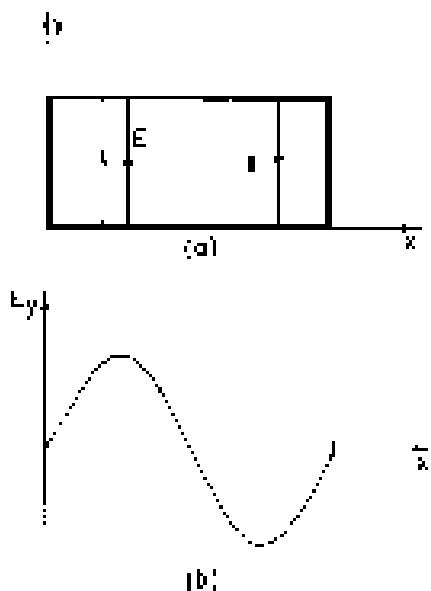

Fig. 24-14. Another possible wave for $\omega < \omega_c$.

Now we consider that the guide walls are perfect conductors. Then, just as in electrostatics, the assumptions of the source will be correct if we add to the field of the wire the field of one or more suitable image wires. The image idea works just as well for electrodynamics as it does for electrostatics, provided, of course, that we also include the retardations. We know that is true because we have often seen a mirror producing an image of a light source. And a mirror is just a "perfect" conductor for electric and magnetic waves with infinite frequencies.

Now let's take a horizontal cross section, as shown in Fig. 24-15, where W_1 and W_2 are the two guide walls and S_1 is the source wave. We call the direction of the current in the wire positive. Now if there were only one wall say W_1 , we could remove it if we placed an image source (with opposite polarity) at the position marked S_1' . But with both walls in place there will also be an image of S_1 in the wall W_2 , which we show as the image S_2 . This source, too, will have an image in W_1 , which we call S_3 . Now both S_1 and S_3 will have images in W_2 at the positions marked S_4 and S_5 , and so on. For our two plane conductors with the source halfway between, the fields are the same as those produced by an infinite line of sources, all separated by the distance a . (It is, in fact just what you would see if you looked at a wire placed half way between two parallel mirrors.) For the fields to be zero at the walls, the polarity of the currents in the images must alternate from one image to the next. In other words, they oscillate 180° out of phase. The waveguide field is, then, just the superposition of the fields of such an infinite set of line sources.

We know that if we are close to the sources, the field is very much like the static fields. We considered in Section 7-5 the static field of a grid of line sources and found that it is like the field of a charged plate except for terms that decrease exponentially with the distance from the grid. Here the average source strength is zero, because the sign alternates from one source to the next. Any field will start slowly but fall exponentially with distance. Close to the source, we see the field mainly of the nearest source; at large distances, many sources contribute and their average offset is zero. So now we see why the waveguide (below cutoff frequency) gives an exponentially decreasing field. At low frequencies, in particular, the static approximation is good, and it predicts a rapid attenuation of the fields with distance.

Now we are faced with the opposite question: Why are waves propagated at all? Just is the *in-phase* part! The reason is that at each k -multiple of the retardation of the fields contained in additional changes in phase will not change the fields of the out-of-phase sources to add instead of canceling. In fact, in Chapter 29 of Vol. I we have already studied just this problem: the fields generated by a row of sources in a uniform posting. There we found that when several sources are linearly arranged, they can give an interference pattern that has a strong signal in some direction but no signal in another.

Suppose we go back to Fig. 24-15 and look at the fields which arrive at a large distance from the array of image sources. The fields will be strong only in certain directions which depend on the frequency, only in those directions for which the fields from all the sources add in phase. At a reasonable distance from the sources the field propagates in these directions as sinusoidal waves. We have sketched such a wave in Fig. 24-16, where the solid lines represent the wave crests and the dashed lines represent the troughs. The wave direction will be the one for which the difference in the retardation for two neighboring sources to the crest of a wave corresponds to one-half a period of oscillation. In other words, the difference between ϵ_1 and ϵ_2 in the figure is one-half of the free space wavelength:

$$\epsilon_2 - \epsilon_1 = \frac{\lambda_0}{2}.$$

The angle θ is then given by

$$\sin \theta = \frac{\lambda_0}{2a}. \quad (24.33)$$

There is, of course, another set of waves traveling downward at the same phase angle with respect to the array of sources. The complete waveguide field (at 100%

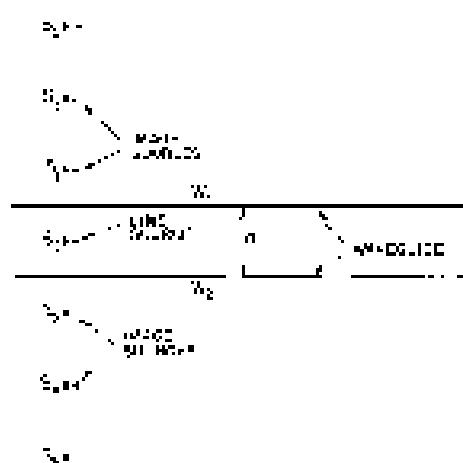

Fig. 24-15. The line source S_1 between the conducting plates W_1 and W_2 . The wave can be replaced by the infinite succession of image sources.

show to the source; & the superposition of these two sets of waves, as shown in Fig. 24-17. The optical fields are easily like this, if one goes only between the two walls of the waveguide.

At points like A and C, the fields of the two waves interfere, and the light will have an amplitude at points like B, both waves having peak negative voltage, and the light has its minimum (or zero) negative voltage. As time goes on, the light in the guide appears to be traveling along the guide with a wavelength λ_m , which is the distance from A to C. This distance is related to θ by

$$\cos \theta = \frac{\lambda_m}{\lambda_0} \quad (24.14)$$

Using Eq. (24.13) for θ , we get that

$$k_m = \frac{\lambda_0}{\cos \theta} = \frac{\lambda_0}{\sqrt{1 - (\lambda_0/\lambda_0)^2}} \quad (24.15)$$

which is just what we found in Eq. (24.10).

Now we see why there is only wave propagation above the "cut-off" frequency ω_c . If the free-space wavelength is longer than λ_0 , there is no angle where the waves shown in Fig. 24-16 can appear. The necessary constructive interference disappears suddenly when λ_0 drops below $2a$, or when ω rises above $\omega_c = \omega_0^2/a$.

If the frequency is high enough, there can be two or more possible directions in which the waves will appear. For our case, this will happen if $k_m < k_0$. In general, however, it could also happen when $k_m > k_0$. These additional waves correspond to the higher guide modes we have mentioned.

It has also been made evident, by our analysis why the phase velocity of the guided waves is greater than c and why this velocity depends on ω . As ω is changed, the angle of the two waves of Fig. 24-16 changes, and therefore so does the velocity along the guide.

Although we have described the guided wave as the superposition of the fields of an infinite array of line sources, you can see that we would arrive at the same result if we imagined two sets of free-space waves being continually reflected back and forth between two perfect mirrors—remembering that a reflection means a reversal of phase. These sets of reflecting waves would all cancel each other unless they were going in just the angle θ given in Eq. (24.13). There are many ways of looking at the same thing.

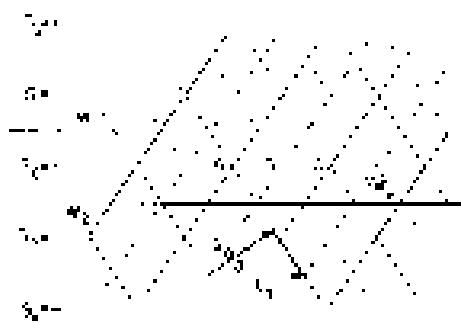

Fig. 24-17. The wave-guide field can be viewed as the superposition of two sets of plane waves.

Electrodynamics in Relativistic Notation

24-1 Four-vectors

We now show the application of the special theory of relativity to electrodynamics. As we have already studied the special theory of relativity in Chapters 15 through 17 of Vol. I, we will just review quickly the basics here.

It is found experimentally that the laws of physics are not coupled if we move with uniform velocity. You can tell if you are moving at speed v by moving with uniform velocity in a straight line, unless you know outside the spaceship, or at least make an observation having to do with the world outside. Any rule law of physics we write down must be arranged so that this fact of nature is built in.

The relationship between the space and time of two systems of coordinates, one S , in uniform motion in the direction with speed v relative to the other, S' , is given by the *Lorentz transformation*:

$$\begin{aligned} t' &= \frac{t - vx}{\sqrt{1 - v^2}}, & x' &= y, \\ x' &= \frac{x - vt}{\sqrt{1 - v^2}}, & z' &= z. \end{aligned} \quad (24.1)$$

The laws of physics must be such that after a Lorentz transformation, the new form of the laws looks just like the old form. This is just like the principle that the laws of physics can't depend on the *coordinates* of our coordinate system. In Chapter 14 of Vol. I, we saw that it was necessary to describe the mathematics of the invariance of physics with respect to rotations was to write our equations in terms of tensors.

For example, if we have two vectors

$$A = (A_x, A_y, A_z) \quad \text{and} \quad B = (B_x, B_y, B_z),$$

we found that the combination

$$A \cdot B = A_x B_x + A_y B_y + A_z B_z,$$

was not changed if we changed over to a rotating coordinate system. So we know that if we want a scalar product like $A \cdot B$ on both sides of an equation, we require it will have exactly the same form in all rotated coordinate systems. We also discussed an operator (see Chapter 2),

$$\nabla = \left(\frac{\delta}{\delta x}, \frac{\delta}{\delta y}, \frac{\delta}{\delta z} \right),$$

which, when applied to a scalar function, gave three quantities which transform just like a vector. With this operator we defined the gradient, and in combination with other vectors, the divergence and the Laplacian. Finally we discovered that by taking sums of certain products of parts of the components of two vectors, we could get three new quantities which behaved like new vectors. We called the cross product of two vectors. Using the cross product with our operator ∇ we then defined the curl of a vector.

Since we will be referring back to what we have done in vector analysis, we have put in Table 24.1 a summary of all the important vector operations in three dimensions that we have used in the past. The point is that it might be possible to write the equations of physics so that both sides transform the same way under

Table 25.1

The important quantities and operations of vector analysis in three dimensions

Definition of:

vector	$\mathbf{A} = (A_x, A_y, A_z)$
scalar product	$A \cdot B$
Differential vector operator:	∇
Gradient	∇V
Divergence	$\nabla \cdot \mathbf{A}$
Laplacian	$\nabla \cdot \nabla = \nabla^2$
Cross product	$\mathbf{A} \times \mathbf{B}$
Curl	$\nabla \times \mathbf{A}$

orientation. One side is a vector, the other side must also be a vector, and both sides will change length in exactly the same way if we rotate our coordinates system. But, finally, if a vector is a vector, the other side must also be a vector, so that both sides change when we rotate coordinates, and so on.

Now in the case of special relativity, time and space are intertwined, since, and we must do the analogous things for four dimensions. We would not expect this to happen just for rotations but also for other invariant frames. That means that the equations will be invariant under the Lorentz transformation, or, in equation (25.1). To give you a taste, this chapter is to show you how that can be done. Before we get started, however, we ought to do some relativity, and guess what? we work in four dimensions, not just three-dimensional space. And that is to choose a unit of length in time so that the speed of light is constant. You might think about us taking that unit of time to be the time that it takes light to go one meter (which is about 3×10^{17} sec). We can then call this time unit "the meter". Using this definition of our equation will allow it to be covariant, i.e., space-time covariant. Also, all the $\partial/\partial x^\mu$ will disappear. They are now absolute derivatives. (If this bothers you, you can always add the c back in by multiplying every derivative, in general, by c , though you know c is needed to make the dimensions of the equations of motion right.) Well, this program works, we are ready to begin. Our program is to do the first dimensionless "homogeneous" of the "Laplace operator" exercises for three dimensions. It is only quite a simple problem, we just work by analogy. The only real complication is the notation, since there is used up the vector symbol for three dimensions and one short list of signs.

First, by analogy with exercises in three dimensions, we define a four-vector to consist of the four quantities $(\rho_0, \rho_1, \rho_2, \rho_3)$, which "travel" like (x_0, x_1, x_2, x_3) when we change to a moving coordinate system. There are several different ways that people use for a four-vector; we will write ρ_μ , by which we mean a group of four numbers: $(\rho_0, \rho_1, \rho_2, \rho_3)$. In other words, the subscripts will take all the four "values" $0, 1, 2, 3$. It will also be convenient, at times, to include the three space components by a three vector, like this: $\rho_1 = (\rho_1, \rho_2, \rho_3)$.

We have already encountered one four-vector, which consists of the energy and momentum of a particle (Chapter 14, Sec. 10). In our new notation we write

$$\rho_1 = (E, \mathbf{p}) \quad (25.2)$$

which means that the "bottom" (ρ_0) is called E , or "energy". From the three components of the three-vector \mathbf{p} of a particle,

it looks as though the game is really very simple. But, and three-vector is physical and we have to consider what the remaining component should be, and we have a four-vector. So see that this is not the case, consider the velocity vector with components

$$v_\mu = \frac{d\rho_\mu}{dt} = \rho_1 \cdot \frac{dx^\mu}{dt} = \rho_1 \cdot \frac{ds}{dt},$$

The question is: What is the time component? (Insure that give the right answer. If the components are like v_x, v_y, v_z , we would guess that the time component is

$$v_0 = \frac{ds}{dt} = 1.$$

This is wrong. The reason is that the s in each denominator is not an invariant when we make a Lorentz transformation. The numerators have the right behavior to make a four-vector, but the s in the denominators, which is the distance in 4-dimensions, and is not the same in two different systems.

To figure out that the four "velocity" components, which we have written down, will become the components of a four-vector, if we just divide by $\sqrt{1 - v^2/c^2}$. We can see that that is true because, if we start with the momentum four-vector

$$\rho_1 = (E, \mathbf{p}) = \left(\frac{mc}{\sqrt{1 - v^2/c^2}}, v^0, \frac{mv^1}{\sqrt{1 - v^2/c^2}}, v^2, \frac{mv^3}{\sqrt{1 - v^2/c^2}} \right), \quad (25.3)$$

the ratio is by the Lorentz transform which is an invariant scalar in four dimensions, we have

$$\frac{p_2}{m} = \left(\sqrt{1 - \frac{v^2}{c^2}}, \frac{v}{\sqrt{1 - v^2}} \right). \quad (25.4)$$

which must still be a four-vector. (Dividing by an invariant scalar doesn't change the transformation properties.) So we can define the "velocity four-vector" \mathbf{v}_v by

$$v_v = \frac{1}{\sqrt{1 - v^2}}, \quad v_v^\mu = \frac{v^\mu}{\sqrt{1 - v^2}}, \quad (25.5)$$

$$v_v^\mu = \frac{v^\mu}{\sqrt{1 - v^2}}, \quad v_v^\mu = \frac{v^\mu}{\sqrt{1 - v^2}}.$$

This four-vector is a useful quantity; we can, for instance, write

$$p_\mu = m v_\nu g^{\mu\nu}. \quad (25.6)$$

This is the typical sort of relation in an equation which is relativistically covariant, just like v is a four-vector. (The right-hand side is an invariant times a four-vector, which is itself a four-vector.)

25-2 The scalar product

It is an accident of fate, if you wish, that under coordinate rotations the distance of a point from the origin does not change. This means mathematically that $x^2 + y^2 + z^2$ is an invariant. In other words, after a rotation $x'^2 + y'^2 + z'^2 = x^2 + y^2 + z^2$

$$x'^2 + y'^2 + z'^2 = x^2 + y^2 + z^2.$$

Now the question is: Is there a similar quantity which is invariant under the Lorentz transformation? There is. From Eq. (25.4) you can see that

$$x'^2 + y'^2 + z'^2 = v^2. \quad (25.7)$$

That is pretty nice except that it's not a point. For choice of the reference. We can fix that up by multiplying x^2 and v^2 . The Lorentz transformation or else a rotation will leave the quantity unchanged. So the quantity which is analogous to $x^2 + y^2 + z^2$ for four dimensions, in three dimensions is

$$v^2 = x^2 + v^2 - z^2.$$

It is an invariant under rot so it's called the "complete Lorentz group", which means the transformation of both translations at constant velocity and rotations.

Now since this invariance is an algebraic matter depending only on the transformation rule of Eq. (25.4) (no rotations), it is true for any four vector (by definition it is a 4D transform the same). So for a four-vector a , we have that

$$a_1^2 + a_2^2 + a_3^2 + a_4^2 = a_1'^2 + a_2'^2 + a_3'^2 + a_4'^2.$$

We will call this quantity the square of "the length" of the four vector a . (Some other people change the sign of all the terms and call the length $a_1^2 + a_2^2 + a_3^2 - a_4^2$, so you'll have to watch out.)

Now if we have two vectors a and b , their corresponding components transform in the same way, so the combination

$$a_\mu b_\nu = a_1 a_1 + a_2 a_2 + a_3 a_3 + a_4 a_4$$

is also an invariant, scalar quantity. (We have in fact already proved this in Chapter 17 of Vol. I.) Clearly this expression is quite analogous to the dot product for vectors. We will, in fact, call it the dot product or scalar product of two four vectors. It would seem logical to write this as $a_\mu b^\mu$, but that would look like a dot product. Unfortunately, it's not done that way; it's usually written without the μ .

So we will follow the convention and write the dot product simply as $a_i b_i$. So, by definition,

$$a_i b_i = a_1 b_1 + a_2 b_2 + a_3 b_3 + a_4 b_4 \quad (25.7)$$

Whenever you see two identical subscripts (not i,j) you will occasionally have to use α, β, γ or some other letter instead of j). It means that you are to take the four products and sum, remembering the same sign for the products of the space components. With this convention the transpose of the scalar product under a Lorentz transformation would be written as

$$a'_i b'_j = a_i b_j.$$

Since the last three terms in (25.7) are just the scalar dot product in three dimensions, it is often more convenient to write

$$a_i b_i = a_1 b_1 + a_2 b_2$$

It is also obvious that the four-dimensional length we described above can be written as $a_i a_i$,

$$a_i a_i = a_1^2 + a_2^2 + a_3^2 + a_4^2 = a^2 = \sigma^2 \quad (25.8)$$

It will also be convenient to sometimes write this quantity as a_i^2

$$a_i^2 = a_i a_i.$$

We will now give you an illustration of the usefulness of four-vector dot products. Antiprotons (\bar{p}) are produced in large accelerators by the reaction

That is, an energetic proton collides with a proton at rest (for example, in a hydrogen target placed in the beam), and if the incident atom has enough energy, a proton-antiproton pair may be produced, in addition to the two original protons.* The question is: How much energy must be given to the incident proton to make this reaction energetically possible?

The easiest way to get the answer is to consider what the reaction looks like in the center-of-mass (CM) system (see Fig. 25-1). We'll call the incident proton a and its laboratory momentum p_a . Similarly, we'll call the target proton b and its lab momentum

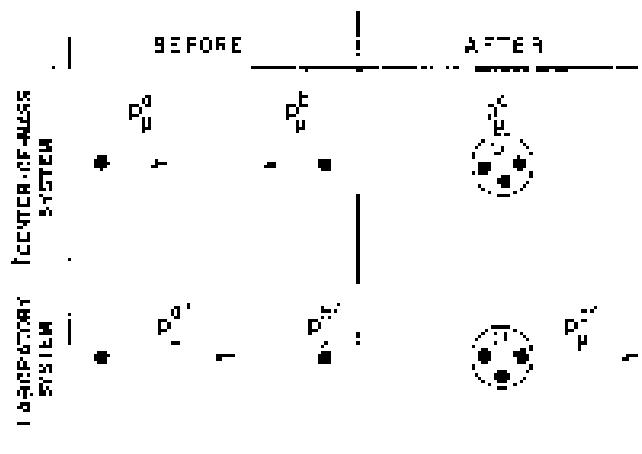

Fig. 25-1. The reaction $p + p \rightarrow p + p + \bar{p} + \bar{p}$ viewed in the laboratory and CM systems. The incident proton is supposed to have just barely enough energy to make the reaction go. Protons are denoted by solid circles; antiprotons, by open circles.

* You may well ask: Why not consider the reaction

$$p + p \rightarrow p + p + \bar{p}$$

or even

$$p + p \rightarrow p + p$$

which clearly looks simpler? The answer is that a process like collision conservation of baryon tells us the quantity "one less proton minus number of antiprotons" cannot change. This quantity is 2 on the left side of our reaction. Therefore, if we want an antiproton on the right side, we must "cancel the two protons" (as in the last eq.).

momentum p_1^4). If the nuclear system has *precisely* enough energy to make the reaction go, the final state (the situation after the collision) will consist of a glob containing three protons and an antiproton at rest in the CM system. If the incident energy were slightly higher, the final state particles would have some kinetic energy and be moving apart; if the incident energy were slightly lower, there would not be enough energy to make the four particles.

If we call ρ^4 the total four-momentum of the whole glob in the final state, conservation of energy and momentum tells us that

$$\rho^0 = p_1^0 + p_2^0 + p_3^0 + p_4^0$$

and

$$E^0 = p_1^0 + p_2^0 + p_3^0 + p_4^0$$

Combining these two equations, we can write that

$$p_1^0 + p_2^0 + p_3^0 = p_4^0. \quad (25.9)$$

Now the important thing is that this is an equation among four-vectors, and is therefore true in any inertial frame. We can use this fact to simplify our calculations. We start by taking the "length" of each side of Eq. (25.9); they are, of course, also equal. We get

$$(p_1^0 + p_2^0 + p_3^0)^2 = p_4^0 p_4^0 \quad (25.10)$$

Since $p_4^0 p_4^0$ is invariant, we can evaluate it in *any* coordinate system. In the CM system, the time component of p_4^0 is the rest mass of four protons, namely $4M$, and the space part \vec{p} is zero; so $p_4^0 = (4M, 0)$. We have used the fact that the rest mass of an antiproton equals the rest mass of a proton, and we have called this combined mass M .

Thus, Eq. (25.10) becomes

$$p_1^0 p_1^0 + p_2^0 p_2^0 + p_3^0 p_3^0 = 16M^2. \quad (25.11)$$

Now $p_1^0 p_1^0$ and $p_2^0 p_2^0$ are very easy to evaluate: the "length" of the momentum four-vector of any particle is just the mass of the particle squared:

$$p_1^0 p_1^0 = E^2 - M^2.$$

This can be shown by direct calculation or, more elegantly, by noting that for a particle at rest $p_1^0 = (M, 0)$, so $p_1^0 p_1^0 = M^2$, but since E is an invariant, it is equal to M^2 in any frame. Using these results in Eq. (25.11), we have

$$2p_1^0 p_1^0 = 14M^2$$

or

$$p_1^0 p_1^0 = 7M^2. \quad (25.12)$$

Now we can also evaluate $p_1^0 p_1^0$ in the laboratory system. The four-vector p_1^0 can be written (E^0, \vec{p}^0) , while $p_1^0 = (M, 0)$, since it describes a proton at rest. Thus, $p_1^0 p_1^0$ must also be equal to M^2 , and since we know the scalar product is an invariant this must be numerically the same as what we found in (25.12). So we have that

$$E^2 = 7M^2,$$

which is the result we were after. The *total* energy of the initial proton must be at least $7M$ (about 6 GeV since $M = 938$ MeV) in order that the rest mass M , the kinetic energy must be at least $6M$ (about ± 6 GeV). The Bevatron accelerator at Berkeley was designed to give about ± 2 GeV of kinetic energy to the protons it accelerates, in order to be able to make antiprotons.

Since scalar products are invariant, they are always interesting to evaluate. What about the "length" of the four-velocity (v, \vec{v}) ?

$$v \cdot v = v^2 = v^0 v^0 + \frac{1}{c^2} \vec{v} \cdot \vec{v} = \frac{c^2}{1 - v^2/c^2} - 1.$$

Thus, v_c is the *light speed factor*.

25.3. The four-dimensional gradient

The next thing that we have to discuss is the four-dimensional analog of the gradient. We recall (Chapter 14) that in three dimensions there are three operators $\partial/\partial x^i$, $\partial/\partial y^i$, $\partial/\partial z^i$ that can be called the three partial derivatives or the gradient. The same scheme ought to work in four dimensions; that is, we might guess that the four-dimensional gradient should be $(\partial/\partial t)$, $(\partial/\partial x)$, $(\partial/\partial y)$, $(\partial/\partial z)$. That is wrong.

To see the error, consider a scalar function ϕ which depends only on x and t , the storage of ϕ . If we make a small change Δx in x while holding t constant, it is

$$\Delta\phi = \frac{\partial\phi}{\partial x} \Delta x \quad (25.13)$$

On the other hand, according to a moving observer,

$$\Delta\phi = \frac{\partial\phi}{\partial x'} \Delta x' = \frac{\partial\phi}{\partial t'} \Delta t'.$$

We can express $\Delta x'$ and $\Delta t'$ in terms of Δx by using Eq. (25.1). Remembering that we are holding t constant, so that $\Delta v = 0$, we write

$$\Delta x' = -\frac{v}{\sqrt{1-v^2}} \Delta x \quad \Delta t' = \frac{\Delta t}{\sqrt{1-v^2}}$$

Thus,

$$\begin{aligned} \frac{\partial\phi}{\partial x'} &= \frac{\partial\phi}{\partial x} \left(-\frac{v}{\sqrt{1-v^2}} \frac{\Delta t}{\Delta x} \right) = \frac{\partial\phi}{\partial t'} \left(\frac{\Delta t}{\sqrt{1-v^2}} \right) \\ &= \left(\frac{\partial\phi}{\partial t'} + v \frac{\partial\phi}{\partial x'} \right) \frac{\Delta t}{\sqrt{1-v^2}} \end{aligned}$$

Comparing this result with Eq. (25.13), we learn that

$$\frac{\partial\phi}{\partial t'} = \frac{1}{\sqrt{1-v^2}} \left(\frac{\partial\phi}{\partial t} + v \frac{\partial\phi}{\partial x} \right) \quad (25.14)$$

A similar calculation gives

$$\frac{\partial\phi}{\partial x'} = -\frac{v}{\sqrt{1-v^2}} \left(\frac{\partial\phi}{\partial x} + v \frac{\partial\phi}{\partial t} \right). \quad (25.15)$$

Now we can see that the gradient is rather strange. The formulas for x and t in terms of x' and t' [obtained by solving Eq. (25.2)] are:

$$t = \frac{t' + vx'}{\sqrt{1-v^2}}, \quad x = \frac{x' + vt'}{\sqrt{1-v^2}}.$$

This is the way a four-vector must transform. But Eqs. (25.14) and (25.15) have a couple of signs wrong!

The answer is that instead of the operator $\partial/\partial t$ (∇), we must define the four-dimensional gradient operator, which we will call ∇_4 , by

$$\nabla_4 = \left(\frac{\partial}{\partial t}, -\nabla \right) = \left(\frac{\partial}{\partial t}, -\frac{\partial}{\partial x}, -\frac{\partial}{\partial y}, -\frac{\partial}{\partial z} \right) \quad (25.16)$$

With this definition, the sign difficulties mentioned above go away, and ∇_4 behaves like a four-vector should. (It's rather awkward to have these minus signs, but that's the way the world is.) Of course, what I mean to say is that ∇_4 behaves like a four-vector because the four-gradient of a scalar is a four-vector. If α is a time-constant invariant field (i.e., α is invariant); then $\nabla_4 \alpha$ is a four-vector field.

All right, now that we have vectors, gradients, and dot products, the next thing is to look for an invariant which is analogous to the divergence of three-dimensional vector analysis. Clearly, the analog is to form the expression $\nabla_4 \cdot b$, where b is a four-vector field whose components are functions of space and time.

We define the divergence of the four-vector $b_\mu = (\nu, \mathbf{b})$ as the dot product of ∇_μ and b_μ :

$$\begin{aligned}\nabla_\mu b_\mu &= \frac{\partial}{\partial t} b_0 + \left(-\frac{\partial}{\partial x}\right) b_x + \left(-\frac{\partial}{\partial y}\right) b_y + \left(-\frac{\partial}{\partial z}\right) b_z \\ &= \frac{\partial}{\partial t} b_0 - \nabla' \cdot \mathbf{b},\end{aligned}\quad (25.17)$$

where $\nabla' \cdot \mathbf{b}$ is the value of three-dimensional divergence of the three-vector \mathbf{b} . Note that one has to be careful with the signs. Some of the minus signs come from the definition of the scalar product, Eq. (15.4); the others are required because the space components of ∇_μ are $(\partial/\partial t, -\partial/\partial x, -\partial/\partial y, -\partial/\partial z)$, as in Eq. (25.9). The divergence as defined by (25.17) is not the same as the three-dimensional divergence system ∇' after a Lorentz transformation.

Let's look at a physical example in which the four-divergence shows up. We can start to solve the problem of the fields around a moving wire. We have already seen (Section 13.7) that the electric charge density ρ and the current density j form a four vector $j_\mu = (\rho, \mathbf{j})$. If an uncharged wire carries the current \mathbf{j} , then in a frame moving parallel with velocity v along x_0 , the wire will have the charge and current density obtained from the Lorentz transformation, Eqs. (25.1), as follows:

$$\rho' = \frac{\rho}{\sqrt{1 - v^2}}, \quad j'_\mu = \frac{j_\mu}{\sqrt{1 - v^2}}.$$

These are just what we found in Chapter 12. We can now use the Lorentz-Maxwell's equation in the moving system to find the fields.

The charge conservation law, Section 13.7, also takes on a simple form in the relativistic situation. Consider first the divergence of j_μ :

$$\nabla_\mu j_\mu = \frac{\partial \rho}{\partial t} + \nabla' \cdot \mathbf{j}. \quad (25.18)$$

The law of the conservation of charge says that the outflow of charge per unit volume τ ms. equals the negative rate of increase of charge density. In other words, that

$$\nabla' \cdot \mathbf{j} = -\frac{d\rho}{dt}.$$

Putting this in to Eq. (25.18), the law of conservation of charge takes on the simple form:

$$\nabla_\mu j_\mu = 0. \quad (25.19)$$

Since $\nabla_\mu j_\mu$ is an invariant scalar, it is zero in one frame if it is zero in all frames. We have the result that if charge is conserved in one coordinate system, it is conserved in all coordinate systems moving with uniform velocity.

As our last example we want to consider the scalar product of the gradient operator ∇_μ with itself. In three dimensions, such a product gives the Laplacian

$$\nabla^2 = \nabla \cdot \nabla = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}.$$

What do we get in four dimensions? That's new. Following on rules for dot products and gradients, we get

$$\begin{aligned}\nabla_\mu \nabla_\mu &= \frac{\partial}{\partial t} \frac{\partial}{\partial t} + \left(-\frac{\partial}{\partial x}\right) \left(-\frac{\partial}{\partial x}\right) + \left(-\frac{\partial}{\partial y}\right) \left(-\frac{\partial}{\partial y}\right) + \left(-\frac{\partial}{\partial z}\right) \left(-\frac{\partial}{\partial z}\right) \\ &= \frac{\partial^2}{\partial t^2} - \nabla'^2.\end{aligned}$$

This quantity, which is the summing of the three-dimensional Laplacian, is called

the D'Alembertian and has a special notation:

$$\square = \nabla_\mu \nabla^\mu - \frac{\partial^2}{\partial t^2} \quad (25.20)$$

From its definition it is an invariant scalar operator; it operates on a four-vector field, it produces a new four-vector field. (Some people define the D'Alembertian with the opposite sign to Eq. (25.20), so you will have to be careful when reading the literature.)

We have now found four-dimensional equivalents of most of the three-dimensional quantities we also listed in Table 25-1. (We do not yet have the equivalents of the cross product and the curl operator, we won't get to them until the next chapter.) It may help you remember how they go if we put all the important definitions and results from 25-1 in one place, so we have made such a summary in Table 25-2.

Table 25-2

The important quantities of vector analysis in three and four dimensions.

	Three dimensions	Four dimensions
Vectors	$\mathbf{A} = (A_x, A_y, A_z)$	$\mathbf{a}_\mu = (a_0, a_1, a_2, a_3) = (a_0, \mathbf{a})$
Scalar product	$A \cdot B = A_x B_x + A_y B_y + A_z B_z$	$a_0 b_0 = a_0 b_0 - a_1 b_1 - a_2 b_2 - a_3 b_3 = a_0 b_0 - \mathbf{a} \cdot \mathbf{b}$
Vector operator	$\nabla = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$	$\nabla_\mu = (\partial/\partial x^0, \partial/\partial x^1 - \partial/\partial y^1, \partial/\partial x^2 - \partial/\partial z^2, \partial/\partial x^3 - \nabla)$
Gradient	$\nabla \psi = \left(\frac{\partial \psi}{\partial x}, \frac{\partial \psi}{\partial y}, \frac{\partial \psi}{\partial z} \right)$	$\nabla_\mu \psi = \left(\frac{\partial \psi}{\partial x^0} + \frac{\partial \psi}{\partial x^1} - \frac{\partial \psi}{\partial y^1} - \frac{\partial \psi}{\partial z^1}, \frac{\partial \psi}{\partial x^2} + \frac{\partial \psi}{\partial x^3} \right) = \left(\frac{\partial \psi}{\partial x} + \nabla_\perp \right)$
Divergence	$\nabla \cdot \mathbf{A} = \frac{\partial A_x}{\partial x} + \frac{\partial A_y}{\partial y} + \frac{\partial A_z}{\partial z}$	$\nabla_\mu \cdot \mathbf{a}_\mu = \frac{\partial a_0}{\partial x^0} + \frac{\partial a_1}{\partial x^1} + \frac{\partial a_2}{\partial x^2} + \frac{\partial a_3}{\partial x^3} = \frac{\partial a_0}{\partial x^0} - \nabla \cdot \mathbf{a}$
Laplacian and D'Alembertian	$\nabla \cdot \nabla = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$	$\nabla_\mu \nabla_\mu = \frac{\partial^2}{\partial x^{02}} + \frac{\partial^2}{\partial x^{12}} - \frac{\partial^2}{\partial y^{12}} - \frac{\partial^2}{\partial z^{12}} + \frac{\partial^2}{\partial x^{22}} + \frac{\partial^2}{\partial x^{32}} - \nabla^2 = \square$

25-4 Electrodynamics in four-dimensional notation

We have already considered the D'Alembertian equation, without going to that much, in Section 18-6. The differential equations we found there for the potentials can be written in the new notations as:

$$\square^2 \psi = \frac{q}{\epsilon_0 c} \quad \square^2 M = \frac{j}{c} \quad (25.21)$$

The four quantities on the right-hand side of the two equations in (25.21) are proportional to each other by q/c , which is a universal constant which will be the same in all coordinate systems if the same unit of charge is used in all frames. So the four quantities $q/\epsilon_0 c$, j/c , ψ , M , also transform as a four-vector. We can write them as \mathbf{A}_μ . The D'Alembertian doesn't change when the coordinate system is changed, so the quantities ψ , A_0 , A_1 , A_2 and A_3 also transform like a four-vector, which means that they are the components of a four-vector. In short

$$\mathbf{A}_\mu = (\phi, \mathbf{A})$$

is a four-vector. Why, we call the scalar and vector potentials are really different aspects of the same physical thing. They belong together. And if they are kept together the elegant structure of the world is obvious. We call \mathbf{A}_μ the four-potential.

In the four-vector notation Eqs. (25.21) become simply

$$\nabla^{\mu} A_{\mu} = \frac{\partial \phi}{\partial t}. \quad (25.22)$$

The physics of this equation is just the same as Maxwell's equations. But there is some pleasure in being able to write them in an elegant form. The pretty form is also meaningful, i.e., shows directly the invariance of electrodynamics under the Lorentz transformation.

Remember that Eqs. (25.21) could be deduced from Maxwell's equations only if we imposed the gauge condition

$$\frac{\partial \phi}{\partial t} = \nabla \cdot \mathbf{A} = 0, \quad (25.23)$$

which just says $\partial_{\mu} A_{\mu} = 0$, the gauge condition says that the divergence of the four-vector A_{μ} is zero. This condition is called the *Lorentz condition*. It is very convenient because it is an invariant condition and therefore Maxwell's equations stay in the form of Eq. (25.23) for all frames.

25-8 The four-potential of a moving charge

Although it is implicit in what we have already said, let us write down the transformation laws which give ϕ and \mathbf{A} in a moving system in terms of ϕ and \mathbf{A} in a stationary system. Since $A_0 = -q\phi/dt$ is a four-vector, the equation must look just like Eqs. (25.21), except that ϕ is replaced by ϕ' and a_0 is replaced by A_0 plus

$$\begin{aligned} \phi' &= \frac{\phi + v A_0}{\sqrt{1 - v^2}}, & A_0 &= A_{00}, \\ A'_0 &= \frac{A_0 - v \phi'}{\sqrt{1 - v^2}}, & A'_0 &= A_0. \end{aligned} \quad (25.24)$$

This assures that the primed coordinate system is moving with speed v in the positive x -direction, as measured in the unprimed coordinate system.

We will consider one example of the usefulness of the idea of the four-potential. What are the vector and scalar potentials of a charge q moving with speed v along the x -axis? The problem is easy in a coordinate system keeping with the charge, since in this system the charge is standing still! Let's say that the charge is at the origin of the S' -frame, as shown in Fig. 25.7. The vector potential in the moving system is then given by

$$A' = \frac{q}{2\pi r v}, \quad (25.25)$$

r being the distance from q to the field point as measured in the moving system. The scalar potential ϕ' is, of course, zero.

Now it is straightforward to find ϕ and A_0 , the potentials as measured in the stationary coordinate system. The answer (due to Eqs. (25.24)) is

$$\begin{aligned} \phi &= \frac{q'}{\sqrt{1 - v^2}}, & A_0 &= A_{00}, \\ A_0 &= \frac{A'_0 + v \phi'}{\sqrt{1 - v^2}}, & A'_0 &= A_0. \end{aligned} \quad (25.26)$$

Using the ϕ' given by Eq. (25.25), and $A'_0 = 0$, we get

$$\begin{aligned} \phi &= \frac{q}{4\pi c} \frac{1}{\sqrt{1 - v^2}} \\ &= \frac{q}{4\pi c} \frac{1}{\sqrt{1 - \beta^2}} \sqrt{\gamma^2 + \gamma^2 \beta^2 + \gamma^2 \beta^2} \end{aligned}$$

Fig. 25.7. The frame S' moves with velocity v (in the x -direction) with respect to S . A charge at rest at the origin of S' is at $x = vt$ in S . The potentials at P can be computed in either frame.

This gives us the scalar potential ϕ we would see in S, but, unfortunately, expressed in terms of the S' coordinates. We can get things in terms of r, θ, ϕ, z by substituting for x', y', z' , and t' using (25.1). We get

$$\phi = \frac{q}{4\pi c} \frac{1}{\sqrt{1 - v^2}} \frac{1}{\sqrt{(1 - v^2) \sin^2 \theta + v^2 + 1 - v^2}}. \quad (25.27)$$

Following the same procedure for the components of A , you can show that

$$A = v\phi. \quad (25.28)$$

These are the same formulae we derived in a different method in Chapter 21.

25.4. The invariance of the equations of electromagnetism

We have found that the potentials ϕ and A taken together form a four-vector which we call A_μ , and that the wave equations—the full equations which determine the A_μ in terms of the v 's—can be written as in Eq. (25.22). This equation, together with the conservation law (Eq. (25.19)), gives us the **fundamental law** of the electromagnetic field:

$$\nabla_\mu A_\nu - \frac{1}{c} L_{\mu\nu} = V_{\mu\nu} = 0. \quad (25.29)$$

There, in one tiny space on the page, are all of the Maxwell equations—beautiful and simple. Did we learn anything from writing the equations this way, besides that they are beautiful and simple? In the first place, is it anything different from what we had before when we wrote everything out in all the various components? Can we from this equation deduce something that could not be deduced from the seven equations for the potentials in terms of the charges and currents? The answer is definitely no. The only thing we have been doing is changing the name of things.

Using a new notation, we have written a square symbol to represent the derivatives, but it still means nothing more nor less than the second derivative with respect to t , minus the second derivative with respect to x , minus the second derivative with respect to y , minus the second derivative with respect to z . And the difference that we have four equations, one each for $\omega = t, x, y$, or z . What does this say about the fact that the equations can be written in this simple form? From the point of view of calculating anything directly, it doesn't mean anything. Perhaps, though, the simplicity of the equations means that nature also has a certain simplicity.

Let us show you something interesting that we have recently discovered: all of the laws of physics can be contained in one equation. That equation is

$$U = 0. \quad (25.30)$$

With a simple example. Of course, it is necessary to know what the symbol means. U is a physical quantity which we will call the "universality" of a situation. And we have a formula for it. Here is how you calculate the universality. You take all of the known physical laws and write them in a special form. For example, suppose you take the law of mechanics, $F = ma$, and rewrite it as $F = m\ddot{x} = 0$. Then you can call $(F = m\ddot{x})$ —which should, of course, be zero—the "universality" of mechanics. Next, you take the laws of thermodynamics and call it U_1 , which can be called the "universality of nonelementary effects." In other words, you take

$$U_1 = (F - m\ddot{x})^2. \quad (25.31)$$

Now you write another physical law, say, $\nabla \cdot H = \rho/c_0$, and define

$$U_2 = \left(\nabla \cdot H - \frac{\rho}{c_0} \right)^2,$$

which you might call "the universal nonexistence of electricity." You continue to write U_3 , U_4 , and so on—and for every physical law there is

Finally you add the individual fluxes \mathbf{U} of the world to sum of the various unworld fluxes \mathbf{U}_i , from all the i phenomena that are available, that is, $\mathbf{U} = \sum \mathbf{U}_i$. Then the great "law of calculus" is

$$\boxed{\mathbf{U} = 0} \quad (25.2)$$

This "law" means, of course, that the sum of the squares of all the individual mismatchings is zero, and the only way the sum of a set of squares can be zero is for each one of the terms to be zero.

So the "beautifully simple" law in Eq. (25.2) is equivalent to the combination of equations that you originally wrote down. It is therefore what many believe that a simple notation that just hides the complexity in the definitions of symbols is more satisfying. At your risk, the beauty that appears in Eq. (25.2) is just from the fact that several equations are hidden within it, is no more than a trick. When you unwrap the whole thing, you get back where you were before.

However, there is more to the simplicity of the laws of electromagnetism written in the form of Eq. (25.2). It means more, just as a theory of vector analysis means more. The fact that the electromagnetic equations can be written in a very particular notation which is convenient for the four-dimensional geometry of the Lorentz transformations—in other words, as a vector equation in the four-space—means that it is invariant under the Lorentz transformations. This is because the Maxwell equations are invariant under those transformations, but they can be written in a beautiful form.

It is not obvious that the equations of electrodynamics can be written in the beautiful form of Eq. (25.2). The theory of relativity was developed however at the same time experimentally that the phenomena predicted by Maxwell's equations were the same in all inertial systems. And it was precisely by studying the transformation properties of Maxwell's equations that Lorentz discovered his transformation as the one which left the equations invariant.

There is, however, another reason for writing our equations this way. It has been discovered, after Einstein guessed that it might be so—that all of the laws of physics are invariant under the Lorentz transformation. That is the principle of relativity. Therefore, if we invent a notation which shows immediately when a law is written down whether it is invariant or not, we can be sure that in trying to make new theories we will write only equations which are consistent with the principle of relativity.

The fact that the Maxwell equations are simple in this particular notation is not a miracle, because the notation was invented with them in mind. But the interesting physical thing is that a certain of physics—the propagation of meson waves or the behavior of neutrinos in beta decay, are as Earth—centric here, as some invariance under the same transformation. Even when you are moving at a uniform velocity in a spaceship, all of the laws of nature remain together in such a way that no new phenomena will show up. It is because the principle of relativity is a fact of nature that in the notation of four-dimensional vectors the equations of the world will look simple.

Lorentz Transformations of the Fields

26-1 The four-potential of a moving charge

We saw in the last chapter that the potential $A_\mu = (\phi, \mathbf{A})$ is to be invariant. The time component is the scalar potential ϕ , and the three spatial components \mathbf{A} the vector potential. We also worked out the potentials of a particle moving with uniform speed on a straight line by using the Lorentz transformation. (We had already found them by another method in Chapter 21.) For a point charge whose position at the time t is (x, y, z) , the potentials at the point (x', y', z') are

$$\begin{aligned} \phi' &= -\frac{\eta}{4\pi\epsilon_0 c^2 \sqrt{1-v^2}} \left[\frac{(x'-vt)^2}{1-v^2} + y'^2 + z'^2 \right]^{1/2} \\ A_x' &= -\frac{v}{2\pi\epsilon_0 c \sqrt{1-v^2}} \left[\frac{y'^2}{1-v^2} + \frac{z'^2}{1-v^2} \right]^{1/2} \quad (26.1) \\ A_y' &= A_z' = 0 \end{aligned}$$

Equations (26.1) give the potentials at x', y', z' at the time t' for a charge whose "present" position (by which we mean the position at the time t) is $x = vt$. Notice that the equations are in terms of $(x = vt), y$, and z , which are the coordinates measured from the current position P' of the moving charge (see Fig. 26-1). The only influence we know really travels at the speed c , or v , is the behavior of the charge back at the retarded position P'' that really counts. The point P'' is at $t = t''$ (where $t'' = t - r/c$ is the retarded time). But, we said that the charge was moving with uniform velocity in a straight line, so naturally the behavior at P'' at the time of position are directly related. In fact, if we make the added assumption that the potentials depend only upon the position and the velocity at the current moment, we can do in equations (26.1) a complete reversal. For the point (x', y', z') a charge moving very fast, it would be very difficult to imagine, in some arbitrary fashion, say $t = t'$ the temporary in Eq. 26.1, and you are trying to find the potentials at the point (x', y', z') . First, you find the retarded position P'' and the velocity v at that point. Then you realize that the charge would keep on moving with the velocity cutting the easy time $t'' = t'$, so that it would then appear at an temporary position P_{temp} , which we call the "projected position," and would move there with the velocity v . (Of course, it doesn't do that; its real position at this t'' is P'' .) Then the potentials at (x', y', z') are just what equations (26.1) would give for the imaginary charge at the projector position P_{temp} . What we are saying is that since the potentials depend only on what the charge is doing at the retarded time, the potentials will be the same whether the charge continued moving at a constant velocity or whether it changed its velocity after t'' —that is, after the potentials that were going to appear at (x', y', z') at the time t'' were already determined.

You know, of course, that the moment that we have the formula for the potentials from a charge moving in any manner whatsoever, we have the complete electrodynamics: we can get the potentials of any charge distribution by super-

[†] The prime, and leading to the subscript μ , means that this does not refer to the primes referring to a Lorentz-transformed frame in the preceding chapter.

26-2 The four-potential of a moving charge

26-3 The fields of a point charge with a constant velocity

26-4 Relativistic transformation of the fields

26-5 The equations of motion in relativistic mechanics

In this chapter: $c = 1$

Review: Chapter 20, Vol. II, Solution of Maxwell's Equations in Free Space

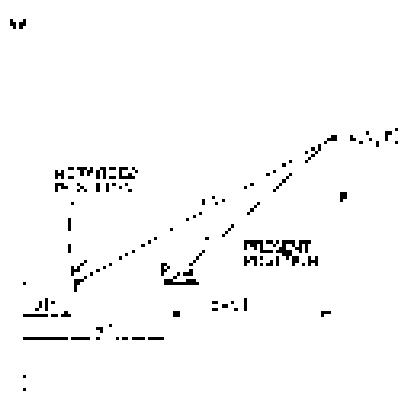

Fig. 26-1. Field of the fields of a charge moving along the x -axis with the constant speed v . The field "now" at the point (x, y, z) can be expressed in terms of the "present" position P , as well as in terms of P' , the "retarded position" ($t' = t - r/c$).

position. Therefore we can summarize all the phenomena of electrodynamics either by writing Maxwell's equations or by the following series of remarks. (These, like them, have you ever been even on a desert island? From them, all can be extrapolated.) As well, of course, knowing the Lorentz transformation; you will never forget where to look if you get lost in a system elsewhere.)

First, ϕ_0 is a function. Again, the Coulomb potential for a stationary charge is such that ϕ_0 , the potential produced by a charge moving in any way depends only upon the velocity and position at the retarded time. With these things being so, we have $\phi_0 = \phi_0(\mathbf{r}, t)$. From this and that \mathbf{A}_0 is a four-vector, we transform the Coulomb potential, which we know, and get the potentials for a constant velocity. Then, by the first statement that potentials depend only upon the past velocity at the retarded time, we can use the projected motion again to find the actual motion systematically, as I was doing earlier. But it is interesting to show that the laws of physics can be given stationary in different ways.

It is sometimes said, by people who are careless, that all of electrodynamics can be reduced solely from the Lorentz invariance and Coulomb's law. Of course, that is completely false. First, we have to suppose that there is a scalar potential ϕ_0 and a vector potential, just kept for book-keeping sake. That tells us how the potentials transform. Then why is it that the effects at the retarded time are the ones "long ago"? Well, just as it is that the potential's depend only on the position and the velocity won't, for instance, on the acceleration? To justify A and B do depend on the acceleration. If you try to make the calculation of a further win respect to them, you would say that they depend only upon the position and velocity at the retarded time. But then the fields from an accelerated charge would be the same as the fields from a charge at the projected position—which is false. The fields depend not only on the position and the velocity along the path, but also on the acceleration. So there are several additional tacit assumptions in this first statement that everything can be deduced from the Lorentz invariance. (Whence you see a sweeping statement that a tremendous amount of work can be done with very small number of assumptions, your always had the type in mind. It can be equally a large amount of impeded assumptions that, as far as I can see, you think about them sufficiently carefully.)

26.2 The fields of a point charge with a constant velocity

Now that we have the potentials from a point charge moving at constant velocity, we ought to find the fields—for practical reasons. There are many cases where we have uniformly moving particles—for instance, cosmic rays going through a cloud chamber, or even slow-moving electrons in a wire. So let's at least see what the fields actually do look like for any speed—even the speeds nearly that of light—assuming only that there is no acceleration. It is an uninteresting question.

We get the fields from the potentials by the usual rules:

$$\mathbf{E} = -\nabla\phi - \frac{\partial\mathbf{A}}{\partial t}, \quad \mathbf{B} = \nabla \times \mathbf{A}.$$

First for E_x ,

$$E_x = -\frac{\partial\phi}{\partial x} = \frac{\partial A_x}{\partial t}.$$

But if we do so, differentiating ϕ in equations (26.1), we get

$$E_x = \frac{q}{4\pi\epsilon_0 v^2(1-v^2)} \left[\frac{x - vx^2}{1 - v^2 + v^2 + z^2} \right] \hat{x}. \quad (26.2)$$

Similarly, for E_y ,

$$E_y = \frac{q}{4\pi\epsilon_0 v^2(1-v^2)} \left[\frac{y - vyt^2}{1 - v^2 + y^2 + z^2} \right] \hat{y}. \quad (26.3)$$

The z -axis project is a little more work. The derivative of ϕ is now complicated

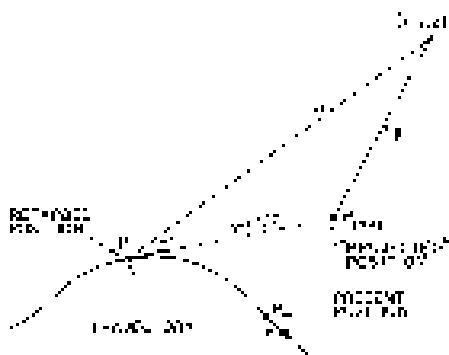

Fig. 24-3. A charge moves on an arbitrary trajectory. The potential's delayed at the time t are determined by the position \mathbf{r}' and velocity v at the retarded time $t' = t - r/c$. They are conveniently expressed in terms of the coordinates over the "projected" position \mathbf{r}_p . (The total position \mathbf{r} is fixed.)

and A_1 is not zero. First,

$$\frac{\partial A_1}{\partial t} = \frac{q}{c^2 r_0 \sqrt{1 - v^2/c^2}} \cdot \frac{(v - ct)(1 - v^2)}{\left[1 - \frac{(v - ct)^2}{c^2} + \frac{y^2}{r_0^2} + \frac{z^2}{r_0^2}\right]^{3/2}}. \quad (26.2)$$

Then, differentiating A_1 with respect to x , we find

$$\frac{\partial A_1}{\partial x} = \frac{q}{c^2 r_0 \sqrt{1 - v^2/c^2}} \cdot \frac{x^2(v - ct)(1 - v^2)}{\left[1 - \frac{(v - ct)^2}{c^2} + \frac{y^2}{r_0^2} + \frac{z^2}{r_0^2}\right]^{5/2}}. \quad (26.3)$$

And finally, taking the sum,

$$E_x = \frac{q}{4\pi \epsilon_0 c^2 r_0 \sqrt{1 - v^2/c^2}} \cdot \frac{x^2(v - ct)(1 - v^2)}{\left[1 - \frac{(v - ct)^2}{c^2} + \frac{y^2}{r_0^2} + \frac{z^2}{r_0^2}\right]^{5/2}}. \quad (26.4)$$

We'll look at the physics of E in a minute, let's first find B . For the z component,

$$B_z = \frac{\partial A_2}{\partial z} = \frac{\partial A_3}{\partial z}.$$

Since A_3 is zero, we have just one derivative to do. Notice, however, that A_2 is, and $\partial A_2/\partial z$ or $\partial A_3/\partial z$ of A_2 is just $-v E_x$. So

$$B_z = -v E_x. \quad (26.5)$$

Similarly,

$$B_y = \frac{\partial A_2}{\partial y} = \frac{\partial A_3}{\partial y} = -1 \cdot \frac{\partial A_3}{\partial z}$$

and

$$B_y = -v E_x. \quad (26.6)$$

Finally, B_x is zero, since A_1 and A_2 are both zero. We can write the magnetic field simply as

$$B = v \times E. \quad (26.7)$$

Now let's see what the fields look like. We will try to draw a picture of the field at various positions around the present position of the charge. It is true that the influence of the charge comes, in a certain sense, from the retarded position, but because the motion is exactly specified, the retarded position is uniquely given in terms of the present position. For uniform velocities, it's nice to relate the fields to the current position, because the field components at (x, y, z) depend only on $(v - ct)$, y , and z (which are the components of the displacement r_0 from the present position to (x, y, z)) (see Fig. 26-2).

Consider first a point with $v = 0$. Then E has only y and z components. From Eqs. (26.4) and (26.6), the ratio of these components is just equal to the ratio of the y - and z -components of the displacement. That means that E is in the same direction as r_0 , as shown in Fig. 26-3. Since E_r is also proportional to v , it is clear that this result holds in three dimensions. In short, the electric field is radial to the charge, and the field lines radiate directly out of the charge, just as they do for a stationary charge. Of course, the field isn't exactly the same as for the stationary charge, because v will be a factor of $(1 - v^2/c^2)$. But we can show something rather interesting: the difference is just v/c ! You know, if you were to have the constant field E in a position r_0 of coordinates in which the static field was expressed by the factor $\sqrt{1 - v^2/c^2}$. If you do that, the field lines will be curved and shifted and bent so the charge will be squeezed together around the ends, as shown in Fig. 26-4.

If we retrace the strength of E to the density of the field lines in the conventional way, we see a stronger field on the sides and a weaker field ahead and behind, which is just what the equations say. Furthermore, if we look at the strength of the field at right angles to the line of motion, that is, for $(v - ct) = 0$, the distance from

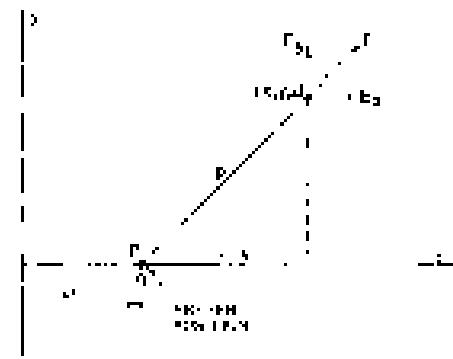

Fig. 26-2. For a charge moving with constant speed, the electric field points radially from the "present" position of the charge.

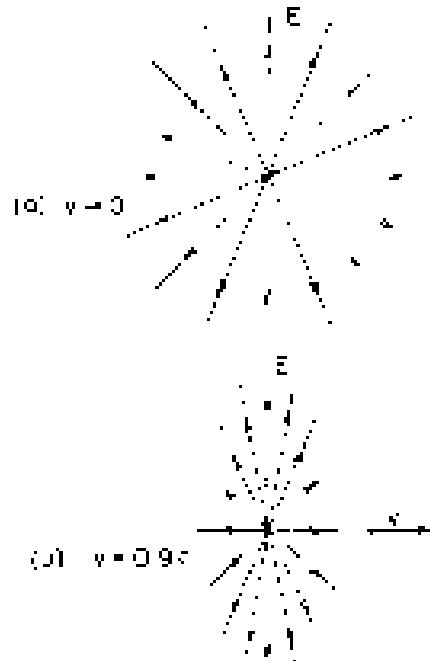

Fig. 26-4. The electric field of a charge moving with the constant speed $v = 0.9c$, part (b), compared with the field of a charge at rest, part (a).

the charge is $(1 - \gamma^{-1})\mathbf{e}$). Here the total field strength is $\sqrt{E_0^2 + E_1^2}$, which is

$$E = \frac{q}{4\pi\epsilon_0\gamma^2} + \frac{1}{c^2}\frac{\mathbf{v} \times \mathbf{B}}{\gamma^2}. \quad (26.10)$$

The field is proportional to the inverse square of the distance—just like the Coulomb field except increased by the constant extra factor $1/\gamma^2 = 1/\gamma$, which is always greater than one. So at the rest of a moving charge, the electric field is stronger than you get from the Coulomb law. In fact, the field in the sidewise direction is bigger than the Coulomb potential by the ratio of the energy of the particle to its rest mass.

Ahead of the charge (and behind), v and c are zero and

$$E = E_0 = \frac{q(1 - \gamma^2)}{4\pi\epsilon_0 c^2 \gamma^2}. \quad (26.11)$$

The field again varies as the inverse square of the distance from the charge but is now reduced by the factor $(1 - \gamma^2)$ in agreement with the picture of the field lines. If γ is small, γ^2/c^2 is still smaller, and the effect of the $1/(1 - \gamma^2)$ terms is very small; we get back to Coulomb's law. But if a particle is moving very close to the speed of light, the field in the forward direction is enormously reduced, and the field in the sidewise direction is enormously increased.

Our results for the electric field of a charge can be put this way: Suppose you were to draw on a piece of paper the field lines for a charge at rest, and then let the particle be travelling with the speed v . Then, of course, the whole picture would be compressed by the Lorentz contraction; that is, the career granules on the paper would appear in different places. The mistake of v , is that the picture you would see as the page lies by would still represent the field lines of the point charge. The contraction moves them closer together at the sides and spreads them out ahead and behind, just in the right way to give the correct line densities. We have emphasized because field lines are not real but are only one way of representing the field. However, here they almost seem to be real. In this particular case, if you make the mistake of thinking that the field lines are somehow really there in space, and transform them, you get the correct field. That doesn't, however, mean the field lines are *more* real. All you must do is remind yourself that they are *not* real, so that's what the electric fields perceived by a charge together will be unequal when the charges interact; new electric fields are produced, and *you* may feel it! I hope not. So the best idea of the contracting picture doesn't work if you act as if v , however, is the only way to remember what the fields *are*; it's better to think of them as like

The magnetic field is $\mathbf{v} \times \mathbf{E}$ [Eq. (26.9)]. If you take the velocity crossed only with the E -field, you get a B whose circles around the line of motion is shown in Fig. 26.5. If we put back E_0 , v , you will see that (in the same result we had for low-velocity charges). A good way to see where the v 's must go is to refer back to the Feynman diagram:

$$F = q(\mathbf{B} - \mathbf{v} \times \mathbf{E}).$$

You see that in velocity terms the magnetic field has the same dimensions as an electric field. So the right-hand side of Eq. (26.9) must have a factor $1/c^2$:

$$\mathbf{B} = \frac{q}{4\pi\epsilon_0 c^2} \frac{\mathbf{v} \times \mathbf{r}}{r^3}. \quad (26.12)$$

For a slow moving charge ($v \ll c$) we can take for E the Coulomb field (from

$$\mathbf{B} = \frac{q}{4\pi\epsilon_0 c^2} \frac{\mathbf{v} \times \mathbf{r}}{r^3} \quad (26.13)$$

this formula corresponds exactly to equations for the magnetic field of a current (see your book, Section 24.7).

We would like to point out, in passing, something interesting for you to think about. (We will come back to discuss it again later.) Imagine two electrons with velocities at right angles, so that one will cross over the path of the other, but in front of it, so they don't collide. At first, instead, the velocities would say will be as in Fig. 26-5(a). We look at the force on q_2 due to q_1 and vice versa. On q_2 , there is only the electric force from q_1 , since q_2 makes no magnetic field along its line of motion. On q_1 , however, there is again the electric force but, in addition, a magnetic force, since it is moving in a B -field made by q_2 . The forces are as shown in Fig. 26-5(b). The electric forces on q_1 and q_2 are equal and opposite. However, the E is a distance (magnetic) force on q_1 and an electric force on q_2 . Does action ever equal reaction? We leave it for you to worry about.

26-3 Relativity in Transformation of the Fields

In Fig. 26-2 we calculated the electric and magnetic fields from the non-relativistic potentials. The fields are important, of course, in spite of the arguments given earlier that there is physical meaning and reality to the potentials. The fields, too, are real. It would be nice just for many purposes to have a way to compute the fields in a moving system if you already know the fields in some "rest" system. We see the transformation laws for ϕ and A , because A is a four-vector. Now we would like to know the transformation laws of E and B . Given E and B in one frame, how do they look in another frame moving past? It is a concrete and rather transparent subject. We could always work back through the potentials, but it is much easier to be able to transform the fields directly. We will now see how that goes.

How can we find the transformation laws of the fields? We know the transformation laws of the ϕ and A , and we know how the fields are given in terms of ϕ and A ; it should be easy to find the transformation for the E and B . (You might think that with every vector there should be something to make it a four-vector, in which E there's got to be something else we can use for the fourth component. And also for B . But it's not so. It's quite different from what you would expect.) To begin with, let's take just a magnetic field B , which is, of course, $\nabla \times A$. Now we know that the vector potential has x , y , and z components; it's only a piece of something; there's also a t component. And we know that, for derivatives like ∇ , besides the x , y , z parts, there's also a derivative with respect to t . So let's try to figure out what happens if we replace a " x " by a " t ", or a " y " by a " t ", or something like that.

First, notice the form of the terms in $\nabla \times A$ when we write out the components:

$$B_x = \frac{\partial A_y}{\partial z} - \frac{\partial A_z}{\partial y}, \quad B_y = \frac{\partial A_z}{\partial x} - \frac{\partial A_x}{\partial z}, \quad B_z = \frac{\partial A_x}{\partial y} - \frac{\partial A_y}{\partial x}. \quad (26.14)$$

The t component is equal to a couple of terms that involve only y and z components. Suppose we call this combination of derivatives and components a "ything" and put it in a structure, E_{yz} . We simply mean that

$$E_{yz} = \frac{\partial A_x}{\partial y} - \frac{\partial A_y}{\partial z}. \quad (26.15)$$

Similarly, B_y is equal to the same kind of "thing," but this time it's an "x thing." And B_z is, of course, the corresponding z "thing." We have

$$B_x = E_{yz}, \quad B_y = E_{xz}, \quad B_z = E_{xy}. \quad (26.16)$$

Now what happens if we multiply by to convert all the "y" type things, like E_{yz} , and E_{xz} , (since none should be zero and symmetric in x , y , z , and t). For instance, what is E_{yt} ? If v_y , of course,

$$\frac{\partial A_t}{\partial z} = \frac{\partial A_z}{\partial t}.$$

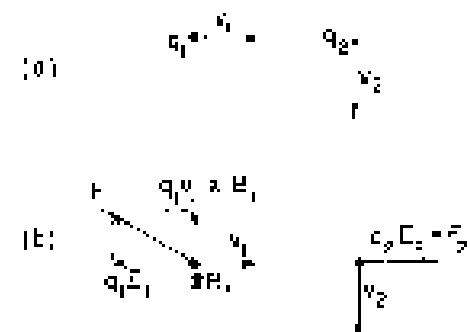

Fig. 26-5. The forces between two moving charges are not always equal and opposite. It appears that "action" is not equal to "reaction."

But remember that $A_0 = \phi$, so it is also

$$\frac{\partial A_0}{\partial t} = \frac{\partial \phi}{\partial t}.$$

You've seen that before: ϕ is the *asymptotic* part of A . Well, indeed, the sign is a sign wrong. But we forget that in the frame associated with the source charge comes with the opposite sign from x , y , and $-z$; so we should really have taken the more convenient expression of A_0 as

$$A_{0x} = \frac{\partial A_0}{\partial x} + \frac{\partial A_x}{\partial t}. \quad (26.17)$$

Then E_x is exactly equal to $-E_0$. Using also E_{0y} and E_{0z} , we find that the three possibilities are

$$E_{0x} = -E_{0y} = E_{0z} = -E_{0x} = E_0 = -E_0. \quad (26.18)$$

What happens if both subscripts are j ? Or, for that matter, if both are k ? We get things like

$$E_{0j} = \frac{\partial A_j}{\partial t} - \frac{\partial A_0}{\partial t},$$

and

$$E_{0k} = \frac{\partial A_k}{\partial x} - \frac{\partial A_x}{\partial k},$$

which give nothing but zero.

We have then six of these E -things. There are six more which you get by reversing the subscripts, but they give nothing really new, either:

$$E_{0j} = -E_{0k}.$$

So, we see, 8 out of sixteen possible combinations of the E_{0j} -subscripts taken in pairs, we get only six different physical objects; and they are the components of B and E .

To represent the *general* form of A , we will use two general subscripts just as we did in section 16.1, 1, 2, or j — meaning in our case four vector indices (x, y, z, t) . Also, everything will be suppressed with one superscript dot. Let us define E_{0j} as

$$E_{0j} = \nabla_j A_0 - \nabla_0 A_j. \quad (26.19)$$

It is now clear that $E_{0j} = (\partial A_0 / \partial x_j) - \partial A_0 / \partial t$ and that $A_0 = (t, A_x, A_y, A_z)$.

What we have found is that there are six quantities that build up an E — the six different aspects of the same thing. The electric and magnetic fields — which we have considered as separate entities in our intervening work (where we didn't worry about the speed of light) are not vectors in flat-space. They are parts of what "slings." Our physical "slings" is really the six-dimensional object E_0 . That is the way we must look at it, for relativity. We summarize our results on E_{0j} in Table 26-1.

Now, the first task we have to do here is to understand the *one* physical E . We begin with the *one* operation, and, in particular, the transformation properties of the E 's are the same as the transformation properties of our vector \mathbf{x} . In ordinary three-dimensional space we studied the position operator, which we typically denote like a vector. Let's focus for a moment on the ordinary cross product. This is a measure, for example, the angle between two vectors. When an object is moving in a plane, the quantity (v_x, v_y) is important. For motion in three dimensions, there are three such independent quantities, which we call the angular momentum:

$$L_{xy} = m v_x p_y - m v_y p_x, \quad L_{xz} = m v_x p_z - m v_z p_x, \quad L_{yz} = m v_y p_z - m v_z p_y.$$

Over all through you may have forgotten, we discussed in Chapter 20 of Vol. 1 the principle that these three quantities can be identified with the components

products of two vectors. In order to do so, we have to make an artificial rule with a right-hand rule again. It may not work. It was luck because ϵ_{ij} is zero if i and j equal to each other. This was our first symmetric identity:

$$E_{ij} = -E_{ji}, \quad E_{ii} = 0.$$

Of the nine possible quantities, there are only three independent numbers. And it just happens that when you change coordinate systems these three objects transform in exactly the same way as the components of a vector.

The same thing happens to represent an element of surface as a vector. A surface element has two parts, say $d\sigma$ and $d\hat{n}$, which we can represent by the vector \hat{n} normal to the surface. But we can't do that in four dimensions. What is the "normal" to a surface? Is it along \hat{n} or along $-\hat{n}$?

In short, for three dimensions it happens by luck that after you've taken a combination of two vectors like E_{ij} , you can represent it again by another vector because there are just three terms that happen to transform like the components of a vector. But in four dimensions that's evidently impossible, because there are six independent terms, and you can't represent six things by four things.

Even in three dimensions it's possible to have combinations of vectors that won't be represented by vectors. Suppose we take any two vectors $a = (a_1, a_2, a_3)$ and $b = (b_1, b_2, b_3)$ and make six various possible combinations of components, like $a_1 b_1, a_1 b_2, a_1 b_3, \dots$. There would be nine possible quantities:

$$\begin{aligned} a_1 b_1 &= a_2 b_2 &= a_3 b_3 \\ a_1 b_2 &= a_2 b_1 &= a_3 b_1 \\ a_1 b_3 &= a_2 b_3 &= a_3 b_2 \end{aligned}$$

We might call these quantities T_{ij} .

Let's now get the original coordinate system (by rotating about the x_3 axis), the new products of a and b unchanged. In the new system, a_3 , for example, gets replaced by

$$a'_3 = a_3 \cos \theta + a_1 \sin \theta,$$

and b_3 gets replaced by

$$b'_3 = b_3 \cos \theta + b_1 \sin \theta.$$

And similarly for other components. The nine components of the product quantity T_{ij} we have mentioned are all changed, too, of course. For instance, $T_{11} = a_1 b_1$ gets renamed to

$$T'_{11} = a'_1 b'_1 (\cos^2 \theta) + a'_1 b_2 (\cos \theta \sin \theta) + a'_1 b_3 (\sin \theta \cos \theta) = a'_1 b'_1 (\sin^2 \theta).$$

Or

$$T'_{11} = T_{11} \cos^2 \theta + T_{12} \cos \theta \sin \theta + T_{13} \sin \theta \cos \theta + T_{22} \sin^2 \theta.$$

Each component T_{ij} is a linear combination of components of T_{ij}' .

So we discover that it's not only possible to have a "vector" product like $a \cdot b$ at one time, it's still possible that a and b are basis vectors, but we end up with a six-vector (another kind of "product") of two vectors T_{ij} , with nine components. But translation under a rotation by a simple law of rules (that we could figure out). Such a thing is called a tensor, and it's the most basic type of tensor. It's called a tensor of the second rank, "because you can play the game with three vectors and get a tensor or the elements, or with four to get a tensor of the fourth rank, and so on." A tensor of the first rank is a vector.

The aim of all this is that our electric magnetic quantity E_{ij} is also a tensor of the second rank, because it has two indices, i and j . It is, however, a tensor in four dimensions. It transforms in a special way which we will work out in more detail. It's just the way a product of vectors transforms. If $a \cdot b$, it happens that if you change the index orientation, E_{ij} changes sign. That's a special case. In a

an antisymmetric tensor. So we say: the electric and magnetic fields are part of an antisymmetric tensor of the second rank in four dimensions.

You've come a long way. Remember why such things were called an "electric circuit"? Now we are talking about "an antisymmetric tensor of the second rank in four dimensions."

Now we have to find the law of the transformation of $E_{\mu\nu}$. It isn't at all difficult to do; it's just tedious—the matrix involved is real, but the work is not. What we want is the Lorentz transformation of $E_{\mu\nu} = E_{\nu\mu}$. Since $E_{\mu\nu}$ is just a special case of a vector, we will work with the general solution of the vector transformation, which we can call $G_{\mu\nu}$:

$$G_{\mu\nu} = a_\mu b_\nu - a_\nu b_\mu. \quad (26.20)$$

(For this purpose, a_0 will eventually be replaced by ∇_j and b_0 will be replaced by the potential A_{j0} .) The components of a_μ and b_μ transform like the Lorentz basis, which is:

$$\begin{aligned} a^0 &= \frac{a_0 + \omega a_\perp}{\sqrt{1 - v^2}}, & b^0 &= \frac{b_0 - vb_\perp}{\sqrt{1 - v^2}}, \\ a^\perp &= \frac{a_\perp - \omega a_0}{\sqrt{1 - v^2}}, & b^\perp &= \frac{b_\perp + vb_0}{\sqrt{1 - v^2}}, \\ a'_0 &= a_0, & b'_0 &= b_0, \\ a'_\perp &= a_\perp, & b'_\perp &= b_\perp. \end{aligned} \quad (26.21)$$

Now let's transform the components of $G_{\mu\nu}$. We start with $a_0 b_0 - G_{00}$:

$$\begin{aligned} G_{00} &= a_0 b_0 - a'_0 b'_0 \\ &= \left(\frac{a_0 + \omega a_\perp}{\sqrt{1 - v^2}} \right) \left(\frac{b_0 - vb_\perp}{\sqrt{1 - v^2}} \right) - \left(\frac{a_\perp - \omega a_0}{\sqrt{1 - v^2}} \right) \left(\frac{b_\perp + vb_0}{\sqrt{1 - v^2}} \right) \\ &= a_0 b_0 - a'_0 b'_0. \end{aligned}$$

But $a_0 = b_0$, so we have the simple result

$$G_{00} = a_0 b_0.$$

We take the same steps

$$G_{0\perp} = \frac{a_0 + \omega a_\perp}{\sqrt{1 - v^2}} b_\perp - a'_0 \frac{b_0 - vb_\perp}{\sqrt{1 - v^2}} = (a_0 b_\perp - a'_0 b'_\perp) \frac{\sqrt{1 - v^2}}{\sqrt{1 - v^2}} = a_0 b_\perp - a'_0 b'_\perp.$$

So we get the:

$$a'_0 b'_\perp = \frac{a_0 b_\perp - a'_0 b'_\perp}{\sqrt{1 - v^2}}.$$

And, of course, at the same way,

$$G_{\perp 0} = \frac{a_0 b_\perp - a'_0 b'_\perp}{\sqrt{1 - v^2}}.$$

It is clear how the rest will go: with the help of induction it is obvious, only now we may as well write them for $E_{\mu\nu}$:

$$\begin{aligned} E'_{00} &= E_{00}, & E'_{0\perp} &= \frac{E_{0\perp} - vE_{\perp 0}}{\sqrt{1 - v^2}}, \\ E'_{\perp 0} &= \frac{E_{\perp 0} + vE_{0\perp}}{\sqrt{1 - v^2}}, & E'_{\perp\perp} &= E_{\perp\perp}, \\ E'_{0\perp} &= \frac{E_{0\perp} - vE_{\perp 0}}{\sqrt{1 - v^2}}, & E'_{\perp 0} &= E_{\perp 0}, \\ E'_{\perp\perp} &= \frac{E_{\perp\perp} + vE_{0\perp}}{\sqrt{1 - v^2}}, & E'_{00} &= \frac{E_{00} - vE_{0\perp}}{\sqrt{1 - v^2}}. \end{aligned} \quad (26.22)$$

From this we will have $E'_0 = -E'_0$ and $E'_0 = 0$.

So we have the transformation of electric and magnetic fields. All we have to do is look at Table 26-1 to convert what our given notation in terms of E , terms of terms of E and B , into just one other of substitution. So that we can see how it looks in the ordinary symbols, and finally our transformation of the field components in Table 26-2.

Table 26-2

The Lorentz transformation of the electric and magnetic fields (Note: $c = 1$)

$E_x' = E_x$	$B_z' = B_z$
$E_y' = \frac{E_y - vB_z}{\sqrt{1 - v^2}}$	$B_y' = \frac{B_y + vE_z}{\sqrt{1 - v^2}}$
$E_z' = \frac{E_z + vB_y}{\sqrt{1 - v^2}}$	$B_x' = \frac{B_x - vE_y}{\sqrt{1 - v^2}}$

The equations in Table 26-2 tell us how E and B change if we go from one inertial frame to another. If we know E and B in one system, we can find what they are in another that moves by with the speed v .

We can write these equations in a form that is easy to remember. We notice that since v is in the x -direction, all the terms will be related to components of the y -axis produce $v \times E$ and $v \times B$. So we can rewrite the equations, which are shown in Table 26-3.

Table 26-3

An alternative form for the field transformations (Note: $c = 1$)

$E_x' = E_x$	$B_z' = B_z$
$E_y' = \frac{(E_y + vB_z)}{\sqrt{1 - v^2}}$	$B_y' = \frac{(B_y - vE_z)}{\sqrt{1 - v^2}}$
$E_z' = \frac{(E_z - vB_y)}{\sqrt{1 - v^2}}$	$B_x' = \frac{(B_x + vE_y)}{\sqrt{1 - v^2}}$

It is now easier to remember which components go where. In fact, the transformation can be written even more simply if we define the field components along x as the "parallel" components E_x and B_x (because they are parallel to the relative velocity of S and S'), and the total transverse components (the vector sum of the y and z components) as the "perpendicular" components E_y and B_y . Then we get the equations in Table 26-4. (We have just put back the $\sqrt{1 - v^2}$, as it will be more convenient when we want to refer back to it.)

Table 26-4

Still another form for the Lorentz transformation of E and B

$E_x' = E_x$	$B_z' = B_z$
$E_y' = \frac{(E_y - vB_z)}{\sqrt{1 - v^2}}$	$B_y' = \frac{\left(B_y + \frac{vE_z}{c}\right)}{\sqrt{1 - v^2}}$

The field transformation part is another way of solving some problems we have done before. For instance, in finding the fields of a moving point charge. We have used and the fields before by calculating the potentials. But we could now do it by transforming the Lorentz field. If we have a point charge at rest in the S -frame, then there is only the unperturbed E -field. In the S' -frame we will see a point charge moving with the velocity v , if the S' -frame moves by the

A frame with the speed $v \ll c$. We will let you show that the transformations of Table 26-3 and 26-4 give the same electric and magnetic fields we got in Section 26-2.

The transformation of Table 26-2 gives us an interesting and simple answer for what we see if we move past a system of fixed charges. For example, suppose we want to know the fields in our frame S' if we are moving along between the plates of a condenser, as shown in Fig. 26-7. (It is, of course, the same thing if we say that a charged condenser is moving past us.) What do we see? The transformation is easy in this case because the B field in the original system is zero. Suppose, first, that our motion is perpendicular to E . Then we will see an E' : $E'_{\parallel} = v/c E_{\perp}$, which is still completely transverse. We will see, in addition, a magnetic field $B'_{\parallel} = v/c E_{\perp}$. (The $\sqrt{1 - v^2/c^2}$ doesn't appear in our formula for B' because we wrote it in terms of E' rather than E , but it's the same thing.) So when we move along perpendicular to a static electric field, we see a reduced E and an added transverse B . If our motion is not perpendicular to E , we break E into E_{\parallel} and E_{\perp} . The parallel part is unchanged, $E'_{\parallel} = E_{\parallel}$, and the perpendicular component does as just described.

Let's take the opposite case, and imagine we are moving through a pure static magnetic field. This time we would see an electric field E' equal to $v \times B$, and the magnetic field changed by the factor $\sqrt{1 - v^2/c^2}$ (assuming it is transverse). So long as v is much less than c , we can neglect the change in the magnetic field, and the main effect is that an electric field appears. As one example of this effect, consider this once famous problem of determining the speed of an airplane flying eastward, since radar can now be used to determine the air speed (it's no longer necessary, since radar can now be used to determine the air speed from ground references), but for many years it was very hard to find the speed of an airplane in bed weather. You could not see the ground, and you didn't know which way was up, and so on. Yet it was important to know how fast you were moving relative to the earth. How can this be done without seeing the earth? Many who knew the transformation formula thought of the idea of using the fact that the airplane moves in the magnetic field of the earth. Suppose that an airplane is flying, where there is a magnetic field, more or less known. Let's just take the simplest case where the magnetic field is vertical. If we were flying, straight west at a constant velocity v , according to our formula, we should see an electric field which is $v \times B$, i.e., perpendicular to the line of motion. If we hang an ordinary wire across the airplane, this electric field will induce charges on the ends of the wire. That's nothing new. From the point of view of someone on the ground, we are moving now to the left, and the $v \times B$ from static charges induces no charges on the ends of the wire. The transformation formulas just say the same thing in a different way. (The fact that we can say this thing more than one way doesn't mean that one way is better than another. We are getting so many different methods and tools that we can usually get the same result in a different way.)

So to measure v , all we have to do is measure the voltage between the ends of the wire. We can't do it with a voltmeter because the same fields will act on the wires in the voltmeter, but there are ways of measuring such fields. We talked about some of them when we discussed atmospheric electricity in Chapter 2. So it should be possible to measure the speed of the airplane.

The important problem was, however, never solved this way. The reason is that the electric field that is developed is of the order of millionths per meter. It is possible to measure such fields, but the trouble is that these fields are, unfortunately, not very different from any other electric fields. The field that is produced by motion through the magnetic field can't be distinguished from static electric fields that was already in the air from another cause, say from electrostatic charges in the air, or in the clouds. We described in Chapter 9 that there are, typically, electric fields above the surface of the earth with strengths of about 100 volt per meter. But they are quite irregular. So as the airplane flies through the air, it sees fluctuations of atmospheric electric fields which are enormous in comparison to the tiny field produced by the $v \times B$ term, and it turns out for practical reasons to be impossible to measure speeds of an airplane by its motion through the earth's magnetic field.

26.4 The equations of motion in relativistic notation*

I doesn't do much good to find electric and magnetic fields from Maxwell's equations unless we know what the fields do when we have them. You may remember that the fields are required to find the forces on charges, and that those forces determine the motion of the charge. So, of course, part of the theory of electrodynamics is the relation between the motion of charges and the forces.

For a single charge in the fields E and B , the force is

$$\mathbf{F} = q\mathbf{E} + q\mathbf{v} \times \mathbf{B}. \quad (26.23)$$

This force is equal to the mass times the acceleration (in low velocities), but the correct law for any velocity is that the force is equal to dp/dt . Writing $p = m\gamma\sqrt{1 - v^2/c^2}$, we find that the relativistically correct equation of motion is

$$\frac{d}{dt} \left(\frac{mv}{\sqrt{1 - v^2/c^2}} \right) = \mathbf{F} = q\mathbf{E} + q\mathbf{v} \times \mathbf{B}. \quad (26.24)$$

We would like now to discuss this equation from the point of view of relativity. Since we have our four Maxwell equations in relativistic form, it would be interesting to see what the equations of motion would look like in relativistic form. Let's see whether we can rewrite the equation in a four-vector notation.

We know that the momentum is part of a four-vector \mathbf{p} , whose time component is the energy $m\gamma$, $\gamma = 1/\sqrt{1 - v^2/c^2}$. So we might think to replace the left-hand side of Eq. (26.24) by $d\mathbf{p}/dt$. Then we need only find a fourth component to go with F . This fourth component must equal the rate-of-change of the energy, or the rate of doing work, which is $F \cdot v$. We would then like to write the right-hand side of Eq. (26.24) as a fourvector like (F_0, F_x, F_y, F_z) . But this does not make a four-vector.

The rate derivative of a fourvector is no longer a fourvector, because the *drift* respects the cause of zero spatial frame for measuring it. We got into that trouble before when we tried to make v into a fourvector. Our first guess was that the new components would be $v \partial/\partial t - v$. But the quantities

$$\left(\gamma, \frac{dx}{dt}, \frac{dy}{dt}, \frac{dz}{dt} \right) = (\gamma, \mathbf{v}) \quad (26.25)$$

are not the components of a fourvector. We found that they could be made into one by multiplying each component by $1/\gamma^2 = v/c^2$. The "four-velocity" η_μ is the fourvector

$$\eta_\mu = \left(\gamma, \frac{c}{\gamma}, \frac{v_x}{\gamma}, \frac{v_y}{\gamma}, \frac{v_z}{\gamma} \right). \quad (26.26)$$

So it appears that the trick is to multiply $d\mathbf{p}/dt$ by $1/\gamma^2 = 1/v^2$, if we want the derivatives to make a fourvector.

Our second guess then is that

$$\frac{1}{\sqrt{1 - v^2/c^2}} \frac{d}{dt} (\mathbf{p}_\mu) \quad (26.27)$$

should be a fourvector. But, wait! It is the velocity of the particle — v_μ , of a coordinate t, x, y, z . Then the quantity \mathcal{F}_μ defined by

$$\mathcal{F}_\mu = \left(\frac{\mathbf{F} \cdot \mathbf{v}}{\sqrt{1 - v^2/c^2}}, \frac{\mathbf{F}}{\sqrt{1 - v^2/c^2}} \right) \quad (26.28)$$

is the extension into four dimensions of a force—we can call it the "four-force." It is indeed a fourvector, and its space components are not the components of \mathbf{F} but of $\mathbf{F}/\sqrt{1 - v^2/c^2}$.

...

* In this section we neglect all of the c^2 s.

The question is: "why is γ a four-vector?" It would be nice to get a little understanding of that fact. After all, since it has come up before now, it is time to see why the γ 's can always be fixed by the same factor. The answer is in the following: When we take the time derivative of some function x , we compute the increment Δx in a small interval Δt in the variable t . But in another frame, the interval Δt might correspond to a change in both t' and x' , so if we vary only t' , the change in x will be different. We have to find a variable for our differentiation that is a measure of an "interval" in space-time, which will then be the same in all coordinate systems. When we take Δx for that interval, it will be the same for all coordinate frames. When a particle "moves" in four-space, choose these ranges $\Delta t, \Delta x, \Delta p, \Delta s$. Can we make an invariant interval out of them? Well, they are the components of the four vector $v_\mu = (c, \mathbf{x}, \mathbf{p})$ so if we choose a quantity Δs by

$$(\Delta s)^2 = \frac{1}{c^2} \Delta t_\mu \Delta s_\mu = \frac{1}{c^2} (c^2 \Delta t^2 - \Delta x^2 - \Delta p^2 + \Delta s^2) \quad (26.29)$$

—which is a four-dimensional dot product—now we have a good four scalar to use as a measure of a four-dimensional interval. For the Δs in its turn ds , we can define a parameter $s = \int ds$. And a derivative with respect to s , ds/ds , is a like four-dimensional operation, because it is invariant with respect to a Lorentz transformation.

It is easy to relate ds to dt for a moving particle. For a moving point particle,

$$dx = v_x dt, \quad dv = v_x' dt, \quad ds = v_x dt, \quad (26.30)$$

and

$$ds = \sqrt{(v_x)^2/c^2} dx^2 = v_x^2 - v_y^2 - v_z^2 = v_x^2 - v^2 = d\tau v \quad = v^2/c. \quad (26.31)$$

So the operator

$$\frac{d}{ds} = \frac{1}{\sqrt{1 - v^2/c^2}} \frac{d}{dt}$$

is an "invariant operator". If we operate it on any function with it, we get another four-vector. For instance, if we operate on $(1, \mathbf{x}, \mathbf{p}, \mathbf{f})$, we get the four velocity v_μ :

$$\frac{dv_\mu}{ds} = u_\mu.$$

We see now why the factor $\sqrt{1 - v^2/c^2}$ fixes things up.

The invariant variable s is a useful physical quantity. It is called the "proper time" along the path of a particle, because ds is always an interval of time for some s that is moving with the particle at any particular instant. (That is, $\Delta s = \Delta \tau = \Delta x = 0$, and $\Delta t = \Delta s$.) If you can imagine some "clock" whose rate doesn't depend on the acceleration, such a clock carried along with the particle would show the time s .

We can now go back and write Newton's law (as corrected by Einstein) in the next form:

$$\frac{dp_\mu}{ds} = f_\mu \quad (26.32)$$

where f_μ is given in Eq. (26.28). Also, the momentum p_μ can be written as

$$p_\mu = m u_\mu = m u_\mu \frac{ds}{dt}, \quad (26.33)$$

where the coordinates $x_\mu = (ct, \mathbf{x})$ now describe the trajectory of the particle. Finally, the four-dimensional notation gives us this very simple form of the equations of motion:

$$f_\mu = m u_\mu \frac{d^2 x_\mu}{ds^2}. \quad (26.34)$$

which is reminiscent of $\ddot{x} = a_0$. It is important to notice that Eq. (26.34) is not the same as $\ddot{x} = a_0$, because the transverse formula Eq. (26.14) has m in the Eq. 12

non-relativistic mechanics which are different from Newton's. Now the high velocities fit in with the rest of Maxwell's equations, where we were able to rewrite the equations in the relativistic form *almost*, except for the *massless* result, or with just a change of notation.

Now let's return to Eq. (26.24) and see how we can write the right-hand side in four-vector notation. The three components, when divided by $\sqrt{1 - v^2/c^2}$, are the components of $v^2 f_0$, so

$$f_0 = \frac{q(E + v \times B)_x}{\sqrt{1 - v^2/c^2}} = q \left[\frac{E_x}{\sqrt{1 - v^2/c^2}} + \frac{v_x B_y}{\sqrt{1 - v^2/c^2}} - \frac{v_y B_x}{\sqrt{1 - v^2/c^2}} \right]. \quad (26.35)$$

Now we must put all quantities in their relativistic notation. First, $v/\sqrt{1 - v^2/c^2}$ and $v_x/v = v_x/c$ and $v_y/v = v_y/c$ are the x , y , and z -components of the four velocity v_0 . And the components of E and B are components of the second rank tensor of the fields $F_{\mu\nu}$. Looking back in Table 26-1 for the components of $F_{\mu\nu}$ that correspond to E_x , B_x , and B_y , we get

$$f_0 = q(v_0 E_{xx} + v_0 F_{xy} - v_0 F_{yz}),$$

which begins to look impressive. Every term has the subscript x , which is reasonable, since we're finding the x -component. Then all the others appear in pairs: y , z , xy , yz , except that the xy term is missing. So we just add it in, and write

$$f_0 = q(v_0 E_{xx} + v_0 F_{xy} + v_0 F_{yz} - v_0 F_{yy}). \quad (26.36)$$

We haven't changed anything because F_{yy} is antisymmetric, and F_{yy} is zero. The reason for wanting to put in the xy terms is so that we can write Eq. (26.36) in the shorthand form

$$f_0 = q v_0 F_{xx}. \quad (26.37)$$

This equation is the same as Eq. (26.36) if we make the rule that whenever any subscript appears twice, it's understood that you automatically sum over terms in the same way as the scalar product, using the same convention for the signs.

You can easily believe that (26.37) works correctly with the $v = c$, $c^2 = \infty$, but what about $v = c^2$? Let's see, for fun, what it says:

$$f_0 = q v_0 F_{xx} + v_0 F_{yy} - v_0 F_{yz} + v_0 F_{xy}.$$

Now we have to translate each term in $F_{\mu\nu}$ s and $B_{\mu\nu}$ s. We get

$$f_0 = q \left(0 - \frac{v_x}{\sqrt{1 - v^2/c^2}} E_x - \frac{v_y}{\sqrt{1 - v^2/c^2}} E_y - \sqrt{1 - v^2/c^2} B_z \right),$$

or

$$f_0 = \frac{qv \cdot E}{\sqrt{1 - v^2/c^2}}. \quad (26.38)$$

But from Eq. (26.26), f_0 is supposed to be

$$\frac{F \cdot v}{\sqrt{1 - v^2/c^2}} = \frac{q(E + v \times B) \cdot v}{\sqrt{1 - v^2/c^2}},$$

That's the same thing as Eq. (26.13), since $(v \times B)$ is zero. So everything comes out all right.

Summarizing, our equation of motion can be written in the elegant form

$$m_0 \frac{d^4 x_\mu}{dt^4} = f_0 = q v_0 F_{xx}. \quad (26.39)$$

Although it is nice to see that the equations can be written that way, this form is not particularly useful. It's usually more convenient to solve for particle motion by using the four-graviton equations (26.24), and that's what we will usually do.

Field Energy and Field Momentum

27-1 Local conservation

It is clear that the energy of matter is not conserved. When an object radiates light it loses energy. However, the energy lost is possibly recoverable in some other way, say in the light. Therefore the theory of the conservation of charge is incomplete without a consideration of the energy which is associated with the light, or, in general, with the electromagnetic field. We take up now the law of conservation of energy and a set of momentum, or the light. Certainly, we cannot treat one without the other, because in the relativity theory they are different aspects of the same four-vector.

Very early in Volume I, we discussed the conservation of energy; we said then merely that the total energy in the world is constant. Now we want to extend the idea of the energy conservation law in an important way—in a way that says something in detail about how energy is conserved. The new law will say that if energy goes away from a region, it's because it flows away through the boundaries of that region. It is a somewhat stronger law than the conservation of energy without such a restriction.

To see what the statement means, let's look at how the law of the conservation of charge works. We described the conservation of charge by saying that, there is a current density j and a charge density ρ , and that when the charge decreases at some place there must be a flow of charge away from that place. We call that the conservation of charge. The mathematical form of the conservation law is

$$\nabla \cdot j = -\frac{\partial \rho}{\partial t}, \quad (27.1)$$

This law has the consequence that the total charge in the world is always constant—there is never any net gain or loss of charge. However, the total charge in the world could be constant in another way. Suppose that there is some charge Q_1 near some point (1) while there is no charge near some point (2) some distance away (Fig. 27-1). Now suppose that, as time goes on, the charge Q_1 were to gradually fade away and that simultaneously with the decrease of Q_1 some charge Q_2 would appear near point (2), and in such a way that at every instant the sum of Q_1 and Q_2 was a constant. In other words, at any one measurable state the amount of charge lost by Q_1 would be added to Q_2 . Then the total amount of all charge in the world would be conserved. That is a "world-wide" conservation, but not what we will call a "local" conservation, because in order for the charge to get from (1) to (2) it didn't have to appear somewhere in the space between point (1) and point (2). Locally, the charge was just "lost."

There is a difficulty with such a "world-wide" conservation law, even in the theory of relativity. This concept of "global charge" means that a distant particle is one which is not experienced in different systems. Two events that are simultaneous in one system are not simultaneous in another system moving past. For "world-wide" conservation of the kind described, it is necessary that the charge lost from Q_1 should appear simultaneously in Q_2 . Otherwise there would be some moments when the charge was not conserved. There seems to be no way to make the law of charge conservation relativistically invariant without making it a "local" conservation law. As a matter of fact, the requirement of the Lorentz relativity seems to restrict the possible laws of nature in surprising ways. In modern quantum field theory, for example, people have often wanted to alter the theory by allowing what we call a "nonlocal" interaction—where something here

27-1 Local conservation

27-3 Energy density and energy flow in the electromagnetic field

27-4 The ambiguity of the field energy

27-5 Examples of energy flow

27-6 Field momentum

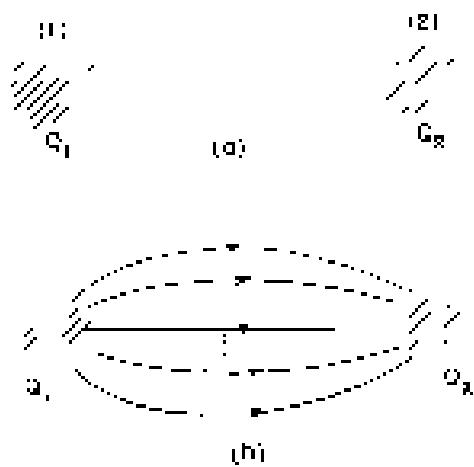

Fig. 27-1. Two ways to conserve charge: (a) $Q_1 + Q_2$ is constant; (b) $dQ_1/dt = i_j \cdot n \hat{n} = -dQ_2/dt$.

has a direct effect on working there—but we just introduced with the relativity principle.

"Local" conservation involves another part. It says that a charge can get from one place to another only if there is something moving in the space between. To describe this law we need not only the density of charge ρ , but also another kind of quantity, namely j , a vector giving the rate of flow of charge across a surface. Then the law is related to the rate of change of charge by Eq. (27.1). This is the more extensive kind of a conservation law. It says that charge is conserved in a special way—what we "locally."

It turns out that energy can have fluxes like a fluid process. There is not only energy density in a given point of space but also a vector to represent the rate of flow of the energy through a surface. For example, when light source radiates, we can find the rate of energy flow out from the source. If we imagine some mathematical surfaces around the light source, the energy lost from inside the surface is equal to the energy that flows out through the surface.

27-2 Energy conservation and electromagnetism

We want now to write quantitatively the conservation of energy for electromagnetism. To do that, we have to describe how much energy there is in any volume element of space, and also the rate of energy flow. Suppose we think first only of the electromagnetic field energy. We will let ϵ represent the energy density in the field (that is, the amount of energy per unit volume in space) and the vector S represent the energy flux of the field (that is, the flow of energy per unit time across a unit area perpendicular to the flow). Then, in parallel analogy with the conservation of charge, Eq. (27.1), we can write the "local" law of energy conservation in the field as

$$\frac{du}{dt} = -\nabla \cdot S. \quad (27.2)$$

Of course, this law is not true in general; it is not true that the field energy is conserved. Suppose you are in a dark room, and then turn on the light, say left. All of a sudden, the room is full of light, so there is energy in the light, although there wasn't any energy there before. Equation (27.2) is not the complete conservation law, because the field energy alone is not conserved; only the total energy in the world—matter is also the energy of matter. The field energy *leaves* if there is some work being done by matter on the field or by the field on matter.

However, if there is matter inside the volume of interest, we know how much energy it has. Each particle has the energy $m c^2 \sqrt{1 - v^2/c^2}$. The total energy of the matter is just the sum of all the particle energies, and the flow of this energy through a surface is just the sum of the energy carried by each particle that crosses the surface. We want now to take only account of the energy in the electromagnetic field. So we must write an equation which says just the total field energy in a given volume decreases either because field energy flows out of the volume or because the field loses energy to matter (or gains energy, which is just a negative loss). The field energy inside a volume V is

$$\int_V u dV,$$

and its rate of decrease is minus the time derivative of this integral. The law of field energy out of the volume V is the integral of the normal component of S over the surface Σ that encloses V ,

$$\int_{\Sigma} S \cdot n d\sigma,$$

so

$$-\frac{\partial}{\partial t} \int_V u dV = \int_{\Sigma} S \cdot n d\sigma + (\text{work done on matter outside } V) \quad (27.3)$$

We have seen before that the field does work on each unit volume δV in the field at the rate $E \cdot j$. [The flux density a satisfies $a \cdot E = q(E \cdot a - B \times B)$, and the rate of doing work is $E \cdot a = qE \cdot a$.] If there are N particles per unit volume, the rate of doing work per unit volume is $NqE \cdot a$, but $Nqz = j$. So the quantity $E \cdot j$ must be equal to the loss of energy per unit time and per unit volume by the field. Equation (27.3) then becomes

$$\frac{\partial}{\partial t} \int_V a \cdot dV = \int_V S \cdot a \, dz + \int_V E \cdot j \, dV. \quad (27.4)$$

It is an interesting thought for energy in the field. We can convert it into a different equation like Eq. (27.2) if we can change the second term to a volume integral. That is, easy to do with Green's theorem. The surface integral of the normal component of S is the integral of its divergence over the volume inside. So Eq. (27.4) is equivalent to

$$\int_V \frac{da}{dt} \, dV = \int_V \nabla \cdot S \, dV + \int_V E \cdot j \, dV,$$

where we have put the time derivative of the first term inside the integral. Since this equation is true for any volume, we can take away the integrals and we have the energy equation for the electromagnetic field:

$$-\frac{\partial u}{\partial t} = \nabla \cdot S + E \cdot j. \quad (27.5)$$

Now this one you doesn't expect a lot of good unless we know what u and S are. And say we should just tell you who they are in terms of E and B , because all we really want is the result. However, we would rather show you the kind of argument that was used by Feynman in 1944 to obtain formulas for S and u , so you can see where they came from. (You won't, however, need to learn this derivation for all other work.)

27-5 Energy density and energy flux in the electromagnetic field

It is often useful to suppose that the e is a field energy density u and the A that depends only upon the fields E and B . (For example, we know that in electrostatics, A and the energy density u are written $\frac{1}{2}\epsilon_0 A \cdot E$.) Otherwise, the E and B might depend on the potentials or something else, but let's see what we can work out. We can try to write the quantity $E \cdot j$ in such a way that it becomes the sum of two terms, one that is the time derivative of one quantity and another that is the divergence of a second quantity. The first quantity would then be u and the second would be S (with suitable signs). Both quantities must be written in terms of the fields only; that is, we want to write our equality as

$$E \cdot j = -\frac{\partial u}{\partial t} - \nabla \cdot S. \quad (27.6)$$

The problem is that j must be expressed in terms of the fields only. How can we do that? By using Maxwell's equations, of course. Then Maxwell's equation for the curl of B ,

$$j = \epsilon_0 c^2 \nabla \times B + \epsilon_0 \frac{\partial B}{\partial t},$$

Substituting this in (27.6) we will have only E 's and B 's.

$$E \cdot j = \epsilon_0 c^2 E \cdot (\nabla \times B) - c \cdot E \frac{\partial B}{\partial t}. \quad (27.7)$$

We are almost partly finished—the last term is a time derivative; it is $(\partial/\partial t)(c \cdot E \times B)$. So $c \cdot E \times B$ is at least one part of u . It's the same thing we found in electrostatics. Now, all we have to do is to make the other term into the divergence of something.

Notice that the first term in the right-hand side of (27.7) is the same as

$$(\nabla \times \mathbf{B}) \cdot \mathbf{E}. \quad (27.8)$$

And, as you know from earlier lectures, if $a \geq 0$, a is the same as $a \cdot (b \times c)$. You can then justify the equation

$$\nabla \cdot (\mathbf{B} \times \mathbf{E}) \quad (27.9)$$

and we have the divergence of "something," just as we wanted. Only that's wrong. We warned you before that, ∇ is "like" a vector, but not "exactly" the same. The reason it is not is because there is an additional *convention* here, concerning what a derivative operator is in front of a product. It works on everything to the right. In Eq. (27.7), the ∇ operates only on \mathbf{B} , not on \mathbf{E} . But, in fact, in (27.9), the normal convention would say that ∇ operates on both \mathbf{B} and \mathbf{E} . So it's not the same thing. In fact, if we take out the components of $\nabla \cdot (\mathbf{B} \times \mathbf{E})$ we can see that it is equal to $\mathbf{E} \cdot (\nabla \times \mathbf{B})$ plus some other terms. It's like when you multiply two vectors and then swap them around. For instance,

$$\frac{\partial}{\partial x}(y\mathbf{z}) = \frac{\partial y}{\partial x}\mathbf{z} + y\frac{\partial \mathbf{z}}{\partial x}$$

Rather than working out all the components of $\nabla \cdot (\mathbf{B} \times \mathbf{E})$ we would like to show you a trick that is very useful for this kind of problem. It is a trick that allows you to use all the rules of vector algebra on expressions with the ∇ operator, without getting into trouble. The trick is to throw out—for a while at least—the rule of the calculus notation about what the derivative operator works on. You see, obviously, the order of terms is used for two separate purposes. One is for derivatives of f (where f is not the same as $\text{rot}(g)\mathbf{f}$), and the other is for vectors: $\mathbf{a} \times \mathbf{b}$ is differentiation, $\mathbf{b} \times \mathbf{a}$. We cannot we want choose or abandon incrementarily the \mathbf{a} -derivative rule. Instead of saying that a derivative operates on everything to its right, we make a new rule that it doesn't depend on the order in which terms are written down. Then we can jumble terms around without worrying.

Here is our new convention: we know, by a subscript, what a well-defined operator works on: the *variables* are missing. Suppose we let the operator D_1 stand for $\partial/\partial x_1$. Then D_1 means \mathbf{i} . Only the derivative of the variable quantity i is taken. Then

$$D_1 f = \frac{\partial f}{\partial x_1}$$

But if we have $D_1 g$, it means

$$D_1 g = \left(\begin{matrix} 0 \\ 1 \end{matrix} \right) g$$

But notice now that according to our new rule, $/ D_1$ means the same thing. We can write the same thing any which way.

$$D_1 f \mathbf{i} = \mathbf{i} D_1 f = f D_{1i} = f_i D_1$$

You see, f is D_1 , an even更深 after everything. It's surprising that such a fancy notation is necessary just for a few basic mathematics or physics.

You may wonder: What if I ever to write the derivative of fg ? I mean the derivative of f with respect to g . That's easy, you just say so, you write $D_g(fg) + D_f(g)$. That is just $g D_g(f) + f D_g(g)$ which is what you mean in the old notation by $D_g(fg)$.

You will see that it is now going to be very easy to work out a new expression for $\nabla \cdot (\mathbf{B} \times \mathbf{E})$. We start by changing to the new notation: we write

$$\nabla \cdot (\mathbf{B} \times \mathbf{E}) = \nabla_x \cdot (\mathbf{B} \times \mathbf{E}) + \nabla_y \cdot (\mathbf{B} \times \mathbf{E}) \quad (27.10)$$

The important we note that we won't need to keep the order straight anymore. We always know that ∇_x operates on \mathbf{B} only, and ∇_y operates on \mathbf{B} only. In these circumstances, we can use ∇ as though it were an ordinary vector. (Of course, \mathbf{E} is)

when we are finished, we will want to return to the "standard" notation that everybody usually uses). So now we can do the various things like interchanging dots and crosses and making other kinds of rearrangements of the terms. For instance, the initially form of Eq. (27.10) can be rewritten as $E \cdot \nabla_B \times B$. (You remember that $a \cdot b \times c = b \cdot c \times a$.) And the last term is the same as $B \cdot E \times \nabla_E$. It looks weird, but it is all right. Now if we try to go back to the ordinary convention, we have to exchange that the ∇ operates only on the "even" variables. The first one is already that way, so we can just leave off the subscript. The second one needs some rearranging to put the ∇ in front of the E , which we can do by keeping the cross product and changing sign:

$$\partial \cdot (E \times \nabla v) = -B \cdot (\nabla_B \times E).$$

Now this is in a conventional order, so we can return to the usual notation. Equation (27.10) is equivalent to

$$\nabla \cdot (B \times E) = B \cdot (\nabla \times E) - E \cdot (\nabla \times B) \quad (27.11)$$

(A quicker way would have been to use components in this special case, but it was worth taking the time to show you the mathematical trick. You probably won't see it anywhere else and it is very good for unlocking vector algebra from the rules about the order of terms with derivatives.)

We now return to our energy conservation discussion and use our new result, Eq. (27.11), to transform the $\nabla \times B$ term of Eq. (27.7). That energy equation becomes

$$E \cdot j = \epsilon_0 c^2 \nabla \cdot (B \times E) + \epsilon_0 c^2 B \cdot (\nabla \times E) - \frac{\partial}{\partial t} (\frac{1}{2} \epsilon_0 E \cdot E) \quad (27.12)$$

Now you see we're almost finished. We have one term which is a time derivative with respect to t to use for \dot{e} and another that is a helicity divergence to represent S . Unfortunately, there is the central term left over, which is neither a divergence nor a derivative with respect to x . So we almost made it, but not quite. After some thought, we look back at the differential equations of Maxwell and discover that $\nabla \times B$ is, technically, equal to $-\partial E/\partial t$, which means that we can turn the extra term into something that is a pure time derivative:

$$B \cdot (\nabla \times E) = B \cdot \left(-\frac{\partial B}{\partial t} \right) + -\frac{\partial}{\partial t} \left(\frac{B \cdot E}{2} \right).$$

Now we have exactly what we want. Our energy equation reads

$$E \cdot j = \nabla \cdot (\epsilon_0 c^2 B \times E) - \frac{\partial}{\partial t} \left(\frac{\epsilon_0 c^2}{2} B \cdot B + \frac{1}{2} E \cdot E \right), \quad (27.13)$$

which is exactly like Eq. (27.6), if we make the definitions

$$u = \frac{\epsilon_0}{2} E \cdot E + \frac{\epsilon_0 c^2}{2} B \cdot B \quad (27.14)$$

and

$$S = \epsilon_0 c^2 B \times E. \quad (27.15)$$

(Reversing the cross product makes the signs come out right.)

Our program was successful. We have an expression for the energy density that is the sum of a "relativistic" energy density and a "magnetic" energy density, whose forms are just like the ones we found in statics when we worked out the energy in terms of the fields. Also, we have found a formula for the energy flow vector of the electromagnetic field. The new vector, $S = \epsilon_0 c^2 B \times E$, is called "Poynting's vector," after its discoverer. It tells us the rate at which the field energy moves around in space. The energy which flows through a small area per second is $S \cdot n \, da$, where n is the unit vector perpendicular to da . (Note that we have our far vector for u and S ; you can forget the subscripts if you want.)

27-4 The ambiguity of the field energy

Before we take up some applications of the Poynting formulae [Eqs. (27.14) and (27.15)], we would like to say that we have not really "proved" them. All we did was to find a *possible* " H " and a *possible* " S ." How do we know that by juggling the terms around some more we couldn't find another formula for " H " and another formula for " S "? The new S and the new H would be different, but they would still satisfy Eq. (27.6). It's possible. It can be done, but the terms that have been found always involve various derivatives of the field (and always with second-order terms like a second derivative or the square of a first derivative). There are, in fact, an infinite number of different possibilities for H and S , and so the question is, is there any experimental way to tell which one is right? People have guessed that it is simple; one is probably the correct one, but we must say that we do not know for certain what is the actual location in space of the exact electromagnetic field energy. So we too will take the easy way out and say that the field energy is given by Eq. (27.14). Then the flow vector S has, by given by Eq. (27.15).

It is interesting that there seems to be no unique way to resolve the indeterminacy in the location of the field energy. It is sometimes claimed that this problem can be resolved by using the theory of gravitation in the following argument. In the theory of gravity, all mass is the source of gravitational attraction. Therefore the energy density of electricity must be created properly if we are to know where it creates the gravity force field. As yet, however, no one has done a very accurate experiment to find the precise location of the gravitational influence of electromagnetic fields on the body around. That gravitational field alone can be the source of gravitational force is not difficult to do without. It has, in fact, been observed that light is deflected as it passes near the sun. We could say that the sun pulls the light down toward it. Do you not want to know that the light pulls equally on the sun? Anyway, everyone always accepts the simple expression we have found for the location of electromagnetic energy and its flow. And although sometimes the results obtained from using them seem strange, nobody has ever found anything wrong with them. That is, no disagreement with experiment. So we will follow the rest of the world—besides, we believe that it is probably perfectly right.

We should make our further remarks about the energy formula. In the first place, the energy per unit volume in the field is very simple: It is the electrostatic energy plus the magnetic energy, if we write the electrostatic energy in terms of E^2 and the magnetic energy as B^2 . We found two such expressions as possible expressions for the energy when we were doing static problems. We also found a number of other formulas for the energy in the electrodynamic field, such as ρ , which is equal to the integral of $E \cdot B$ in the electrostatic case. However, in an electrodynamic field the equality failed, and there was no obvious chance as to which was the right one. Now we know which is the right one. Similarly, we have found the formula for the magnetic energy, that is correct in general. The right formula for the energy density of dynamic fields is Eq. (27.14).

27-5 Examples of energy flow

Our formula for the energy flow vector S is something quite new. We will now see how it works in some special cases and also to see whether it checks out with anything that we knew before. The first example we will take is light. In a light wave we have an E vector and a B vector at right angles to each other and to the direction of the wave propagation. (See Fig. 27-2.) In an electromagnetic wave, the magnitude of B is equal to c/ϵ_0 times the magnitude of E , and since they are at right angles,

$$|E \times B| = \frac{cE^2}{\epsilon_0}$$

Therefore, for light, the flow of energy per unit area per second is

$$S = \epsilon_0 c E^2. \quad (27.16)$$

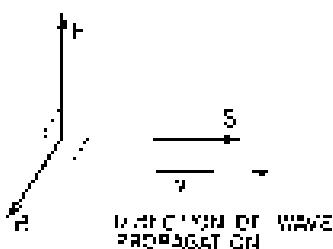

Fig. 27-2. The vectors E , B , and S for a light wave.

For a light wave in which $E = E_0 \cos(\omega t - z/\lambda)$, the average rate of energy flow per unit area, $\langle S \rangle_{av}$,—which is called the "intensity" of the light—is the mean value of the square of the electric field times $c\varepsilon_0$:

$$\text{Intensity} = \langle S \rangle_{av} = c\varepsilon_0 \langle E^2 \rangle_{av}. \quad (27.17)$$

Believe it or not, we have already derived this result in Section 21.3 of Vol. 1, when we were studying light. We can believe that it is right because it also checks against something else. When we have a light beam, there is no energy density in space given by Eq. (27.14). Using $cE = E_0$ for a light wave, we get that

$$E = \frac{E_0}{\sqrt{2}} E_0 + \frac{E_0}{\sqrt{2}} \left(\frac{E^2}{c\varepsilon_0} \right) = c\varepsilon_0 E^2.$$

But E varies in space, so the average energy density is

$$\langle \epsilon \rangle_{av} = c\varepsilon_0 \langle E^2 \rangle_{av}. \quad (27.18)$$

Now the wave travels at the speed c , so we should think that the energy that goes through a square meter in a second is c times the amount of energy in one cubic meter. So we would say that

$$\langle S \rangle_{av} = c\varepsilon_0 \langle E^2 \rangle_{av}.$$

And it's right: it is the same as Eq. (27.17).

Now we take another example. There is a rather curious one. We look at the energy flow in a capacitor that we are charging slowly. (We don't want frequencies so high that the capacitor is beginning to leak like a resonant cavity, but we don't want too either.) Suppose we use a circular parallel plate capacitor of our usual kind, as shown in Fig. 27-3. There is a nearly uniform electric field inside which is changing with time. At any instant, the total electromagnetic energy inside is ϵ times the volume. If the plates have a radius a and a separation b , the total energy between the plates is

$$\epsilon = \left(\frac{1}{2} E^2 \right) (\pi a^2 b). \quad (27.19)$$

This energy changes when E changes. When the capacitor is being charged, the volume between the plates is receiving energy at the rate

$$\frac{d\epsilon}{dt} = \epsilon \pi a^2 b B. \quad (27.20)$$

So there must be a flow of energy into that volume from somewhere. Of course you know that it must come in via the charging wires—not at all! It can't enter the space between the plates from that direction, because B is perpendicular to the plates: $B \times E$ must be parallel to the plates.

You remember, of course, that there is a magnetic field that circles around the axis when the capacitor is charging. We discussed that in Chapter 21. Using the last of Maxwell's equations, we found that the tangential field at the edge of the capacitor is given by

$$2\pi a^2 B = E \cdot \pi a^2,$$

or

$$B = \frac{\sigma}{2\pi a} E.$$

Its direction is shown in Fig. 27-4. So there is an energy flow proportional to $B \times E$ that comes in all around the edges, as shown in the figure. The energy isn't actually coming down the wires, left from the space just outside the capacitor.

Let's check whether or not the total amount of flow through the whole surface between the edges of the plates checks with the rate of change of the energy inside it had better; we won't though, of course, since Eq. (27.19) is already set.

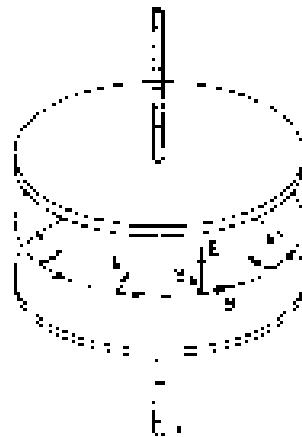

Fig. 27-2. Near a charging capacitor, the Poynting vector S points inward toward the axis.

for ϵ_0 is ϵ_0 . The net current density is J_{net} , and $S = \pi r^2 E \times R$ is the major side

$$r^2 \epsilon_0 E \left(\frac{R}{2} \right)^2 J_{net},$$

so the total flux of energy is

$$\pi r^2 \epsilon_0 E J_{net} R.$$

It does check with Eq. (27.20). But it tells us a peculiar thing: that when we are charging a capacitor, the energy is not coming down the wires; it is coming in through the edges of the gap. That's what this theory says!

How can that be? That's not an easy question, but here is one way of thinking about it. Suppose that we have some charges above and below the x -axis points, and far away. When the charges are far away, there is a weak but exponentially spreading-out field that surrounds the capacitor. (See Fig. 27-4.) Then, as the charges come together, the field gets stronger nearer to the capacitor. So the total energy which is way out moves toward the capacitor and eventually ends up between the plates.

As another example, we ask what happens in a piece of resistance wire when it is carrying a current. Since the wire has resistance, there is an electric field along it, driving the current. Because there is a potential drop along the wire, there is also an electric field just outside the wire, parallel to the surface. (See Fig. 27-5.) There is, in addition, a magnetic field which goes around the wire because of the current. The E and B are at right angles; therefore there is a Poynting vector directed radially outward, as shown in the figure. There is a flow of energy out the wire all around. It is, of course, equal to the energy being lost in the wire as heat. So our "theory" theory says that the electrons are getting their energy to generate heat because of the energy flowing out the wire from the field outside. Intuition would seem to tell us that the electrons get their energy from being pushed along the wire, so the energy should be flowing down (or up) along the wire. But the theory says that the electrons are really being pushed by an electric field, which was come from some charges very far away, and that the electrons get their energy for generating heat from these fields. The energy somehow flows from the distant charges into a wide area of space and then inward to the wire.

Finally, in order to really convince you that this theory is absolutely crazy, we will take one more example—an example in which an *object* is charged and a magnet are at rest near each other—but without quite such. Suppose we take the example of a point charge sitting near the center of a ring magnet, as shown in Fig. 27-6. Everything is at rest, so the energy is not changing with time. Also, E and B are quite static. But the Poynting vector says that there is a flow of energy, because there is an $E \times B$ that is not zero. If you look at the energy flow, you find that it just circulates around and around. There isn't any change of the energy anywhere—every little bit of energy flows into one volume, flows out again. It is like water flowing around. So there is a circulation of energy in this *stationary* condition. How weird it gets!

For me, it isn't so terribly puzzling. I taught when you remember that what we call an "empty" magnet is really a circulating permanent current. In a permanent magnet the electrons are spinning (or, incidentally, oscillating). So maybe a circulation of the energy outside still occurs to me.

You can never begin to get the impression that the Poynting theory at least partially violates your intuition as to what really is better in an electromagnetic field. You might believe that you just haven't yet learned enough, and, therefore, have a lot of things to study here. But it seems really and necessary. You don't need to feel that you will be in great trouble if you forget some of it while you the energy in a wave is flowing into the wire from the outside, rather than along the wire. It seems to bring a lot of value when using the idea of energy conservation, no matter in detail or not, that the energy is taking. The calculation of energy around a magnet and a simple series of most common shapes, to be quite cumbersome. It is not a vital action, but it is clear that our ordinary intuitions are quite wrong.

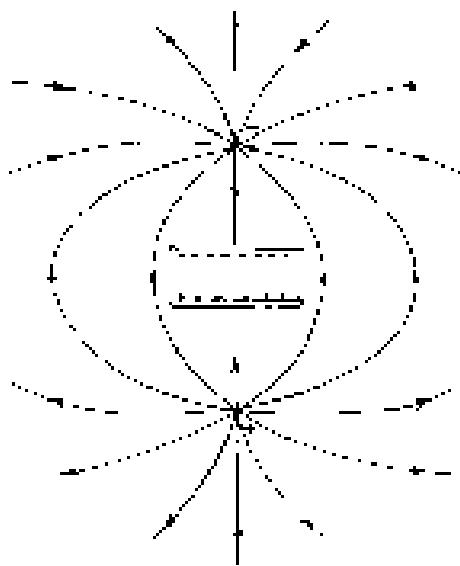

Fig. 27-4. The E -fields outside a capacitor when it is being charged by bringing two charges from a large distance.

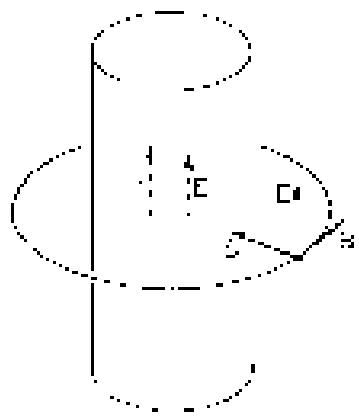

Fig. 27-5. The Poynting vector S near a wire carrying a current.

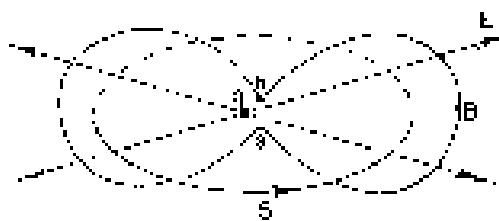

Fig. 27-6. A charge and a magnet produce a Poynting vector that circulates in closed loops.

27.6 Field momentum

Now we would like to talk about the momentum in the electromagnetic field. Just as the field has energy, it will have a certain momentum per unit volume. Let us call that momentum density g . Of course, momentum has various possible directions, so g ought to be a vector. Let's talk about one component at a time: first, we take the x -component. Since each component of momentum is conserved we should be able to write down a law that looks something like this:

$$-\frac{\partial}{\partial t} \left(\text{momentum} \right)_x = \frac{\partial g}{\partial x} + \left(\text{outflow} \right).$$

The left side is easy. The rate-of-change of the momentum of matter is just the force on it. For a particle, it is $F = q(E - v \times B)$; for a distribution of charges, the force per unit volume is $(qE - j \times B)$. The "momentum outflow" term, however, is strange. It cannot be the divergence of a vector because it is not a scalar; it is, rather, an x -component of some vector. Any way, it should probably look something like

$$\frac{\partial a}{\partial x} + \frac{\partial b}{\partial y} + \frac{\partial c}{\partial z},$$

because the x -momentum could be flowing in any one of the three directions. In any case, whatever a , b , and c are, the combination is supposed to equal the outflow of the x -momentum.

Now the game would be to write $pE - j \times B$ in terms only of E and B —eliminating p and j by using Maxwell's equations—and then to juggle terms and make substitutions to get it into a form that looks like

$$\frac{\partial a}{\partial t} + \frac{\partial a}{\partial x} + \frac{\partial b}{\partial y} + \frac{\partial c}{\partial z}$$

Then, by identifying terms, we would have expressions for g_{xx} , a , b , and c . It's a lot of work, and we are not going to do it. Instead, we are only going to find an expression for g , the momentum density—and by a different route.

There is an important theorem in mechanics which is this: whenever there is a flow of energy in any circumstance (still field energy or any other kind of energy), the energy flowing through a unit area per unit time, when multiplied by $1/c^2$, is equal to the momentum per unit volume in the space. In the special case of electromagnetism, this current gives the result that g is $1/c^2$ times the Poynting vector

$$g = \frac{1}{c^2} S. \quad (27.21)$$

So the Poynting vector gives not only energy flow but, if you divide by c^2 , also the momentum density. The same result would come out of the other analysis we suggested—but it is more interesting to notice this more general result. We will now give a number of interesting examples and applications to convince you that the general theorem is true.

First example: Suppose that we have a lot of particles in a box—let's say N per cubic meter—and that they are moving along with some velocity v . Now let's consider an imaginary plane surface perpendicular to v . The energy flow through unit areas of this surface per second is equal to Nv , the number which flows through the surface per second, times the energy carried by each one. The energy in each particle is $m_0 c^2 / \sqrt{1 - v^2/c^2}$. So the energy flow per second is

$$Nv \frac{m_0 c^2}{\sqrt{1 - v^2/c^2}}.$$

But the momentum of each particle is $m_0 v / \sqrt{1 - v^2/c^2}$, so the density of momentum is

$$g = \frac{N m_0 v}{\sqrt{1 - v^2/c^2}}.$$

which is just $1/c^2$ times the energy flow, as the theorem says. So the theorem is true for a bunch of particles.

This is also true for light. When we studied light in Volume 1, we saw that when the energy is absorbed from a light beam, a certain amount of momentum is added to the absorber. We have, in fact, shown in Chapter 16 of Vol. 1 that the momentum is $1/c$ times the energy absorbed [Fig. 16.24] of Vol. 1]. If we let M_0 be the energy arriving at us in unit area per second, then the momentum arriving at a unit area per second is M_0/c . But the momentum is travelling at the speed c , so the distance in front of the absorber must be M_0/c^2 . So again the theorem is right.

Finally we will give an argument due to Einstein which demonstrates the same thing once more. Suppose that we have a railroad car on wheels (assume frictionless) with a certain big mass M . At one end there is a device which will shoot out some particles or light, for anything it doesn't make any difference what it is, which are then stopped at the opposite end of the car. There was sonic energy originally at one end—say the energy U indicated in Fig. 27-7(a)—and then later it is at the opposite end, as shown in Fig. 27-7(c). The energy U has been displaced the distance L , the length of the car. Now the energy U has the mass M/c^2 , so if the car stayed still, the center of gravity of the car would be moved. Einstein didn't like the idea that the center of gravity of an object could be moved by looking around only on the inside, so he assumed that it is impossible to move the center of gravity by doing anything inside. But if that is the case, when we move the energy U from one end to the other, the whole car must have moved some distance x , as shown in part (b) of the figure. You can see, in fact, that the total mass of the car, times x , must equal the mass of the energy mover, M/c^2 times L (assuming that L/c is much less than M/c):

$$Mx = \frac{U}{c^2} L. \quad (27.20)$$

Let's now look at the special case of the energy being carried by a light flash. (The argument would work as well for particles, but we will follow Einstein, who was interested in the problem of light.) What causes the car to be moved? Einstein argued as follows: When the light is emitted there must be a recoil, some unknown recoil with momentum p . It is this recoil which makes the car roll backwards. The recoil velocity v of the car will be this momentum divided by the mass of the car,

$$v = \frac{p}{M}.$$

The car moves with this velocity until the light energy U gets to the opposite end. Then, when it hits, it gives back its momentum and stops the car. If x is small, then the time the car moves is nearly equal to L/v , so we have that

$$x = v t = c \frac{L}{p} = \frac{p}{M} \frac{L}{c}.$$

Putting this in Eq. (27.20), we get that

$$p = \frac{U}{c}.$$

Again we have the relation of energy and momentum for light. Dividing by c we get the momentum density $\rho = p/c$, we get once more that:

$$\rho = \frac{U}{c^3}. \quad (27.21)$$

You may well wonder: What is so unexpected about the center-of-gravity theorem? Maybe it is wrong. Perhaps, but then we would also lose the conservation of a lighter momentum. Suppose that our buscar is moving along a track at some speed v and that we absorb sonic light energy from the rear to the front of the car, say, from A to B in Fig. 27-8. Now we look at the angular momentum of the system about the point A. Before the energy U leaves A, it has the mass $M/10$

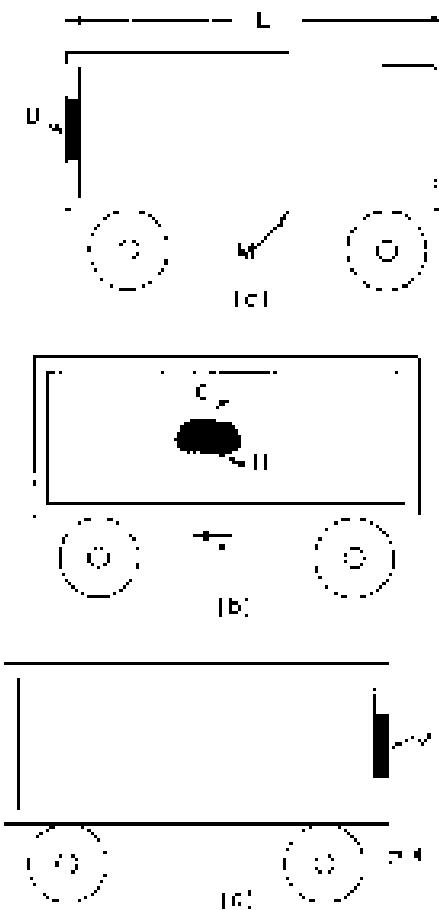

Fig. 27-7. The energy U in motion at the speed c carries the momentum U/c .

$m = U^2/c$ and the velocity v , so it has the angular momentum $m\omega_0$. When it arrives at S , it has the same mass and, if the linear momentum of the whole barge is not to change, it must still have the velocity v . Its angular momentum about P is then $m\omega_0$. The angular momentum will be changed unless the right recoil motion α is given to the s —when the light was emitted—that is, unless the light carries the momentum (U/c) . It turns out that the angular momentum conservation and the theory of center-of-mass velocity are closely related in the relativity theory. So the conservation of angular momentum would also be demonstrated if our theorem were just true. A very nice derivation turned out to be a law proposed long ago in the case of electrodynamics, so you can't forget the momentum in the field.

We will mention two further examples of momenta in the electromagnetic field. We pointed out in Section 26-2 that during the law of action-reaction when two charged particles were moving on nonparallel trajectories, the forces on the two particles can't sum to zero, so the velocity Δv satisfies $\propto \Delta v \times \text{force}$. Therefore the momentum of the matter must be changing. It is not necessarily. But the momentum of the field is also changing in such a situation. If you work out the amount of momentum given by the Poynting theorem, it is not constant. However, the change of the particle momenta is just made up by the field momentum, so the total momentum of particles plus field is conserved.

Finally, another example is the situation with the magnet and the charge, shown in Fig. 27-6. We were unhappy to find that energy was flowing around in circles, but now, since we know that energy flow and momentum are proportional, we know also that there is momentum circulating in the space. But a circulating momentum means that there is angular momentum. So there is angular momentum in the field. Do you remember the paradox we described in Section 17-4 about a solenoid and some charges mounted on a disc? I assumed that when the current turned off, the whole disc should start to turn. The puzzle was: Where did the angular momentum come from? The answer is that you have a magnetic field and some charges. There will be some angular momentum in the field. I can at least begin thinking when the field was built up. When the field is turned off, the angular momentum is given back. So the disc on the paradox really starts rotating. This magnetic circulating flow of energy, which we first seemed so ridiculous, is absolutely necessary. There is really a momentum flow. It is needed to maintain the conservation of angular momentum in the whole world.

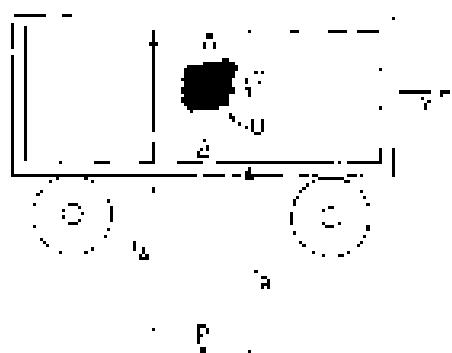

Fig. 27-6. The energy B must carry the same form B' if the angular momentum around P is to be conserved.

Electromagnetic Mass

28-1 The field energy of a point charge

In bringing together relativity and Maxwell's equations, we have finished our main work on the theory of electromagnetism. There are, of course, some details we have skipped over and one large area that we will be concerned with in the future—the interaction of electromagnetic fields with matter. But we want to stop for a moment to show you that this tremendous edifice, which is such a beautiful success in explaining so many phenomena, ultimately falls on its face. When you follow any of our physics today, you find that it always gets into some kind of trouble. Now we want to discuss a serious trouble—the failure of the classical electromagnetic theory. You can appreciate that there is a failure of all classical physics because of the quantum-mechanical effects. Classical mechanics is a mathematically consistent theory; it just doesn't agree with experience. It is interesting, though, that the classical theory of electromagnetism is an unsatisfactory theory all by itself. There are difficulties associated with the ideas of Maxwell's theory which are not solved by and are directly associated with quantum mechanics. You may say, "Perhaps there's no one worrying about these difficulties." Since the quantum mechanics is going to change the laws of electrodynamics, we should wait to see what difficulties arise after the modification." However, when electromagnetism is joined to quantum mechanics, the difficulties remain. So it will not be a waste of time now to look at what these difficulties are. Also, they are of great historical importance. Furthermore, you may get some feeling of accomplishment from being able to go the length with less trouble to see everything—indeed, all of the troubles.

The difficulty we speak of is associated with the concepts of electromagnetic energy and energy, when applied to the electron or any other particle. The concepts of a single charge, particles and the electromagnetic field are in some way incompatible. To introduce the difficulty, we begin by doing some exercises with our energy and momentum concepts.

First, we compute the energy of a charged particle. Suppose we take a simple model of an electron in which all of its charge q is uniformly distributed on the surface of a sphere of radius a , which we may take to be zero for the special case of a point charge. Now let's calculate the energy in the electromagnetic field. If the charge is standing still, there is no magnetic field, and the energy per unit volume is proportional to the square of the electric field. The magnitude of the electric field is $q/4\pi\epsilon_0 r^2$, and the energy density is

$$\epsilon = \frac{\epsilon_0}{2} E^2 = \frac{q^2}{32\pi^2\epsilon_0 r^4}.$$

To get the total energy, we must integrate this density over all space—using the volume element $4\pi r^2 dr$, the total energy, which we will call E_{total} , is

$$E_{\text{total}} = \int \frac{q^2}{32\pi^2\epsilon_0 r^4} dr.$$

This is readily integrated. The lower limit is a , and the upper limit is ∞ , so

$$E_{\text{total}} = \frac{1}{2} \frac{q^2}{4\pi\epsilon_0 a^3}. \quad (28-1)$$

28-1 The field energy of a point charge

28-2 The field momentum of a moving charge

28-3 Electromagnetic mass

28-4 The force of an electron on itself

28-5 Attempts to modify the Maxwell theory

28-6 The nuclear force field

If we use the electronic charge e , the q and the symbol e' for $q^2/4\pi\epsilon_0$, then

$$U_{ext} = \frac{1}{2} \frac{e^2}{a}. \quad (28.2)$$

It is all fine until we set a equal to zero for a point charge—here's the great difficulty. Because the energy of the field varies inversely as the fourth power of the distance from the center, its volume integral is infinite. There is an infinite amount of energy in the field surrounding a point charge.

What's wrong with an infinite energy? If the energy can't get out, you must stay there forever, is there any real difficulty with an infinite energy? Of course, a quantity that comes out infinite may be annoying, but what really matters is only whether there are any observable physical effects. To answer that question, we must turn to something else besides the energy. Suppose we ask how the energy changes when we move the charge. Then, if the charges are infinite, we will be in trouble.

28-2 The field momentum of a moving charge

Suppose an electron is moving at a uniform velocity through space, assuming that the velocity is low compared with the speed of light. Associated with this moving electron there is a momentum—even if the electron had no mass because it was charged—because of the momentum in the electromagnetic field. We can show that the field momentum p is in the direction of the velocity v of the charge and is, for small velocities, proportional to v . For a point P at the distance r from the center of the charge and at the angle θ with respect to the line of motion (see Fig. 28-1) the electric field is radial and, as we have seen, the magnetic field is $v \times E/c^2$. The momentum density, Eq. (27.21), is

$$g = e_p E \times B.$$

It is directed radially outward along the line of motion, as shown in the figure, and has the magnitude

$$g = \frac{ev}{c^2} E^2 \sin \theta.$$

The fields are symmetric about the line of motion, so when we integrate over space, the transverse components will go to zero, giving a resultant momentum parallel to v . The component p of p in this direction is $g \sin \theta$, which we must integrate over all space. We take as our volume element a ring with its plane perpendicular to v , as shown in Fig. 28-2. Its volume is $2\pi r^2 \sin \theta dr$. The total momentum is then

$$p = \int \frac{ev}{c^2} E^2 \sin^2 \theta 2\pi r^2 \sin \theta dr.$$

Since E is independent of θ (for $v \ll c$), we can immediately integrate over θ ; the integral is

$$\int \sin^2 \theta d\theta = \int (1 - \cos^2 \theta) d(\cos \theta) = -\cos \theta = \frac{\cos^2 \theta}{3}.$$

For limits of $\theta = 0$ and π , the $d\theta$ -integral gives merely a factor of 4/3, and

$$p = \frac{8\pi}{3} \frac{ev^2}{c^2} \int E^2 r^2 dr.$$

The integral (for $v \ll c$) is the one we have just evaluated to find the energy; it is $q^2/16\pi^2\epsilon_0 a$, and

$$p = \frac{2}{3} \frac{q^2}{4\pi\epsilon_0} \frac{v}{a}.$$

$$(28.3)$$

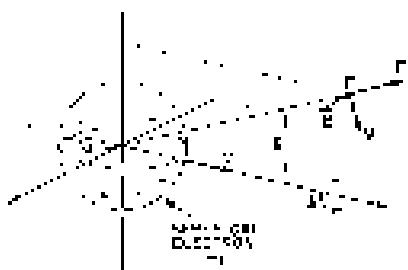

Fig. 28-1. The fields E and B and the momentum density g for a positive electron. For a negative electron, E and B are reversed but g is not.

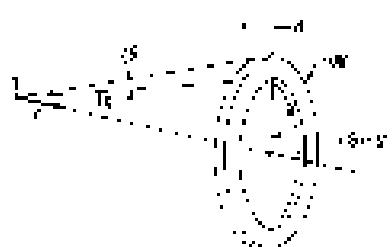

Fig. 28-2. The volume element $2\pi r^2 \sin \theta dr$ used for calculating the field momentum.

The momentum in the field—the electromagnetic component of \mathbf{p} —is proportional to v . It is just what we should have for a particle with the mass equation we derived at the end of 26. We can, therefore, call this effect of the electromagnetic field, m_1, \dots , and write it as

$$m_1 v_{\text{eff}} = \frac{2}{3} \frac{e^2}{mc^2} v. \quad (26.4)$$

26-3 Electromagnetic mass

Where does the mass come from? In our laws of mechanics we have supposed that every object "carries" a charge; we call the mass—which also means that it "carries"—a quantity proportional to its velocity. Now we discover that it is conceivable that a charged particle carries a momentum proportional to its velocity. It might, in fact, be true that most of the effect of electrodynamics is the origin of mass we have now been surprised. We have, at last, in the theory of electrodynamics a good opportunity to understand something that we never understood before. It comes out of the blue—or rather, from Maxwell and Poynting—that any charged particle will have a momentum proportional to its velocity just from electromagnetic influences.

Let's be conservative and say, for a moment, that there are two kinds of mass: that the total momentum of an object could be the sum of a mechanical momentum and the electromagnetic momentum. The mechanical momentum is the "mechanical" mass, m_1, \dots , times v . In experiments where we measure the mass of a particle by seeing how much momentum it has, or how it swings around in an orbit, we are measuring the total mass. We say generally that the momentum is the total mass (in, \dots , c) times the velocity. So the observed mass can consist of two pieces (or possibly more if we include other fields): a mechanical piece plus an electromagnetic piece. We know that there is definitely an electromagnetic piece, and we have a formula for it. And there is the limiting possibility that the mechanical piece is not there at all—that the mass is all electromagnetic.

Let's now calculate the electron mass if there is no mechanical mass. We can find out by setting the electromagnetic mass of Eq. (26.1) equal to the observed mass m_0 of an electron. We find

$$v = \frac{2}{3} \frac{e^2}{mc^2}. \quad (26.5)$$

The quantity

$$r_0 = \frac{e^2}{mc^2} \quad (26.6)$$

is called the "classical electron radius"; it has the numerical value 1.62×10^{-18} m, about one-one-hundred-thousandth of the diameter of an atom.

Why is r_0 called the electron radius, rather than r_0 or r ? Because we could equally well do the same calculation with other assumed distributions of charges—the charge might be spread uniformly through the volume of a sphere or it might be smeared out like a fuzzy ball. For any particular assumption, the factor $2/3$ would change to some other fraction. For instance, for a charge uniform distributed throughout the volume of a sphere, the $2/3$ gets replaced by $4/3$. Rather than to argue over which distribution is correct, it was decided to define r_0 as the "terminal" radius. Then different theories could supply their own values.

Let's pursue our electromagnetic theory of mass. Our calculation was to say v : what happens if we go to high velocities? Early attempts led to a certain amount of confusion, but, eventually, clear the charged sphere would contract into a ellipsoid at high velocities and that the index would change in accordance with the formulas (26.6) and (26.7) we derived in the relativistic section (Chapter 26). If you carry through the integrals for v in that way, you find that for an arbitrary velocity v , the mechanical mass altered by the factor $\gamma/\sqrt{1 - v^2/c^2}$:

$$p = \frac{2}{3} \frac{e^2}{mc^2} \gamma \frac{v}{\sqrt{1 - v^2/c^2}}. \quad (26.7)$$

In other words, the electromagnetic mass rises with velocity inversely as $\sqrt{1 - v^2/c^2}$, a discovery that was made before the theory of relativity.

Early experiments were proposed to measure the changes with velocity in the observed mass of a particle in order to determine how much of the mass was mechanical and how much was electrical. It was believed at the time that the electrical part would vary with velocity, whereas the mechanical part would not. But while the experiments were being done, the theorists were also at work. Soon the theory of relativity was developed, which proposed that no matter what the origin of the mass, it all should vary as $m_0/\sqrt{1 - v^2/c^2}$. Equation (28.7) was the beginning of the theory that mass depended on velocity.

Let's now go back to our calculation of the energy in the field, which led to Eq. (28.2). According to the theory of relativity, the energy E will have the mass G/c^2 ; Eq. (28.2) then says that the field of the electron should have the mass

$$m_{\text{elect}} = \frac{U_{\text{elect}}}{c^2} = \frac{e}{c} \frac{v^2}{mc^2}, \quad (28.8)$$

which is not the same as the electromagnetic mass, $m_0/\sqrt{1 - v^2/c^2}$. In fact, if we just combine Eqs. (28.2) and (28.4), we would write

$$U_{\text{elect}} = \frac{1}{4} m_{\text{elect}} c^2.$$

This formula was discovered before relativity, and when Einstein and others began to realize that it must always be that $E = mc^2$, there was great confusion.

28-4 The Force of an electron on itself

The discrepancy between the two formulas for the electromagnetic mass is especially annoying, because we have usually agreed that the theory of electrodynamics is consistent with the principle of relativity. Yet the theory of relativity implies without question that the momentum must be the same as the energy times c/v^2 . So we are in some kind of trouble, we must have made a mistake. We did not make an algebraic mistake in our calculations, but we have left something out.

To derive our equations for energy and momentum, we assumed the conservation laws. We assumed that all forces were taken into account and that any work done and any momentum carried by other "nonelectrical" machinery was included. Now if we have a sphere of charge, the electrical forces are all repulsive and an electron would tend to fly apart. Because the system has unbalanced forces, we can get all kinds of errors in the laws relating energy and momentum. To get a consistent picture, we must imagine that something holds the electron together. The charges must be held to the sphere by some kind of rubber bands—something that keeps the charges from flying off. It was first pointed out by Poincaré that the rubber bands—or whatever it is that holds the electron together—must be included in the energy and momentum calculations. For this reason the extra nonelectrical forces are also known by the more elegant name "the Poincaré stresses." If the extra forces are included in the calculations, the masses obtained in two ways are changed (in a way that depends on the detailed assumptions). And the results are consistent with relativity; i.e., the mass that comes out from the momentum calculation is the same as the one that comes from the energy calculation. However, both of them contain two contributions: an electromagnetic mass and one due to the Poincaré stresses. Only when the two are added together do we get a consistent theory.

It is therefore impossible to get all the mass to be electromagnetic in the way we hoped. It is not a legal theory if we have nothing but electromagnetism. Some force, else has to be added. Whatever you call them—"rubber bands," or "Poincaré stresses," or something else—there have to be other forces in nature to make a consistent theory of this kind.

Clearly, as soon as we have to put forces on the inside of the electron, the beauty of the whole idea begins to disappear. Things get very complicated. You would want to ask: How strong are the stresses? How does the electron shake? Does it oscillate? What are all its internal properties? And so on. It might be possible that an electron does have some complicated internal properties. If we made a theory of the electron along those lines, it would make odd properties, like modes of oscillation, which aren't apparently over or over. We say "apparently" because we observe a lot of things in nature that still do not make sense. We may someday find out that one of the things we don't understand today (for example, the mean) can, in fact, be explained as an oscillation of the Poincaré stresses. It doesn't seem likely, but no one can say for sure. There are so many things about fundamental particles that we still don't understand. Anyway, the complex structure implied by this theory is undesirable, and the attempt to explain all this in terms of electromagnetism — just in the way we have described — has led to a blind alley.

We would like to think a little more about why we say we have a mass when the momentum in the field is proportional to the velocity. Easy. The mass is the coefficient between momentum and velocity. But we can look at the mass in another way: a particle has mass if you have to exert a force in order to accelerate it. So it may help our understanding if we look a little more closely at where the forces come from. How do we know that there has to be a force? Because we have proved the law of the conservation of momentum for the fields. If we have a charged particle and push on it for awhile, there will be some momentum in the electromagnetic field. Momentum must have been poured into the field somehow. Therefore there must have been a force pushing on the electron in order to get it going — (we're addition to the required by its mechanical inertia, a force due to its electromagnetic interaction). And there must be a compensating force back on the "particle." But a force does just force to be zero."

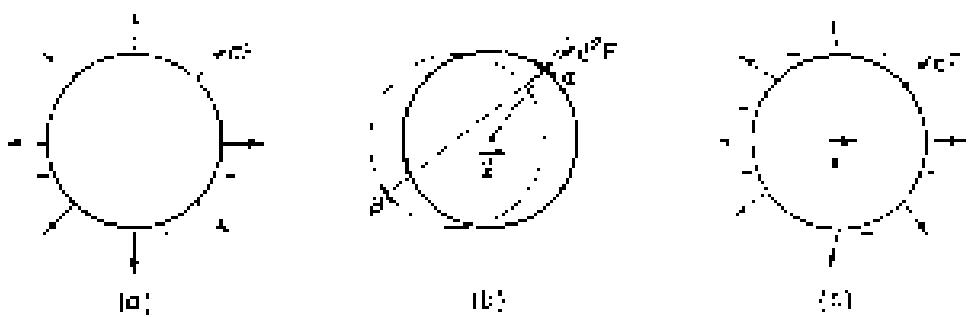

Fig. 28-3. The self-force on an accelerating electron is not zero because of the retardation. (By dF we mean the force on a surface element dS ; by dP we mean the force on the surface element dS , from the charge on the surface element dS .)

The picture is something like this. We can think of the electron as a charged sphere. When it is at rest, each piece of charge needs electrically some other place, but the forces all balance in pairs, so that there is no net force. (See Fig. 28-3(a).) However, when the electron is being accelerated, the forces will no longer be in balance because of the fact that the electromagnetic field of forces take time to propagate one piece to another. For instance, the force on the piece a in Fig. 28-3(a) from a piece b on the opposite side depends on the position of a at an earlier time, as shown. Both the magnitude and direction of the force depend on the motion of the charge. If the charge is accelerating, the forces on various parts of the electron might be as shown in Fig. 28-3(b). When all these forces are added up, they don't cancel out. They would cancel for a uniform velocity, even though it looks at first glance as though the retardation would give an unbalanced force even for a uniform velocity. That reminds us that there is no net force unless the electron is being accelerated. With acceleration, if we look at the forces between

the various parts of the electron motion and reaction are not exactly equal, and the electron exerts a force on itself that tries to slow back the acceleration. It holds itself back by its own "resistance".

It is possible, but difficult, to calculate this self-resistance force. However, we don't want to go into such subtle calculations here. We will tell you what the result is for the case of a uniform charge distribution, which is the simplest case, see *e.g.* [1]. Then, the self-force can be written in series. The first term in the series depends on the separation R , the next term is proportional to R^{-1} and so on. The result is

$$F_{self} = \frac{e^2}{4\pi c^2 R} - \frac{2}{3} \frac{e^2}{c^4} R + \frac{5}{3} \frac{e^2}{c^4} R^3 + \dots \quad (28.9)$$

where e and c are numerical coefficients of the order of 1. The coefficient a_0 of the R^{-1} term depends on what charge distribution is assumed; if the charge is distributed uniformly over a sphere, then $a_0 = 2/3$. So there is a term proportional to the acceleration, which varies inversely as the radius R of the electron, and agrees exactly with the value we get in Eq. (28.8) for m_∞ . If the charge distribution is chosen to be different, so that a_0 is changed, the fraction $2/3$ in Eq. (28.8) would be changed in the same way. The term in R^{-1} is independent of the assumed radius R , and also of the assumed distribution of the charge, its coefficient a_1 is of order $5/3$. The next term is proportional to the radius R , and its coefficient a_2 depends on the charge distribution. You will notice that if $R = 0$, the electron radius R goes to zero, the last term (and all higher terms) will go to zero, the second term remains constant. In the first term, the electromagnetic mass m_∞ goes to infinity. And we can see that the term by a factor because of the force of one part of the electron on another.

Because we have allowed now at perhaps a silly thing, the possibility of the "proper" electron acting on itself.

28.5 Attempts to modify the Maxwell theory

We would like now to discuss how it might be possible to modify Maxwell's theory of electrodynamics so that the idea of an electron as a simple point charge could be maintained. Many attempts have been made, and some of the theories were even able to change things so that all the electron mass was electromagnetic. But all of these theories have failed. It is still interesting to discuss some of the possibilities that have been suggested. To see the struggles of the human mind.

We started out our theory of electricity by talking about the interaction of one charge with another. Then we made up a theory of these interacting charges and ended up with a field theory. We believe it so much that we allow it to tell us about the force of one pair of an electron on another. Perhaps the entire difficulty is that electrons do not live on themselves; perhaps we are making too great an extrapolation from the interaction of separate electrons to the idea that an electron interacts with itself. Therefore some theories have been proposed in which the possibility that an electron acts on itself is ruled out. Then there is no longer the infinity due to the self-action. Also, there is no longer any electromagnetic mass associated with the particle; all the mass is back to being mechanical, but there are new difficulties in the theory.

We know, say immediately, that such theories require a modification of the idea of the electromagnetic field. You remember we said at the start that the force on a particle of any point was determined by just two quantities— E and B . If we allow for the "self-force" this cannot longer be true, because if there is an electron in a certain place, the force isn't given by the field E and B , but by only two parts due to other charges. So we have to keep track always of how much of E and B is due to the charge on which you are calculating. We have said now which is due to the other charges. This makes the theory much more elaborate, but it gets rid of the difficulty of the infinity.

¹ When using the notation $x = a^2 v/c$, $y = a^2 v^2/c^2$, $r = a^2 v^3/c^3$, v_{∞}

As we can, if we have to, say that there is no such thing as the electron's action upon itself, and "throw away" the second set of forces in Eq. (28.9). However, we have then thrown away the baby with the bath! Because the second term in Eq. (28.9), the term in \dot{x} , is needed. That force does something very definite. If you throw it away, you're in trouble again. When we accelerate a charge, it radiates electromagnetic waves, so it loses energy. Therefore, to accelerate a charged object, we must require more force than is required to accelerate a neutral object; of the same mass; otherwise energy wouldn't be conserved. The rate at which we do work on an accelerating charge must be equal to the rate of loss of energy per second by radiation. We have talked about this effect before. It is called the radiation resistance. We still have to answer the question: Where does the extra force, against which we must do this work, come from? When a big nucleus is radiating, the forces come from the influence of one part of the atomic current on another. For a single nonrelativistic electron radiating into otherwise empty space, there would seem to be only one place the force could come from—the action of one part of the electron on another part.

We found back in Chapter 32 of Vol. I that an oscillating charge radiates energy at the rate

$$\frac{dW}{dt} = \frac{2 e^2 (\dot{x})^2}{3 c^3}. \quad (28.10)$$

Let's see what we get for the rate of doing work by a charge against the bootstrap force of Eq. (28.9). The rate of work is the force times the velocity, or $F\dot{x}$,

$$\frac{dW}{dt} = e \frac{\dot{x}^2}{m^2} \dot{x} \dot{x} = \frac{2}{3} \frac{e^2}{c^3} \dot{x} \dot{x} + \dots \quad (28.11)$$

The first term is proportional to \dot{x}^2/\dot{t} , and therefore just corresponds to the rate of change of the kinetic energy $\frac{1}{2}mv^2$ associated with the electromagnetic waves. The second term should correspond to the radiated power in Eq. (28.10). But it is different. The discrepancy comes from the fact that the term in Eq. (28.11) is generally zero, whereas Eq. (28.10) is right only for an oscillating charge. We can show that the two are equivalent if the motion of the charge is periodic. To do this, we rewrite the second term of Eq. (28.11) as

$$= \frac{2 e^2}{3 c^3} \frac{d}{dt} (\dot{x} \dot{x}) + \frac{2}{3} \frac{e^2}{c^3} (\dot{x})^2,$$

which is just an algebraic transformation. If the motion of the electron is periodic, the quantity $\dot{x} \dot{x}$ returns periodically to the same value, so that if we take the average of its time derivative, we get zero. The second term, however, is always positive (it's a square), so its average is also positive. This term gives the net work done and is just equal to Eq. (28.10).

The term in \dot{x} of the bootstrap force is required in order to have energy conservation in radiating systems, and we can't throw it away. It was, in fact, one of the triumphs of Lorentz to show that there is such a force and that it comes from the action of the electron on itself. We must believe in the idea of the action of the electron on itself, and we need the term in \dot{x} . The problem is how we can get that term without getting the first term in Eq. (28.9), which gives all the trouble. We don't know how. You see that the classical electron theory has pushed itself into a tight corner.

There have been several other attempts to modify the laws in order to straighten the thing out. One way, proposed by Born and Infeld, is to change the Maxwell equations in a complicated way so that they are no longer Lorentz. Then the electromagnetic energy and momentum can be added to come out right. But the laws they suggest predict phenomena which have never been observed. Their theory also suffers from another difficulty we will come to later, which is nothing to do with the attempt to avoid the anomalies we have described.

The following possibility was suggested by Dirac. He said, "Let's admit that an electron gets on itself through the second term in Eq. (28.9) but not through the first." He then had to implement this by getting rid of one but not the

other. Look, as we, we made a similar assumption when we took only the retarded wave part of Maxwell's equations. If we were to take the advanced waves instead, we would get something different. The equation for the self-force would be

$$F = \gamma \frac{c^2}{3\epsilon_0^2} S - \frac{\gamma c^2}{\epsilon_0^2} V + \frac{\gamma A_0}{\epsilon_0} \tau \quad (28.21)$$

This equation is just like Eq. (28.9) except for the sign of the second term, and some higher terms of the series. [Changing from retarded to advanced waves is just changing the sign of the charge which, it is not hard to see, is equivalent to changing the sign of τ everywhere.] The only effect on Eq. (28.9) is to change the sign of all the odd time derivatives.⁷ So, Dirac suddenly makes the new rule that an electron does on itself by one-half the difference of the retarded and advanced fields at high frequencies. The difference of Eqs. (28.9) and (28.12), divided by two, is then

$$F = -\frac{2}{3} \frac{c^2}{\epsilon_0^2} x + \text{higher terms.}$$

In all the higher terms, the factor γ appears to some positive power in the variables. Thus, too, when we go to the limit of a point charge, we get only the retardation, just what is needed. In this way, Dirac gets the radiation resistance force and none of the self-forces. There is no electro-magnetic energy, but the classical theory is saved, indeed, at the expense of an arbitrary assumption about the self-force.

The astrophysics of the electro-negative atom of Dirac was reviewed, to some extent at least, by Wheeler and Feynman, who proposed a still stranger theory. They suggest that point charges interact only with other charges, but that the interaction is half through the advanced and half through the retarded waves. It turns out, more surprisingly, that in most situations you won't see any effects of the advanced waves, but they do have the effect of producing just the radiation reaction force. The radiation resistance is not due to the field acting on itself, but from the following point of view. When an electron is accelerated at the time t , it shakes all the other charges in the world at a later time $t' = t + r/c$ (where r is the distance to the other charge), because of the retarded waves. But then these other charges react back on the original electron through their advanced waves, which will arrive at the time t' , equal to t minus r/c , which is, of course, just t . (They also react back with their retarded waves; no, but that just corresponds to the normal "reflected" waves.) The combination of the advanced and retarded waves insures that at the instant it is accelerated an oscillating charge feels a force from all the charges that are "going to" absorb its radiated waves. You see what I mean; know people have gotten into trying to get a theory of the electron!

We'll describe now still another kind of theory, to show the kind of things that people think of when they are stuck. This is another modification of the laws of electrodynamics, proposed by Bopp. You realize then once you decide to change the equations of electromagnetism you can start anywhere you want. You can change the Faraday law for an electron, or you can change the Maxwell equations (as we saw in the examples we have described), or you can make a change somewhere else. One possibility is to change the formulae that give the potentials in terms of the charges and currents. One of our formulas has been that the potentials are to be given by the charge density (or charge) at each other point at an earlier time. (Up until the *second* equation for the potentials, we wrote

$$A_i(t, \vec{r}) = \frac{1}{4\pi \epsilon_0 c^2} \int \frac{\rho(t')}{r_{ij}} dV_j \quad (28.19)$$

Bopp's beautifully simple idea is this: Maybe the trouble is in the *third* term of the integral. Suppose we were to start out by assuming only that the potential at one point depends on the charge density at any other point as some function of the distance between the points, say as $f(r_{ij})$. The total potential at point i

will then be given by the "mean" of j_0 times this function over all space:

$$A_0(t) = \int j_0(\mathbf{r}) f(r_{12}) dV_{12}.$$

That's all. No differential equation, nothing else. Well, one more thing. We also ask that the result should be relativistically invariant. So by "invariant" we should take the invariant "distance" between two points in space-time. This distance squared (with a sign which doesn't matter) is

$$\begin{aligned} r_{12}^2 &= c^2(t_1 - t_2)^2 + r_{12}^2 \\ &= c^2(t_1 - t_2)^2 + (x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2. \end{aligned} \quad (28.14)$$

So, for a relativistically invariant theory, we should take some function of the magnitude of r_{12} , or what is the same thing, some function of r_{12}^2 . As Bopp's theory is that

$$A_0(t_1, t_2) = \int j_0(\mathbf{r}_1, t_2) f(r_{12}^2) dV_{12} dt_2. \quad (28.15)$$

(The integral must, of course, be over a finite range of time t_2 about t_1 .)

All that remains is to choose a suitable function for f . We assume only one thing about f : that it is very small except when its argument is near zero, so that a graph of f would be a curve like the one in Fig. 28-4. It is a smooth curve with a finite area centered at $r_{12}^2 = 0$, and with η with which we can say it roughly c^2 . We can say, crudely, that when we calculate the potential at point (1), only those points (2) produce any appreciable effect if $r_{12}^2 = c^2(t_2 - t_1)^2 + r_{12}^2$ is within $\pm \eta^2$ of zero. We can indicate this by saying that η is important only for

$$r_{12}^2 + c^2(t_1 - t_2)^2 + r_{12}^2 \approx \pm \eta^2. \quad (28.16)$$

You can make it more mathematical if you want to, but that's the idea.

Now suppose that η is very small in comparison with the size of ordinary objects like motors, generators, and the like so that for normal problems $r_{12} \gg \eta$. Then Eq. (28.16) says that charges contribute to the integral of Eq. (28.15) only when $t_2 = t_1$ is in the small range

$$c(t_1 - t_2) \approx \sqrt{r_{12}^2 + \eta^2} \approx r_{12} \sqrt{1 + \frac{\eta^2}{r_{12}^2}}.$$

Since $\eta^2/r_{12}^2 \ll 1$, the square root can be approximated by $1 + \eta^2/2r_{12}^2$, so

$$t_2 = t_1 + \frac{r_{12}}{c} \left(1 + \frac{\eta^2}{2r_{12}^2} \right) = \frac{r_{12}}{c} + \frac{\eta^2}{2r_{12}^2}.$$

What is the significance? This result says that the only times t_2 that are important in the integral of A_0 are those which differ from the time t_1 at which we sent the potential by the delay r_{12}/c —with a negligible correction as long as $r_{12} \gg \eta$. In other words, this theory of Bopp approaches the Maxwell theory—so long as we are far away from any particular charge—in the sense that it gives the retarded wave effects.

We can, in fact, see approximately what the integral of Eq. (28.15) is going to give. If we integrate first over r_{12} from $-\infty$ to $+\infty$ —keeping t_2 fixed—then A_0 is also going to go from $-\infty$ to $+\infty$. The integral will all come from r_{12} 's in a small interval of width $\Delta r_{12} \approx 2 \times \eta^2/2r_{12}$, centered at $r_{12} = r_{12}/c$. Say that the function $f(r_{12}^2)$ has the value K at $r_{12}^2 = 0$; then the integral over r_{12} is approximately $K r_{12} \delta(r_{12})$,

$$\frac{K r_{12}^2}{c} \delta_{r_{12}}.$$

We should, of course, take the value of j_0 at $t_2 = t_1 + r_{12}/c$, so that Eq. (28.15) becomes

$$A_0(t_1, t_2) = \frac{K a^2}{c} \int_{-r_{12}}^{r_{12}} j_0(\mathbf{r}_1, t_1 + r_{12}x/c) dx.$$

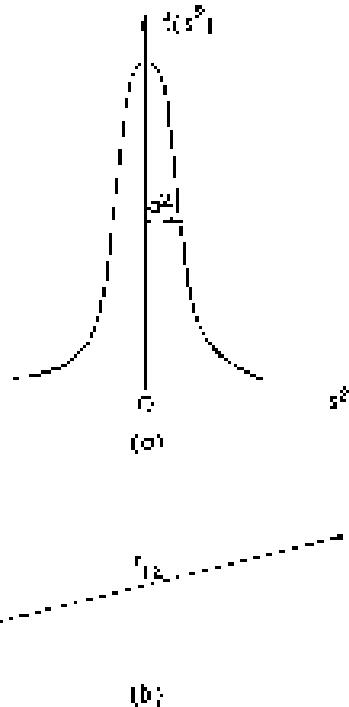

Fig. 28-4. The function $f(r^2)$ used for the nonlocal theory of Bopp.

If we pick $\kappa = q^2/c^2 \pi e^2 c^2$, we are right back to the correct potential solution of Maxwell's equations, including curiously just the $1/r$ -dependence! And it will come out of the same properties that the accuracy at one point in spacetime depends on the current density at a farther point in spacetime, but not a weighting factor that is zero or, say, the ratio of the densities or the distance between the two points. This theory again predicts a finite electrostatic energy for the electron, and the energy and mass have the right relation for the relativistic theory. This means, because the theory is relativistically invariant, that $m = \sqrt{E}$, and everything seems to be all right.

There is, however, one fundamental objection to this theory and to all the other theories we have described. As far as we know now, the laws of quantum mechanics, as a quantum-mechanical modification of electrodynamics, has to be made. Light behaves like photons. It isn't 100 percent like the Maxwell theory. So the electrodynamics theory has to be changed. We have already mentioned that it might be a waste of time to work so hard to straighten out the classical theory, because it could turn out that in quantum electrodynamics the difficulties will disappear or may be resolved in some other fashion. But the difficulties do not disappear in quantum electrodynamics. That is one of the reasons four people have spent so much effort trying to straighten out the classical difficulties, hoping that if they could straighten out the classical difficulty and then make the quantum modifications, everything would be straightened out. The Maxwell theory will have the difficulties after the quantum-mechanical modifications are made.

The quantum effects do make some changes—the formula for the mass is modified, and Planck's constant \hbar appears—but the answer will comes out infinite unless you cut off an integration somehow—just as we had to stop the classical integration at $r = 0$. And the answer depends on how you stop the integrals. We cannot, unfortunately, do anything for you here, that the difficulties are really basically the same, because we have developed so little of the theory of quantum mechanics and even less of quantum electrodynamics. So you must just take our word that the quantized theory of Maxwell's theory contains a serious infinite mass for a point electron.

It turns out, however, that nobody has ever succeeded in making a self-consistent quantum theory out of any of the modified theories. Some and Infeld's ideas have never been satisfactorily made into a quantum theory. The theory as well as the advanced and extended ideas of Debye and Wheland and Feynman have never been represented satisfactorily quantum theory. The theory of Rupp has never been made into a satisfactory quantum theory. So far, there is no known solution to this problem. We do not know how to make a consistent theory—including the quantum mechanics—which does not give zero infinity for the self-energy of an electron, of any point charge. And at the same time, there is no satisfactory theory that describes a non-point charge. It's an unsolved problem.

So today, if I'm daring to rush off to make a theory, how much the action of an electron on itself is completely removed, so that electromagnetic mass is no longer meaningful, and then to make a quantum theory of it, you should be warned that you're certain to be in trouble. There is definite experimental evidence of the existence of electromagnetic mass. There is evidence that some of the mass of charged particles is electromagnetic in origin.

It used to be said in the older books that, since Nature will obviously not present us with two particles—one neutral and the other charged, but otherwise the same—we will never be able to tell how much of the mass is electromagnetic and how much is mechanical. But, if it is true that Nature has been kind enough to present us with such such objects, so that by comparing the observed mass of the charged one with the observed mass of the neutral one, we can tell exactly where is the electromagnetic mass. For example, here are the neutrinos and nucleons. They interact with the same forces—the nuclear forces—which origin is unknown. However, as we have already described, the nuclear forces have very remarkable properties. So far as they're concerned, the neutrino and nucleon are exactly the same. The nuclear forces exchange scalar, or meson, negative-pion, and pion-like particles—all identical as far as we can tell. Only the little

electromagnetic forces are different: electrically the proton and neutron are as different as night and day. This is just what we wanted. There are two particles, identical from the point of view of their strong interactions, but different electrically. And they have a small difference in mass. The mass difference between the proton and the neutron—expressed as the difference in the rest-energy m^2 in units of Mev—is about 1×10^{-3} Mev, which is about 7.6 times the electron mass. The classical theory would then predict a ratio of about $\frac{1}{2} \times \frac{1}{2}$ the classical electron radius, or about 10^{-14} cm. Of course, one should really use the quantum theory, and by some strange accident, all the constants α_N and α_S , etc., come out so that the quantum theory gives roughly the same result as the classical theory. The only trouble is that the sign is wrong! The neutron is heavier than the proton.

Table 28-1

Particle Masses

Particle	Charge (electronic)	Mass (Mev)	Δm^2 (Mev 2)
n (neutron)	0	939.5	—
p (proton)	+1	938.2	-1.3
π^+ meson	0	139.8	
	+1	139.6	+1.6
K^+ (K-meson)	0	497.8	
	+1	491.4	-1.5
π^- (signor)	0	1191.5	
	+1	1189.4	-2.1
		1196.0	+4.9

* $\Delta m^2 = (\text{mass of charged}) - (\text{mass of neutral})$.

Nature has also given us several other pairs—or triplets—of particles which appear to be exactly the same except for their electrical charge. They interact with protons and neutrons through the same three “strong” interactions of the nuclear forces. In this interpretation, the particles of a given kind—say the π -mesons—believe in every way like one object except for their electrical charge. In Table 28-1 we give a list of such particles, together with their masses in Mev. The charged π -mesons, positive and negative, have a mass of 139.6 Mev, and the neutral π -meson is 4.6 Mev lighter. We believe that this mass difference is electro-magnetic; it would correspond to a particle radius of $3 \text{ to } 4 \times 10^{-14}$ cm. You will see from the table that the mass differences of the other particles are usually of the same general size.

Now the size of these particles can be determined by other methods, for instance by the diameters they appear to have in high-energy collisions. So the electromagnetic mass seems to be in general agreement with electromagnetic theory, if we stop our integrals of the total energy at the same radius obtained by these other methods. That's why we believe that the differences do represent electromagnetic mass.

You are no doubt worried about the different signs of the mass differences in the table. It is easy to show by the classical rules that the charged ones should be heavier than the neutral ones. But is it possible that particles like the neutron, where the charged ones comes out the other way? Well, it turns out that these particles are complicated, and the computation of the electromagnetic mass must be more elaborate for them. For instance, although the neutron has no net charge, it does have a charge distribution inside it. It is only the overcharge that is zero. In fact, we believe that the neutron looks at lower energies like a proton with a negative π -meson in a “cloud” around it, as shown in Fig. 28-5. Although the neutron is “neutral,” because its total charge is zero, there are still electromagnetic energies,

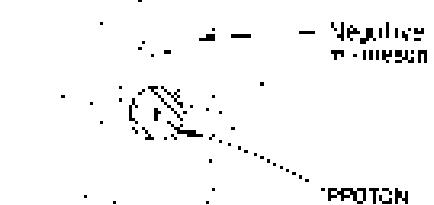

Fig. 28-5. A neutron may exist, at times, as a proton surrounded by a negative π -meson.

for example, to have a magnetic moment, so it's not easy to tell the sign of the electromagnetic mass difference without a detailed theory of the internal structure.

We only wish to emphasize here the following points: (1) the electro-magnetic theory predicts the existence of an electromagnetic mass, but it at all fails on its face in doing so, because it does not produce a consistent theory; (2) the same is true with the quantum modifications; (3) there is experimental evidence for the existence of electromagnetic mass; and (4) all these masses are roughly the same as the mass of an electron. So we come back again to the original idea of Lorentz: maybe all the mass of an electron is purely electromagnetic, maybe the whole 0.511 Mev is due to electrodynamics. Is it, or isn't it? We haven't got a theory, so we cannot say.

We must mention one more piece of information, which is the most annoying. There is another particle in the world called a muon—or pion— which, so far as we can tell, differs in no way whatsoever from an electron except for its mass. It acts in every way like an electron: i. interacts with neutrinos and with the electromagnetic field, and it has no nuclear forces. It does nothing different from what an electron does—at least nothing which cannot be understood as merely a consequence of its lighter mass (206.77 times the electron mass). Therefore, whenever we need finally *genuine* the explanation of the mass of an electron, we will have the puzzle of where a muon gets its mass. Why? Because whatever the electron does, the muon does the same—as the mass ought to come out the same. This is why those who believe faithfully in the idea that the muon and the electron are the same particle and that in the final theory of the mass, the formula for the mass will be quadratic equal, with two roots—one for each particle. There are also those who propose it will be a transverse-field equation with infinite number of terms, and who are engaged in guessing what the masses of the other particles in the series will be, and why these particles haven't been discovered yet.

28-6 The nuclear force field

We would like to make some rather remarks about the part of the mass of nuclear particles. Let us set electron aside. Where does this extra charge factor come from? There are other forces besides electromagnetism, like nuclear forces, that have their own field—waves, although no one knows as yet if the current theories are right. These waves are probably total energy which gives the nuclear particles a mass, or something to do with strong interaction, but until now the “nuclear field mass.” It is presumably very large, because the mass is great, and it is the possible origin of the mass of the heavy particles. But the nuclear field theories are still in a most rudimentary state. Even with the well-developed theory of electromagnetism, we found it impossible to get beyond first basis in explaining the electromagnetic. With the theory of the nucleus, we strike out.

We may take a moment to continue the history of the nucleus, because of its interesting connection with electrodynamics. In electrodynamics, the field can be described in terms of a four-potential that satisfies the equation

$$\partial_\mu A_\nu = \text{source}.$$

Now we have seen that waves of the field can be farther away so long they exist separated from the sources. These are the photons of light, and they are described by a differential equation with no source:

$$\partial_\mu \partial_\nu A_\rho = 0$$

People have argued that the field of nuclear forces might also be based on short “photons,” they would presumably be the *nucleons*. And that they should be described by an analogous differential equation. Because as the weakest of the human brain, we can't think of something really new, so we argue by analogy with what we know. So the present equation might be

$$\partial_\mu \partial_\nu A_\rho = 0.$$

where ω could be a different four-vector or perhaps a scalar. It turns out that the pion has no polarization, so ω should be a scalar. With the simple equation $\nabla^2\phi = 0$, the meson field would vary with distance from a source as $1/r^2$, just as the electric field does. But we know that nuclear forces have much shorter distances of action, so the simple equation won't work. There is one way we can change things without destroying the relativistic invariance: we can add or subtract from the D'Alembertian a constant, times ω . So Yukawa suggested that the free quanta of the nuclear force field might obey the equation

$$\nabla^2\phi - \mu^2\phi = 0 \quad (28.17)$$

where μ^2 is a constant—but an invariant scalar. (Since ∇^2 is a scalar differential operator in four dimensions, its invariance is unchanged if we add another scalar to it.)

Let's see what Eq. (28.17) gives for the nuclear force when charges are not changing with time. We want a spherically symmetric solution of

$$\nabla^2\phi - \mu^2\phi = 0$$

located at a point source at, say, the origin. If ϕ depends only on r , we know that

$$\nabla^2\phi = \frac{1}{r} \frac{\delta^2}{\delta r^2}(\phi r) = \mu^2\phi = 0.$$

So we have the equation

$$\frac{1}{r} \frac{\delta^2}{\delta r^2}(r\phi) = \mu^2\phi = 0$$

or

$$\frac{\delta^2}{\delta r^2}(r\phi) + \mu^2(r\phi) = 0.$$

Taking $r\phi$ as our dependent variable, this is an equation we have seen many times. Its solution is

$$r\phi = K e^{-\mu r}.$$

Clearly, ϕ cannot become infinite for large r , so the sign in the exponent is ruled out. The solution is

$$\phi = K' \frac{e^{-\mu r}}{r}. \quad (28.18)$$

This function is called the Yukawa potential. For a $1/r$ interaction, μ is a constant, but the "range" λ must be adjusted to fit the experimentally observed strength of the forces.

The Yukawa potential of the nuclear forces dies off more rapidly than $1/r$ by the exponential factor. The potential—and therefore the force—falls to zero much more rapidly than $1/r$ for distances beyond $1/\mu$, as shown in Fig. 28-6. The "range" of nuclear forces is much less than the "range" of electrostatic forces. It is found experimentally that the nuclear forces do not extend beyond about 10^{-11} cm, say, $\sim 10^{-10}$ m.

Finally, let's look at the free-wave solution of Eq. (28.17). If we substitute

$$\phi = \phi_0 e^{i(kz - \omega t)}$$

into Eq. (28.17), we get that

$$\frac{\omega^2}{c^2} - k^2 - \mu^2 = 0$$

Relating frequency to energy and wave number to momentum, as we did at the end of Chapter 26 of Vol. 1, we get that

$$\frac{E'}{c^2} = p'^2 = \mu^2 c^2$$

which says that the Yukawa "photon" has a mass equal to μc . If we use this

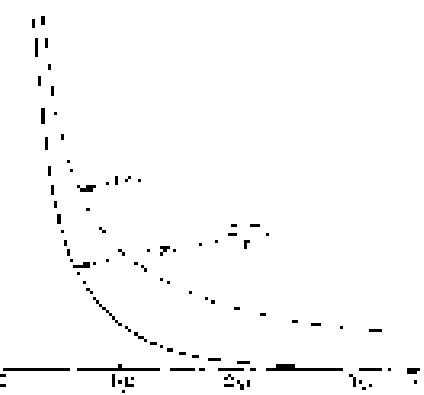

Fig. 28-6. The Yukawa potential $\phi \sim 1/r$, compared with the Coulomb potential $1/r$.

the estimate 10^{41} m^{-1} , which gives the observed range of the nucleon force, the mass comes out to be $\sim 10^{-25} \text{ gm}$, or 170 Mev, which is roughly the masslessness of the π -meson. So, by an analogy with electrodynamics, we would say that the π -meson is the "hyphoton" of the nuclear force field. But now we have pushed the ideas of electrodynamics into regions where they may not really be valid - we have gone beyond electrodynamics to the problem of the nuclear forces.

The Motion of Charges in Electric and Magnetic Fields

29-1 Motion in a uniform electric or magnetic field

We want now to describe—mainly in a qualitative way—the motion of charges in various circumstances. Most of the interesting phenomena in which charges are moving in fields occur in very complicated situations, with many charges all interacting with each other. For instance, when an electromagnetic wave goes through a block of material or a plasma, billions and billions of charges are interacting with the wave and with each other. We will come to such problems later, but, now we just want to discuss the much simpler problem of the motion of a steady charge in a given field. We can then discuss what other charges—several, of course, other charges and currents—which as it were somewhere to produce the field, are well known.

We should probably ask first about the motion of a particle in a uniform electric field. At low velocities, the motion is not particularly interesting; it is just a uniform acceleration in the direction of the field. However, if the particle picks up enough energy to become relativistic, then the motion gets more and more奇特, let me tell you the bottom line for that case for you to play with.

Next, we consider the motion of a charge in a magnetic field with zero electric field. We have already solved this problem: one assumes that the particle goes in a circle. The magnetic force $qv \times B$ is always at right angles to the motion, so dv/dt is perpendicular to p and, for the range $R = vp/B$, where R is the radius of the circle,

$$F = qvB = \frac{mv^2}{R}.$$

The radius of the circular orbit is then

$$R = \frac{p}{qB}. \quad (29-1)$$

There is only one possibility: if the particle has a component of its motion along the field direction, that motion is constant, since there can be no component of the magnetic force in the x direction of the field. If the particle has a motion in a uniform magnetic field in a constant velocity parallel to B and v is the speed at right angles to B , the trajectory is a cylindrical helix (Fig. 29-1). The radius of the helix is given by Eq. (29-1) if we replace p by p_z , the component of momentum at right angles to the field.

29-2 Momentum analysis

A uniform magnetic field is often used in making a "momentum analyzer," or "momentum spectrometer." For high-energy charged particles, suppose that charged particles are shot into a uniform magnetic field as the point A in Fig. 29-2(a); the magnetic field being perpendicular to the plane of the drawing. Each particle will go into an orbit which is a circle whose radius is proportional to its momentum. If all the particles enter perpendicularly to the edge of the field, they will be at the helical angle of $\pi/2$. The orbit is perpendicular to the momentum p . A suitable grid of slanted plates (see Fig. 29-2) will detect only those particles whose momentum is proportional to their mass: $p = qBm/v$.

If, of course, not exactly, that the particles go through 180° before they are accelerated to $\pi/2$, a so-called "180° spectrometer" has special properties. It is not

Review: Chapter C, Vol. I, Configuration

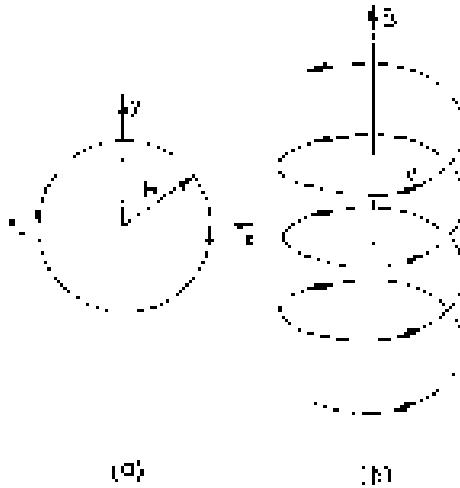

Fig. 29-1. Motion of a particle in a uniform magnetic field.

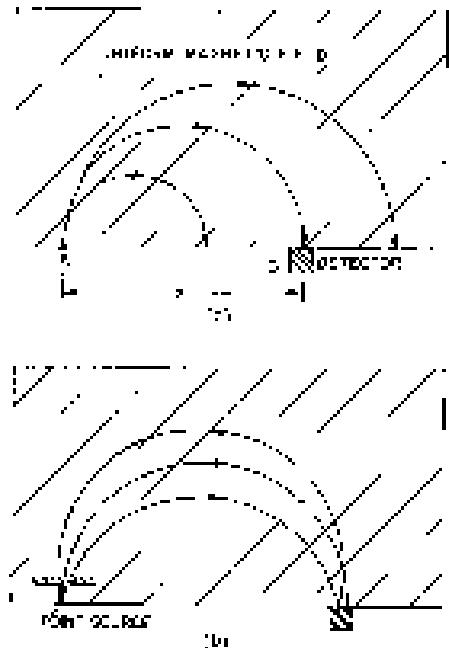

Fig. 29-2. A uniform-field, momentum spectrometer with 180° focusing: (a) different momenta, (b) different angles. (The magnetic field is directed perpendicular to the plane of the figure.)

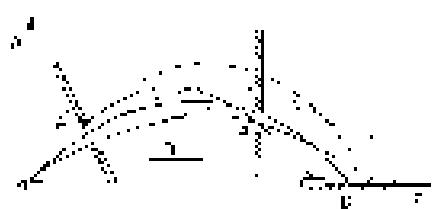

Fig. 29-3. An axis-feed spectrometer.

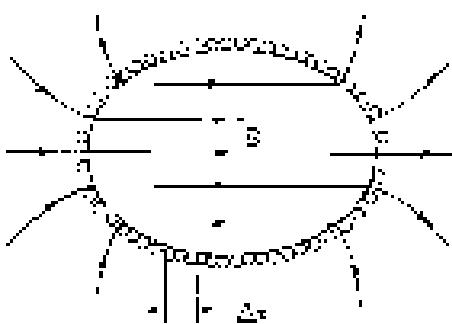

Fig. 29-4. An ellipsoidal coil with coils wound in each axial interval Δx produces a uniform magnetic field inside.

necessary than if the particles enter at right angles to the field edge. Figure 29-3(b) shows the trajectories of three particles, all with the same momentum but entering the field at different angles. You see that they make different trajectories, but all leave the field very close to the point α . We say that there is a "focus." Such a focusing property has the advantage that larger angles can be accepted at a although some "focusing" is imposed, as shown in the figure. A larger angular acceptance usually means that more particles are counted in a given time, decreasing the time required for a given measurement.

By varying the magnetic field, or moving the counter along its x , or by using many counters to cover a range of x , the "momentum spectrum" ($f(p)$, we mean that the number of particles with momenta between p and $p + dp$) is obtained. Such measurements have been made, for example, to determine the distribution of energies in the α -decay of various nuclei.

There are many other forms of momentum spectrometers, but we will describe just one more, which has an especially large solid angle of acceptance. It is based on the radial orbits in a uniform field, like the one shown in Fig. 29-1. Let's think of a cylindrical coordinate system— (p, θ, z) —set up with the z -axis along the direction of the field. If a particle is emitted from the origin at some angle θ with respect to the z -axis, it will move along a spiral whose equation is

$$y = a \sin k z, \quad z = b z,$$

where a , b , and k are parameters you can calculate with the help of p , θ , and the "magnetic field" B . If we plot the distance y from the z -axis as a function of z as a good coordinate, for the several starting angles, we will get curves like the ones shown in Fig. 29-3. (Remember that this is just a kind of projection of a helical trajectory y . When the angle between z -axis and the starting direction is larger, the peak value of y is larger but the longitudinal velocity v_z less, so the trajectories for different angles tend to "join" to a kind of "cloud" near the point β on the right.) If we put a narrow aperture of A , particles with a range of initial angles can still get through and pass on to the side, where they can be counted by the long detector D .

Particles are not forced to start at the origin with a big initial momentum but at the same angles, follow the paths shown by the broken lines and just go through the aperture at β . So the spectrometer selects a small interval of momenta. The advantage over the first spectrometer described is that the aperture A —and the aperture A' —can be much larger so that particles which "leave the source" in a rather large solid angle are measured. A large fraction of the particles from the source are used—an important advantage for weak sources or for very precise measurements.

One pays a price for this advantage, however, because a large volume of uniform magnetic field is required, and this is usually only practical for low-energy particles. One way of making a uniform field, you remember, is to wind a coil on a sphere with a surface current density proportional to the sine of the angle. You can also show that the same thing is true for an ellipsoid of rotation. So such spectrometers are often made by winding an elliptical coil on a wooden (or aluminum) ellipsoid. All that is required is that the current in each interval of axial distance Δz be the same, as shown in Fig. 29-4.

29-3 An electrostatic lens

Particle focusing has many applications. For instance, the electrons that leave the cathode in a TV picture tube are brought to a focus at the screen—to make a bright spot. In this case, one wants to take electrons all of the same energy but with different impact angles and bring them together in a small spot. The problem is like focusing light with a lens, and the question is what the corresponding focusing particles are called a lens.

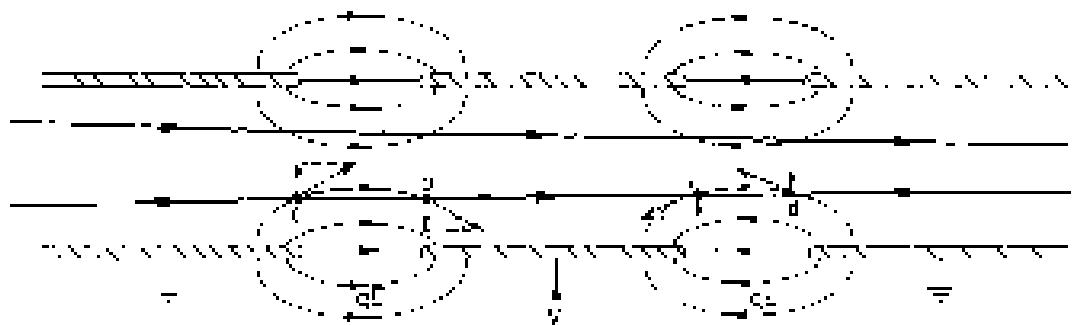

Fig. 29-5. An electrostatic lens. The field lines shown are "lines of force," since they "curve" the law of qE .

One example of an electron lens is sketched in Fig. 29-5. It is an "electrostatic" lens whose operation depends on the electric field between two adjacent electrodes. Its operation can be understood by considering what happens to a particle, being bent away from the axis. When two electrodes are used, the region in between a particle will have a component of force which points them toward the axis. You might think that they would get an equal and opposite impulse in the region B , but that's not so. By the time the electrons reach B , they have gained energy and so pass far now in the region A . The forces are the same, but the time is shorter, so the impulse is less. In going through the regions A and B , there is a net axial impulse, and the electrons are bent away from the axis. In passing the high-voltage region, the particles get slowed or sick toward the axis. The force is outward, in a region very靠近 the axis, so the particle stays longer in the last region, so there is again a net impulse. For distances not too far from the axis, the total impulse through the lens is proportional to the distance from the axis. Can you see why? And this is the axial or accessory for lens-type focusing.

You can use the same arguments to show that there is focusing if the potential of the middle electrode is either positive or negative with respect to the other two. Electrostatic lenses of this type are commonly used in cathode-ray tubes and in some electron microscopes.

29-4 A magnetic lens

Another kind of lens—often found in electron microscopes—is the magnetic lens sketched schematically in Fig. 29-6. A cylindrically symmetric electromagnet has very sharp circular pole tips which produce a strong, non-uniform field in a small region. Electrons which travel radially through this region are focused. You can understand this mechanism by looking at the longitudinal view of the pole tip region shown in Fig. 29-7. Consider two electrons, 1 and 2, that leave the source S of Fig. 29-6 with respect to the axis. As electron 1 moves horizontally toward the field, it is deflected away from the axis by the horizontal component of the field. But since it will have a lateral velocity, as that which it passes through the air, or vacuum, field, it will get an impulse toward the axis. As this motion is taken out by the magnetic force as it leaves the field, so the net effect is an impulse toward the axis, plus a "sidetoss" about the axis. At the same time particle 2 also passes through the air, it is deflected toward the axis. By the figure, the divergent electrons are brought into parallel paths. The action is just like a lens with an image at the focal point. Another similar lens upstream can be used to focus the electrons back to a single point, giving an image of the source S .

29-5 The electron microscope

You know that electron microscopes can "see" objects too small to be seen by optical microscopes. We discussed in Chapter 20 of Vol. I the basic limitations of any optical system due to diffraction of the lens opening. If a lens opening with

Fig. 29-6. A magnetic lens.

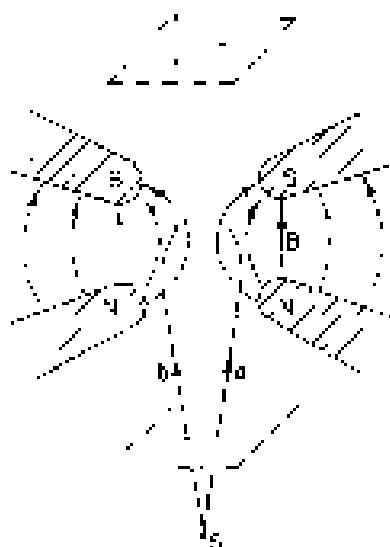

Fig. 29-7. Electron motion in the magnetic lens.

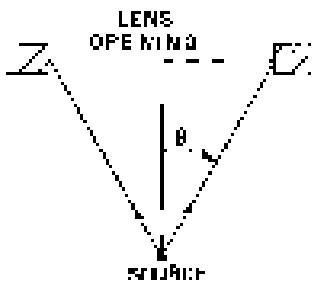

Fig. 24-0. The resolution of a microscope is limited by the angle subtended from the source.

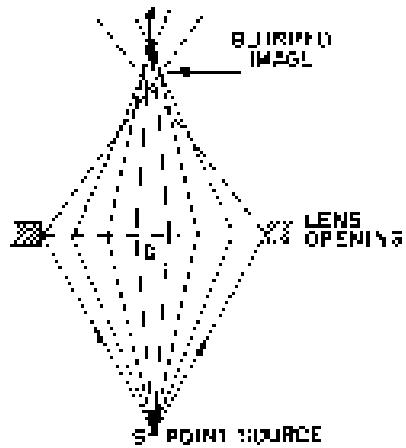

Fig. 2P-5. Spherical aberration of a lens.

turns the angle α_A from zero (see fig. 2a-3). Two initial bearing signs at the source can now be seen in sequence if they are closer than about

$$\phi = \frac{\lambda}{\sin \theta}$$

where λ is the wavelength of the light. With the best optical microscopes, θ approaches the theoretical limit of 90° , so δ is about equal to λ , or approximately 500 to 800 nm.

The same limitation would also apply to our electron microscope, but there the wavelength is the Planck-Jewett distance, about 0.03 angstrom. If one could use a lens opening of even $\times 10^4$, it would be possible to see objects only ± 0.001 angstrom apart. Since the distance of the DNA is typically 1 or 2 angstroms apart, we could get photographs of such DNA. But why would be easy; we would need a photograph of the DNA structure. What a tremendous thing that would be! Most of present-day research in materials' biology is an attempt to figure out the shapes of various protein molecules. How could one be satisfied?

Uniformly, the best case single power that has been employed in an electron microscope is more like 13 magnifications. The reason is that the objective lens has its diaphragm at a large opening. A 13-magn. lens "hyperfocal" distance, which means that rays at large angles from the axis have a different point of inflection than the rays nearer the axis, as shown in Fig. 20-19. By special techniques, optical microscope lenses can be made with a negligible aberration at infinity, but no one has yet been able to make an electron lens which avoids spherical aberration.

In fact, one can show that any electrostatic or magnetic lens of the type we have described must have an irreducible amount of spherical aberration. This aberration—together with diffraction limits the resolving power of electron microscopes to their apertural value.

The limitation we have mentioned does not apply to electric and magnetic fields which are not axially symmetric or which are not constant in time. Perhaps some day someone will think of a new kind of electron lens that will overcome the inherent aberration of the simple electron lens. Then we will be able to photograph atoms directly. Perhaps one day chemical compounds will be analyzed by looking at the positions of the atoms rather than by looking at the color of some photographic film.

29-4 Accelerator with feedback

Magnetic fields are also used to produce special particle trajectories in high-energy particle accelerators. Machines like the cyclotron and synchrotron bring particles to high energies by passing the particles repeatedly through a strong electric field. The particles are held on their orbits by a magnetic field.

We have seen that a particle in a uniform magnetic field will go in a circular orbit. This, however, is true only for a perfectly uniform field. Imagine a field B which is nearly uniform over a large area, but which is slightly stronger in one region than in another. If we put a particle of a magnetomagnetic field, it will go in a nearly circular orbit over the entire $B = \mu_0 H$. The radius of curvature will, however, be slightly smaller in the region where the field is stronger. The orbit is not a closed circle but will "walk" through the field, as shown in Fig. 36-10. We can, if we wish, consider that the "light" "on" in the field produces an extra angular kick which sends the particle off on a new track. If the particles travel millions of revolutions in an accelerator, some kind of "light trapping" is needed which will tend to keep the trajectory close to some design orbit.

Another difficulty with a uniform field is that the particles do not remain in a plane. If they start out with the slightest angle—or are given a slight angle by any small error in the field—they will go in a helical path that will eventually take them into the magnet pole or the ceiling or floor of the vacuum tank. Some arrangement must be made to inhibit such vertical drifts; the field must provide "guiding centers," as well as radial focusing.

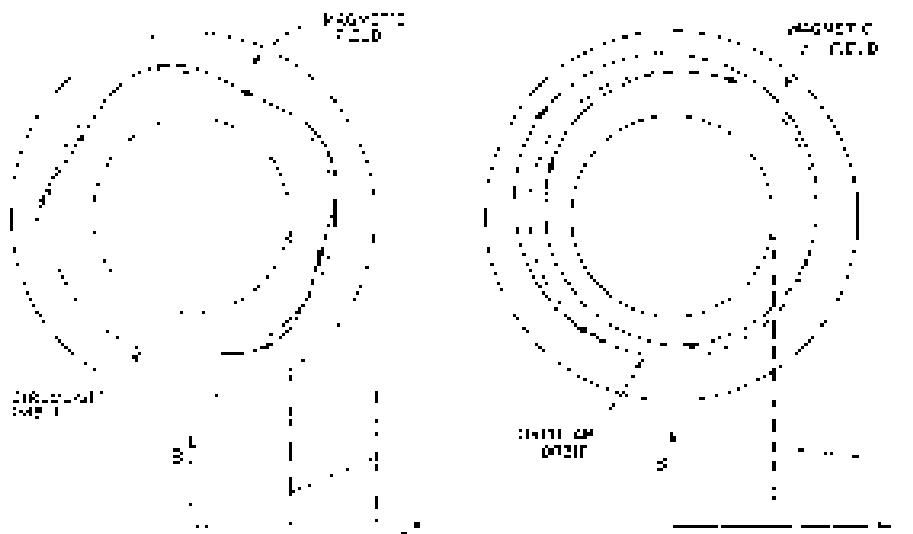

Fig. 29-11. Radial motion of a particle in a magnetic field with a large positive slope.

Fig. 29-12. Radial motion of a particle in a magnetic field with a small negative slope.

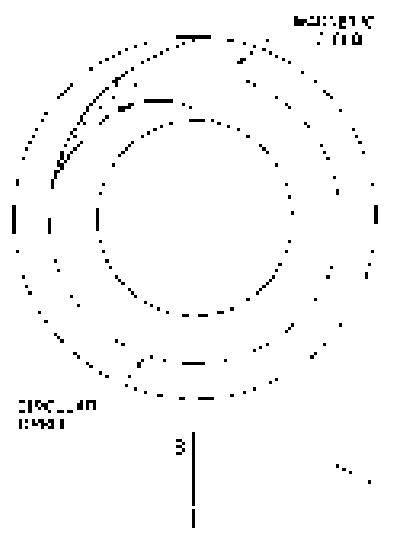

Fig. 29-12. Radial motion of a particle in a magnetic field with a large negative slope.

One would, at first, guess that radial focusing could be provided by making a magnetic field which increases with increasing distance from the center of the design path. Then if a particle goes out to a large radius, it will be in a stronger field where it will bend back toward the central radius. If it goes to too small a radius, the bending will be less, and it will be returned toward a larger radius. If the particle is once started off, say angle α with respect to the design orbit, it will tend to return to the design orbit, as shown in Fig. 29-11. The radial focusing would keep the particle on the circular path.

Actually there is still some radial focusing even with the opposite field slope. This can happen if the radius of curvature of the trajectory does not increase as rapidly as the increase in the distance of the particle from the center of the field. The particle orbits will be as drawn in Fig. 29-12. If, however, the field is too large, however, the orbits will not return to the design radius but will spiral inward to a point as shown in Fig. 29-13.

We quickly see that we must add the right equations of the "relative gradient" at $y = 0$ and $x = 0$:

$$\alpha = \frac{\partial B_x}{\partial r}, \quad (29.2)$$

A guide field gives no focusing if this relative gradient is greater than -1.

A radial field gradient will also produce vertical forces on the particles. Suppose we have a field that is stronger nearer to the center of the orbit and weaker at the outside. A section cross section of the magnet at right angles to the orbit might be as shown in Fig. 29-14. (For present the orbits would be coming out of the page.) If the field is to be stronger to the left and weaker to the right, the lines of the magnetic field must be curved as shown. We can see that this must be so by using the fact that the circulation of B is zero in free space. If we take coordinates as shown in the figure, then

$$(\nabla \times B)_x = \frac{\partial B_z}{\partial y} - \frac{\partial B_y}{\partial z} = 0,$$

$$\text{or} \quad \frac{\partial B_z}{\partial y} = \frac{\partial B_y}{\partial z}. \quad (29.3)$$

Since we assume that $\partial B_z/\partial x$ is negative, there must be some negative $\partial B_y/\partial z$.

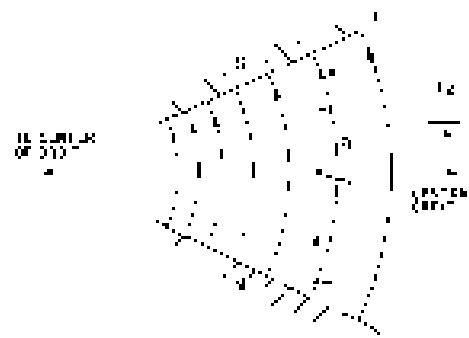

Fig. 29-14. A section guide field as seen in a cross section perpendicular to the orbits.

If the "horizontal" plane of the orbit is a plane of symmetry where $B_0 = 0$, then the radial component B_r will be negative above the plane and positive below. This must be cured as shown.

Such a field will have no real focusing properties. Imagine a particle that is travelling more or less parallel to the central orbit path, say at $\theta = 90^\circ$. The horizontal component of B will exert a downward force on it. If the proton is beyond the central orbit, the force is reverse. So there is an effective "spring" that holds the vertical orbit. From our arguments just will be vertical focusing provided that the vertical field decreases with increasing radius. In the field B which is positive, there will be "vertical defocusing." So for real focusing up the field must be less than zero. We know, however, that the radial focusing a had to be greater than -1. The parameter a is taught to give the condition that

$$-1 < a < 0$$

The particle must be kept in stable orbits in any attractive values very near zero so we must keep the focusing and defocusing small. The value $a = -1$ is typically used.

29-7 Alternating-gradient Focusing

Since the focusing of w_0 is then "weak" focusing, it is clear that much more effort is required than up until now given by a large positive gradient (w_0) . By this, the vertical forces would be strongly defocusing. Similarly, large negative slopes in w_0 would give stronger vertical forces and would cause radial defocusing. It was realized a year 10 years ago, however, that a force that alternates between strong focusing and strong defocusing can still have total focusing force.

To explain how alternating-gradient focusing works, we will first describe the operation of a quadrupole lens, which is based on the same principle. Imagine that a uniform negative magnetic field is added to the field of Fig. 29-15, with the strength adjusted to make zero field at the orbit. The resulting field, at small distances from the central point, would be like the field shown in Fig. 29-15. Such a four-pole magnet is called a "quadrupole lens." A positive particle that enters (from the rest) to the right or left of the center is pushed back toward the center. If the particle enters above or below, it is pushed away from the center. This is a horizontal focusing lens. If the horizontal gradient is reversed—it can be done by reversing all the polarities—the signs of all the forces are reversed and we have a vertical focusing lens, as in Fig. 29-16. For each lens, the field strength—and therefore the focusing forces—increases linearly with the distance of the lens from the axis.

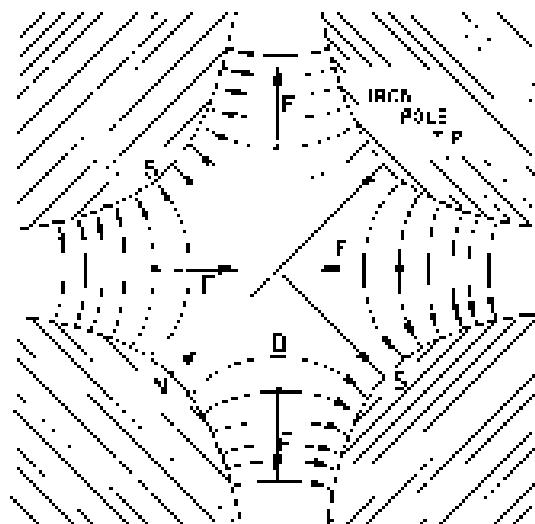

Fig. 29-15. A horizontal focusing quadrupole lens.

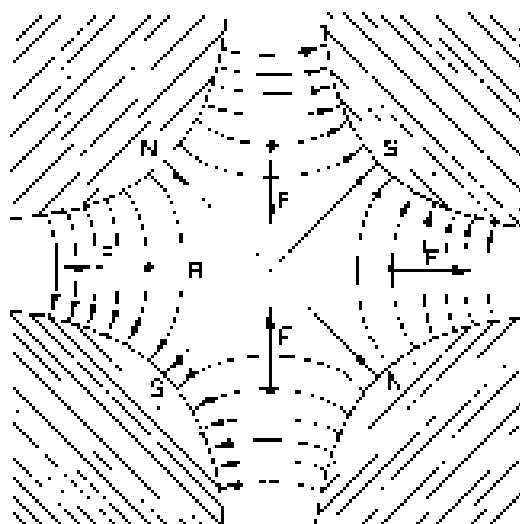

Fig. 29-16. A vertical focusing quadrupole lens.

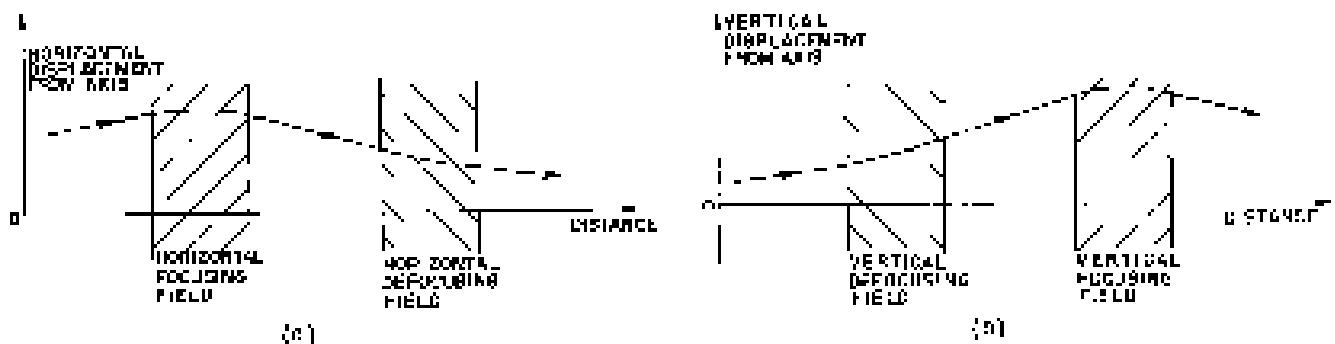

Fig. 29-17. Horizontal and vertical focusing with a pair of quadrupole lenses.

Now imagine that two such lenses are placed in series. If a particle enters with some horizontal displacement from the axis as shown in Fig. 29-17(a), it will be deflected toward the axis in the first lens. When it arrives at the second lens it is closer to the axis, so the force exerted is less and the outward deflection is less. There is a net horizontal toward the axis, the energy effect is horizontally focusing. On the other hand, if we look at a particle which enters off the axis in the vertical gradient, the path will be as shown in Fig. 29-17(b). The particle is first deflected along from the axis, but then it arrives at the second lens with a larger displacement. Since a stronger force, and this is best toward the axis. Again the net effect is focusing. Thus a pair of quadrupole lenses acts independently for horizontal and vertical motion, very much like the septuads. Quadrupole lenses are used to focus and control beams of particles in all the same way that optical lenses are used for light beams.

We should point out that an alternating-gradient system does not always produce focusing. If the gradients are too large (in relation to the particle momentum or to the spacing between the lenses), the net effect can be a defocusing one. You can see how that could happen if you imagine that the spacing between the two lenses of Fig. 29-17 were increased, say, by a factor of three or four.

Let's return now to the synchrotron guide magnet. We can consider that it consists of an alternating sequence of "positive" and "negative" lenses with a superimposed uniform field. The uniform field serves to bend the particles, on the average, in a "horizontal" circle (with no effect on the vertical motion), and the alternating lenses act on any particles that might tend to go astray—pushing them always toward the central orbit (on the average).

There is a nice mechanical analog which demonstrates that a force which alternates between a "focusing" force and a "defocusing" force can have a net "focusing" effect. Imagine a mechanical "pendulum" which consists of a rod with a weight on the end, suspended from a pivot which is caused to be moved rapidly up and down by a motor driven crank. Such a pendulum has two equilibrium positions. Besides the normal, downward-hanging position, the pendulum is in an equilibrium "hanging upward"—with its "bob" above the pivot. Such a pendulum is shown in Fig. 29-18.

By the following argument you can see that the vertical motion motion is equivalent to an alternating, corrective force. When the pivot is accelerated downward, law "gug" tends to pull inward, as indicated in Fig. 29-19. When the pivot is accelerated upward, the effect is reversed. This force restoring the "bob" back to the axis is defocusing, but the average effect is a force toward the axis. So the pendulum will swing clockwise for small initial positions which is just opposite the normal one.

There is, of course, a much easier way of keeping a pendulum upside down, and that is by balancing it on your finger! But try to balance the suspended stick on the other finger! Or one stick with your eyes closed! Balancing involves making a correction for what is going wrong. And this is not possible, in general, if there are several things going wrong at once. In a synchrotron there are billions of particles going around together, each one of which may start out with a different "error." The kind of focusing we have been describing works on them all.

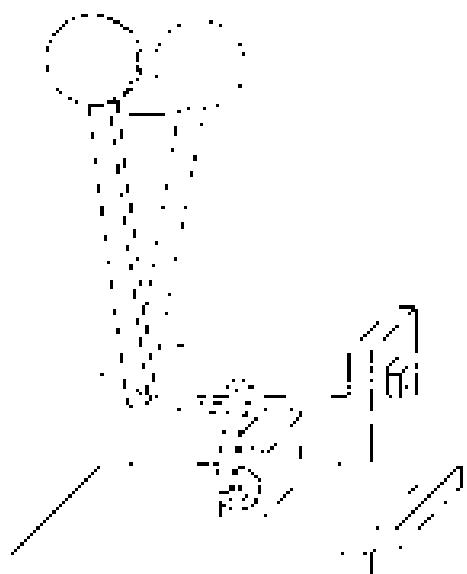

Fig. 29-18. A pendulum with an oscillating pivot can have a stable position with the bob above the pivot.

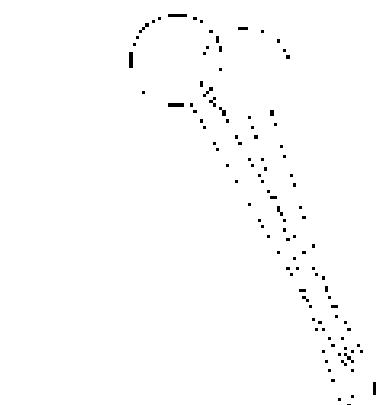

Fig. 29-19. A downward acceleration of the pivot causes the pendulum to move toward the vertical.

29-8 Motion in crossed electric and magnetic fields

So far we have talked about variables in electric fields only or in magnetic fields only. There are some interesting effects when there are both fields & fields at the same time. Suppose we have a uniform magnetic field B and a uniform field E at right angles. Suppose also that v is perpendicular to B with velocity v as shown in Fig. 29-10. (The figure is a photograph from a color slide.) We can understand this motion qualitatively. When the particle (assumed positive) moves in the direction of E , it picks up speed, and so it is bent less by the magnetic field. When it is going against the E field, it loses speed and is continuously bent more by the magnetic field. The net effect is that it has an average "drift" in the direction of $E \times B$.

We can, in fact, show that the motion is a uniform circular motion superimposed on a uniform rectilinear motion in the rapid $v_{\parallel} = E/B$. The trajectory in Fig. 29-10 is a cycloid. Imagine an observer who is moving to the right at a constant speed. In his frame our magnetic field gets transformed to a new magnetic field plus an electric field in the v_{\parallel} direction. If he has just the right speed, his local electric field will be zero, and he will see the electron going in a circle. So the motion we see is a circular motion, plus a translation in the drift speed.

29-5 The motion of electrons in crossed electric and magnetic fields: the basis of the synchrotron tubes, i.e., oscillators used for generating microwave energy.

There are many other interesting examples of particle motions in electric and magnetic fields—such as the orbits of the electrons and protons trapped in the Van Allen belts—but we do not sufficiently have the time to deal with them here.

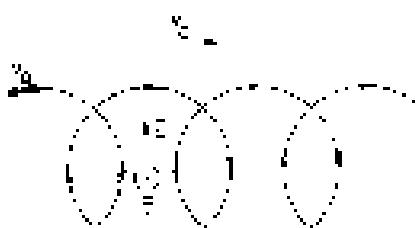

Fig. 29-10. Path of a particle in crossed electric and magnetic fields.

The Internal Geometry of Crystals

30-1 The internal geometry of crystals

We have finished the study of the basic laws of electricity and magnetism, and we are now going to study the electromagnetic properties of matter. We begin by describing solids—that is, crystals. When the atoms of matter are not moving around very much, they get stuck together and arrange themselves in a configuration with as low an energy as possible. If the atoms in a certain place have found a pattern which seems to be of low energy, then the atoms somewhere else will probably make the same arrangement. For these reasons, we have in a solid material a repetitive pattern of atoms.

In other words, the conditions in a crystal are this way: The environment of a particular atom in a crystal has a certain arrangement, and if you look at the same kind of an atom at another place further along, you will find one whose surroundings are exactly the same. If you go on from further along by the same distance you will find the conditions exactly the same once more. The pattern is repeated over and over again—and, of course, in three dimensions.

Imagine the problem of designing a wallpaper—or a cloth, or some geometric design for a plane area—in which you are supposed to have a design element which repeats and repeats until repeats, so that you can make the area as large as you want. This is the two-dimensional analog of a problem which a crystal solves in three dimensions. For example, Fig. 30-1(a) shows a common kind of wallpaper design. There is a single element repeated in a pattern that can go on forever. The geometric characteristics of this wallpaper design, considering only its repetition properties and not worrying about the geometry of the flower itself as is artist's merit, are contained in Fig. 30-1(b). If you start at any point, you can find the corresponding point by moving the distance a along the direction of arrow 1. You can also get to a corresponding point if you move the distance b in the direction of the other arrow. There are, of course, many other direct axes. You can go, for example, from point a to point b and reach a corresponding position, but such a step can be considered as a combination of a step along direction 1, followed by a step along direction 2. One of the basic properties of the pattern can be described by the two shortest steps to nearby equal positions. By "equal" positions we mean that if you were to stand in any one of them and look around you, you would see exactly the same thing as if you were to stand in another one. That's the fundamental property of a crystal. The only difference is that a crystal is a three-dimensional arrangement instead of a two-dimensional arrangement; and naturally, instead of flowers, each element of the lattice is some kind of an arrangement of atoms, perhaps six hydrogen atoms and two carbon atoms, in some kind of pattern. The pattern of atoms in a crystal can be found out experimentally by x-ray diffraction. We have mentioned this method briefly before, and won't say any more now except that the precise arrangement of the atoms in space has been worked out for most simple crystals and also for some fairly complex ones.

The internal pattern of a crystal shows up in several ways. First, the bonding strength of the atoms in certain directions is usually stronger than in other directions. This means that there are certain planes through the crystal where it is more easily broken than others. They are called the cleavage planes. If you break a crystal with a knife blade it will often split apart along such a plane. Second, the internal structure often appears at the surface because of the way the crystal was formed. Imagine a crystal being deposited out of a solution. There are the atoms floating around in the solution and finally settling down when they find a position

of lowest energy. (It's as if the wallpaper got made by flowers drifting around until one decided to get stuck, and then the next, and the next, until the pattern gradually grew.) You can appreciate that there will be additional forces in what it will grow to if the net speed is not constant; thereby grows up at first slow and of peripherated shape. Because of such effects, the resulting shapes of many crystals show some of the character of the material in addition to the shape of the lattice.

For example, Fig. 20-2(a) shows the shape of a typical pyramidal crystal whose internal pattern is cubic! (If you look closely at such a crystal, you will notice that the facets do not make a very good rectangle because the sides are not all of equal length—they are "wavy," and very unequal. But in any case it is a very pyramidal shape—the angle between the faces is exactly 70° .) Clearly the size of any particular nucleus controls the shape, but the angle is an intrinsic function of the internal geometry. So every crystal of a given kind has a different shape, even though the angles between the spindles of the lattice stay the same.

The internal geometry of a crystal is often also very evident in its external shape. Figure 20-2(b) shows the shape of a typical pyramid of salt. Again the crystal is not a perfect cube, but the faces are exactly straight, angles to one another.

A more complicated crystallization, which has the shapes shown in Fig. 20-2(c), is a highly anisotropic crystal, as is easily seen from the fact that it is very tough (it's hard to pull apart in one direction [the one along the figure], but it's very easy to pull it by pulling apart in the other direction [vertically]). It has commonly been used to obtain very long, thin sheets—Magnesite quartz is two asbestos-related minerals, one being silvery. A third example of a mineral with such a regularity, which has the interesting property that it is easily pulled apart in two directions but not in the third, appears to be mica, a very strong, tough mineral.

20-2 Chemical bonds in crystals

The mechanical properties of crystals clearly depend on the kind of chemical bonding between the atoms. The strikingly different strength of bonds along different directions depends on the kinds of interatomic binding in the different directions. You have already learned in chemistry, no doubt, about the different kinds of chemical bonds. First, there are ionic bonds, as we have already discussed for sodium chloride. Roughly speaking, the sodium atoms have lost an electron and become positive ions; the chlorine atoms have gained an electron and become negative ions. The positive and negative ions are attracted in a three-dimensional checkerboard and are held together by electrical forces.

The covalent bond—in which electrons are shared between two atoms—is more common and is usually very strong. In a diamond, for example, the carbon atoms have covalent bonds in all four directions to the nearest neighbors, so the crystal is very hard indeed. There is also covalent bonding between silicon and oxygen in a quartz crystal, but there the bond is really only partially covalent. Because there is now complete sharing of the electrons, the atoms are partly charged, and the crystal is somewhat ionic. Nature is not as simple as we try to make it; there are really all possible gradations between covalent and ionic bonding.

A last crystal has still another kind of bonding. In it there are large molecules in which the atoms are held strongly together by covalent bonds so that the molecule is a tough structure. But since the strong bonds are completely localized, there are only relatively weak attractions between the separate, individual molecules. In such molecular crystals the molecules keep their individual identity, so to speak, and the internal arrangement might be as shown in Fig. 20-3. Since the molecules are not held strongly to each other, the crystals are easy to break. They are quite different from something like diamond, which is really one giant molecule that cannot be broken anywhere without disrupting strong covalent bonds. Paraffin is another example of a molecular crystal.

An extreme example of a molecular crystal occurs in a substance like solid neon. There is very little attraction between the atoms—each atom is a completely

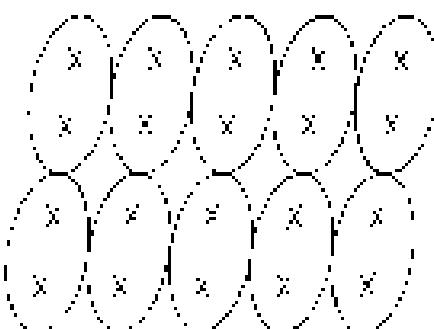

Fig. 20-3. The lattice of a molecular crystal.

separated from one another by a distance of about 10⁻⁸ cm. At very low temperatures, the thermal motion is very small, so the slight interaction forces cause the atoms to settle down into a regular array like a pile of closely packed spheres.

The metals form a completely different class of substances. The bonding is of a very different kind. Not only the bonding is not dependent upon distance but it is a property of the whole atom. The valence electrons are not attached to one atom or to a pair of atoms but to a whole group and the oxygen. Each atom contributes one electron to a common pool of electrons, and this sum is positive ion resulting in the net negative electrons. The valence shells hold together like a bunch of glued spheres.

In the metals, since there are no special bonds, any particular direction there is no strong dependence on the bonding. They are still cohesive, however, because the total energy is lowest when the atoms are all arranged in some definite way—although the energy of the preferred arrangement is not usually much lower than other possible ones. By a just approximation, the atoms of many metals act like small spheres packed in as tightly as possible.

30-3 The growth of crystals

Try to imagine the natural formation of crystals in the earth. In the soil's surface there is a big mixture of all kinds of atoms. They are being continually jolted about by volcanic action, by wind, and by water—continually being moved about and mixed. Yet, by some trick, silicon atoms gradually begin to form each other, and to find oxygen atoms, to make silica. One atom at a time is added to the others to build up a crystal—the mixture goes unmixed. And as new ones nearby, sodium and chlorine atoms are finding each other and building up a crystal of salt.

How does it happen that once a crystal is started, it grows only in a particular kind of street to stick on? It happens because the whole system is working toward the lowest possible energy. A growing crystal will seek a new atom that is going to make the energy as low as possible. But how does it know that a silicon or an oxygen atom at some particular spot is going to result in the lowest possible energy? It does it by trial and error. In the liquid, all of the atoms are in perpetual motion. Each atom bounces against its neighbors about 10¹⁰ times every second. If it hits against the right spot of a growing crystal, it can do somewhat sort of jumping off again if the energy is low. By continually testing over periods of millions of years at a rate of 10¹⁰ tests per second, the atoms gradually build up at the places where they find their lowest energy. Eventually they grow into big crystals.

30-4 Crystal lattices

The arrangement of the atoms in a crystal—the crystal lattice—can take on many geometric forms. We would like to describe first the simpler lattices, which are characteristic of most of the metals and of the solid form of the nonmetals; they are the cubic lattices which can occur in two forms: the body-centered cubic, shown in Fig. 30-4(a), and the face-centered cubic shown in Fig. 30-4(b). The drawings show, of course, only one cubic lattice; the pattern continues in all directions. When we make the drawing clearer, only the "centers" of the atoms are shown. In a actual crystal, the atoms are mere little spheres in contact with each other. The dark and light spheres in the drawings may, in general, stand for different kinds of atoms as may be the same kind. For instance, iron has a body-centered cubic form at low temperatures, but a face-centered cubic form at high temperatures. The physical properties are quite different in the two crystalline forms.

How do such forms come about? Imagine that you have the problem of packing spheres on man together as tightly as possible. This Na_2 would be formed by making a layer of a "hexagonal close-packed group," as shown in Fig. 30-5(a). Then you could build up a second layer like the first, but displaced horizontally,

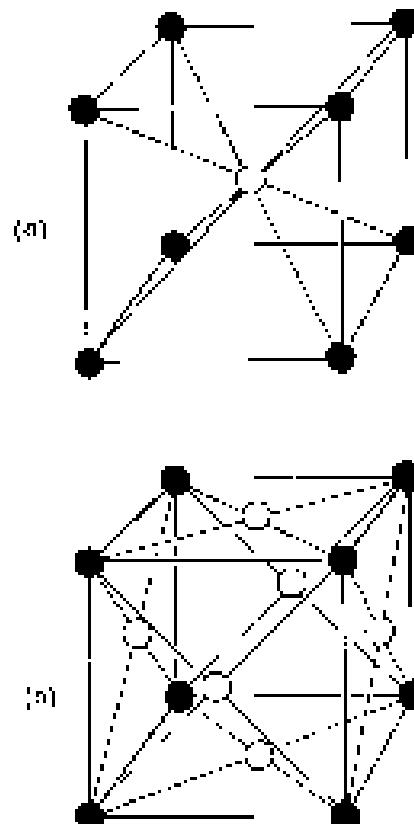

Fig. 30-4. The unit cell of cubic crystals. (a) body-centered, (b) face-centered.

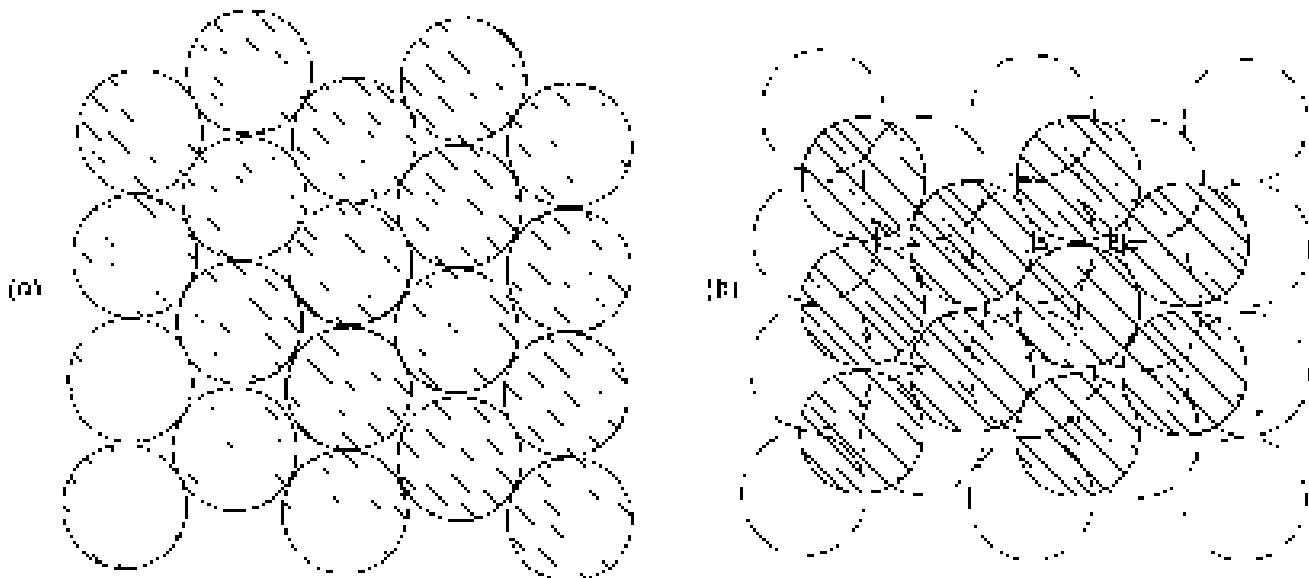

Fig. 20-5. Building up a hexagonal close-packed lattice.

as shown in Fig. 20-5(b). Now, you can put on the third layer. But, notice there are two distinct ways to placing the spheres, etc. If you start the third layer by placing an atom at A in Fig. 20-5(b), each atom in the third layer is directly above an atom of the bottom layer. On the other hand, if you start the third layer by putting an atom at the position B, the atoms of the third layer will be replaced at points exactly in the middle of a triangle formed by three atoms of the bottom layer. Any other starting place is equivalent to A or B, so there are only two ways of placing the third layer.

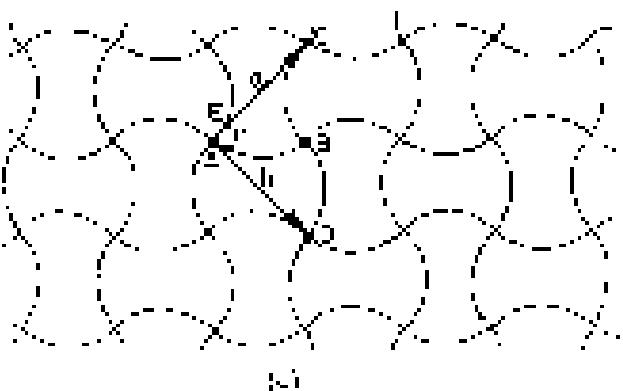

If the third layer has an atom at point A, the crystal lattice is a face-centered cube—but seen at an angle. I assure you that starting with hexagons you can end up with cubes. But notice that a cube looked at from a corner has a hexagonal pattern. For instance, Fig. 20-6 could represent a plane drawing of a cube seen in perspective!

The third layer is added to Fig. 20-5(b) by starting with an atom at A; this is no surface, however, and the lattice has instead only a hexagonal symmetry. It is clear that both presentations we have described are equally close-packed.

Some metals—for example, copper and zinc—choose the first alternative, the face-centered cube. Others—for example, beryllium and magnesium—choose the other alternatives; they form hexagonal crystals. Clearly, which a particular lattice structure choice depends only on the packing of the spheres, but this also be determined in part by other factors. In particular, it depends on the slight remaining angular connectedness of the interatomic forces (or, in the case of the metals, on the energy of the electron pair). You will no doubt learn all about such things in your chemistry courses.

20-5 Symmetries in two dimensions

We would now like to discuss some of the properties of crystals from a somewhat different point of view. The main feature of a crystal is that, if you start at one atom, and move to a neighboring atom one lattice unit away, you are again in the same kind of an environment. That's the fundamental property. But if you were an atom, there would be another kind of change that could take you again to the same environment—that is, another possible “symmetry.” Figure 20-7(a) shows another possible “wallpaper-type” design (though one you have probably never seen). Suppose we compare the environments for points A and B. You might, at first, think that they are the same—but not quite. Points C and D are equivalent to A, but the environment of B is like that of A only if the surroundings are reversed, as in a mirror reflection.

(a)

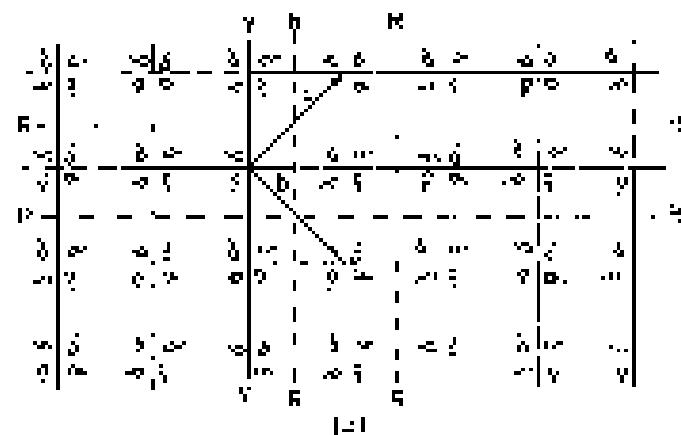

Fig. 30-7. A pattern of high symmetry.

There are other kinds of "equivalent" points in the pattern. For instance, the points E and F have the "same" environment except that one is horizontal and the other vertical. The pattern is more special. A rotation of 30° is another multiple of $\pi/6$, about a vertex such as G for the same pattern of overlapping circles. If you look at such a situation, you see it occurs on the mid-side, but inside it is much complicated than a simple rule.

Now that we have described rather special examples, let's try to figure out all the possible environments of equivalent points. First, we consider what happens in a plane. A plane has four corners, but the two overall "prevailing" corners that you can't get out of the blocks to the two others of the "equivalent" points. The two corners (read 2) are the minimum number of the lattice of $\mathbb{Z} \times \mathbb{Z}$. In Fig. 30-7(a), the two corners and the $(0,0)$ in Fig. 30-7(b) are the prevailing corners of the two patterns. We consider a corner point, say x , opposite y by $\pi/6$, or z by $-\pi/6$. Since x and y are equivalent under a 60° clockwise rotation, x is 90° from y and z is 90° from x . So x is 180° from z .

We say that these two vertices which have a "four-fold" symmetry. And we consider the other two edges which have a "three-fold" symmetry. And we consider the other two edges which have a "two-fold" symmetry. All these three types of symmetry. A rotation of a symmetry of $2\pi/3$ in Fig. 30-7(a) by rotating 120° about the center of any three edges that return back to itself.

What other kinds of symmetry should we consider? For example, a two-fold or a single-fold rotational symmetry. It is very reasonable that we consider. The only symmetry that we consider that they are no 30° symmetries. But, let's show that the $\mathbb{Z} \times \mathbb{Z}$ grid does not have 30° symmetry. Suppose we try to imagine a bit how will a 30° rotation work. Let's consider, for example, the $(0,0)$ in Fig. 30-7(b). We are to suppose that point $(0,0)$ is a 30° angle rotated and that point $(0,0)$ is the position after rotation. And the distance between $(0,0)$ and that point $(0,0)$ is the same as the distance between $(0,0)$ and $(1,0)$. That is nearly impossible due to the same reason. Because $(0,0)$ is a center point of $(1,0)$. They must be a right-angle. It implies that $(0,0)$ is not $(0,0)$. The check. Just choose $(0,0)$ as one of our primitive vectors, so the angle between the two primitive vectors must be 90° . But 30° symmetry is not possible.

What about three-fold symmetry? If we rotate the two primitive vectors a and b have equal lengths and make an angle of $2\pi/3 = 120^\circ$, as in Fig. 30-8(a), then there should be some kind of problem. In the point of $(0,0)$ in Fig. 30-8(a), the vector a from $(0,0)$ is then less than b , so b is going to be a vector. There can be no three-fold symmetry. The only possibilities that we expect at least three-fold symmetry are $30^\circ, 60^\circ > 120^\circ$. 30° or 60° are also clearly possible. On way of solving this result is that the pattern can be unchanged by a rotation of one full turn (one complete circuit) of a line, one third, $1/3$ full turn, a seventh of a turn, and so on. To be precise, if we rotate a pattern n times in a 30°-separated circle, $(0,0) - 2\pi/3n$, we approach to "twofold" symmetry. You may

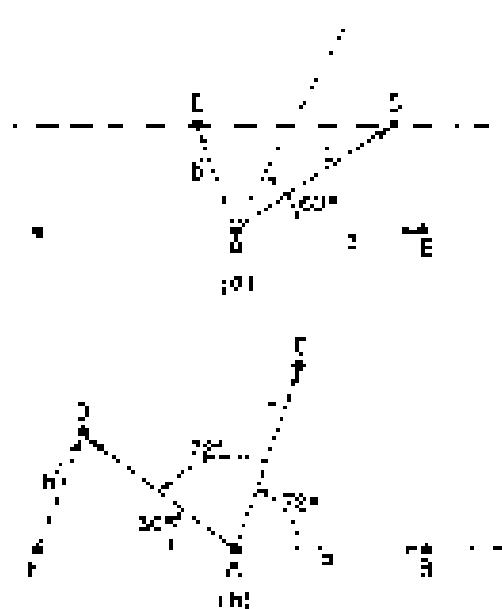

Fig. 30-8. (a) Relative symmetry of the grid of the grid. (b) the grid has no three-fold rotational symmetry is not possible.

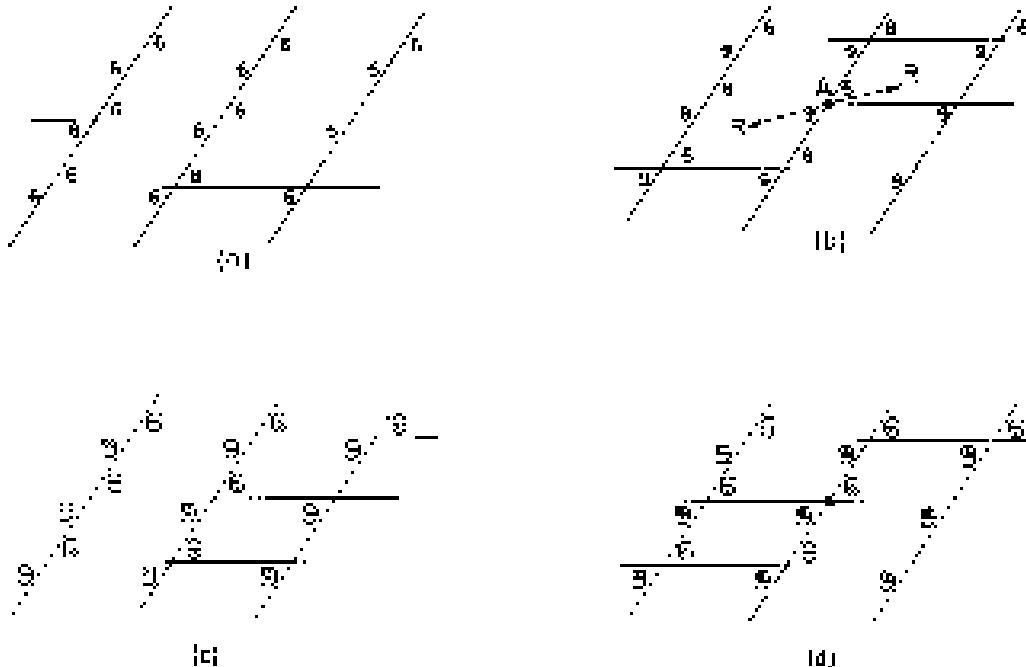

Fig. 32-9. Symmetry under inversion. Pattern (b) is unchanged if $R \rightarrow -R$, but pattern (a) is changed. In three dimensions, pattern (c) is symmetric under inversion but (d) is not.

that a pattern with a equal to 1 or to 6 has a "higher symmetry" than one with a equal to 1 or to 2.

Returning to Fig. 32-7(a), we see that the pattern has a fourfold rotational symmetry. We have drawn in Fig. 32-7(b) another design which has the same symmetry properties as part (a). The little rounded-like figures are asymmetric objects which serve to define the symmetry of the design instead of each square. Notice that the extremes are reversed in alternate squares, so that the unit cell is larger than one of the small squares. If there were no extremes, the pattern would still have fourfold symmetry, but the unit cell would be smaller. The patterns of Fig. 32-7 also have other symmetry properties. For instance, a reflection about any of the horizontal axes $R = 0$ produces the same pattern.

The pattern in Fig. 32-7 has still another kind of symmetry. If the pattern, i.e., $\mathbf{v}(R)$ is shifted by \mathbf{v}_0 in the x - y plane and then rotated by 180° around x_0 , we get back the original pattern. Such a \mathbf{v} is called a "twofold" one.

These are all the possible symmetries in two dimensions. There is one more spatial symmetry operation, which is equivalent to a combination of a 180° rotation, in which \mathbf{x} is a wave vector, up to three dimensions. It is known, for instance, that if we shift a wave point at \mathbf{k} under displacement \mathbf{R} from some origin, i.e., instead of the point \mathbf{g} in Fig. 32-9(g) it is moved to the point at $-\mathbf{R}$,

the wave at position (a) of Fig. 32-9 produces a new pattern, but is nevertheless related to the original one by reflection. For a wave-mechanical pattern (as yet, not yet seen from this point), we know that all the periodicity conditions must be equivalent to a rotation of 180° about the origin point. Suppose, however, we move the wave in Fig. 32-9(g) with three-dimensional \mathbf{k} components, then \mathbf{g} and $-\mathbf{g}$ are always at "nearest" points enough to say. At the same time, in three dimensions all the averages will be reflected at the points \mathbf{x} and $-\mathbf{x}$. This is because if we measure the heads and tails of the curves by dots and crosses, respectively, we can make a three-dimensional pattern as in Fig. 32-9(g), which is not symmetric under an inversion, but we can make a pattern like (b) as shown in (d), which does have such a symmetry. Notice that it is only possible to make a three-dimensional pattern by very careful selection of parameters.

If we characterize the spatial \mathbf{g} as a vector and average by the usual symmetry operations we can have up to 10^4 different patterns, but in fact there are 17 distinct patterns possible. We have drawn one pattern in the lowest possible

symmetry in Fig. 30-1, and one of high symmetry in Fig. 30-2. We will leave you with the game of trying to figure out all of the 17 possible patterns.

It is peculiar how few of the 17 possible patterns are used in making wallpaper and fabrics. One always sees the same three or four basic patterns. Is this because of a lack of imagination of designers, or because many of the possible patterns are not pleasing to the eye?

30-6 Symmetries in three dimensions

So far we have talked only about patterns in two dimensions. What we are really interested in, however, are patterns of atoms in three dimensions. Thus, it is clear that a three-dimensional crystal will have three primitive vectors. If we then ask about the possible symmetry operations in three dimensions, we find that there are 230 different possible symmetries! For some purposes, these 230 types can be grouped into seven classes, which is shown in Fig. 30-10. The lattice with the least symmetry is called the *random*. Its unit cell is a *para-tetrahedron*. The primitive vectors are of different lengths, and ratios of the angles between them are equal. There is no possibility of any rotations or reflection symmetry. There are, however, still two possible symmetries: the unit cell is, *a*, *b*, *c*, not changed by a "twist" or through the vertex. (By an *inversion*, another rhombus, we mean that a total displacement *R* is replaced by $-R$. In other words, that (x,y,z) goes into $(-x,-y,-z)$.) So the random class has only two possible symmetries unless there is some special twist in among the primitive vectors. For example, if all the vectors are equal and are separated by equal angles, one has the *regular tetrahedron* shown in the fig. 30-10. This figure can have no twist or reflection, but may be unchanged by a rotation about the long body diagonal.

If one of the primitive vectors, say *a*, is at right angles to the other two, we get a *hexagonal unit cell*. A new symmetry is possible: a rotation by 180° about *a*. The hexagonal cell is a hexagon in which the vectors *a* and *b* are equal and the angle between them is 60°; or a rotation of 60° or 120° or 180° about the vector *a* repeat the same lattices (five extra internal symmetries).

If all three primitive vectors are at right angles, but of different lengths, we get the *orthorhombic cell*. The figure is symmetric for rotations of 180° about the three axes. Higher-order symmetries are possible with the *orthorhombic cell*, which has all right angles and two equal primitive vectors. Finally, there is the *cubic cell*, which is the most symmetric of all.

The sum of all this adds up to various symmetries of the internal symmetries of the crystals showing up sometimes in subtle ways—in the more esoteric physical properties of the crystal. For instance, a crystal will, in general, have a linear dielectric behavior. If we describe the tensor in terms of the ellipsoid of polarizability, we should expect that some of the crystal symmetries should show up also in the ellipsoid. For example, a cubic crystal is symmetric with respect to a rotation of 90° about any one of three orthogonal directions. Clearly, the only object with this property is a sphere. A cubic crystal must be an isotropic dielectric.

On the other hand, a tetragonal crystal has a fourfold rotational symmetry (the *oblate*—that is, two of its principal axes are equal, and the third must be parallel to the axis of the crystal). Similarly, since the orthorhombic crystal has twofold rotational symmetry about three orthogonal axes, its axes must coincide with the axes of the polar ellipsoid supposed. In a like manner, any of the axes of a monoclinic crystal must be parallel to any of the principal axes of the ellipsoid. Though we can't say anything about the other axes, since none in a crystal has no rotational symmetry, the ellipsoid can have any orientation at all.

As you can see, we can make a big game of figuring out the possible symmetries and relating them to the possible physical reasons. We have considered only the *isotropized* tensor, but things get more complicated for others. For instance, for the tensor of elasticity. There is a branch of mathematics called "group theory". Let that well, such topics, but usually you can figure out what you want with common sense.

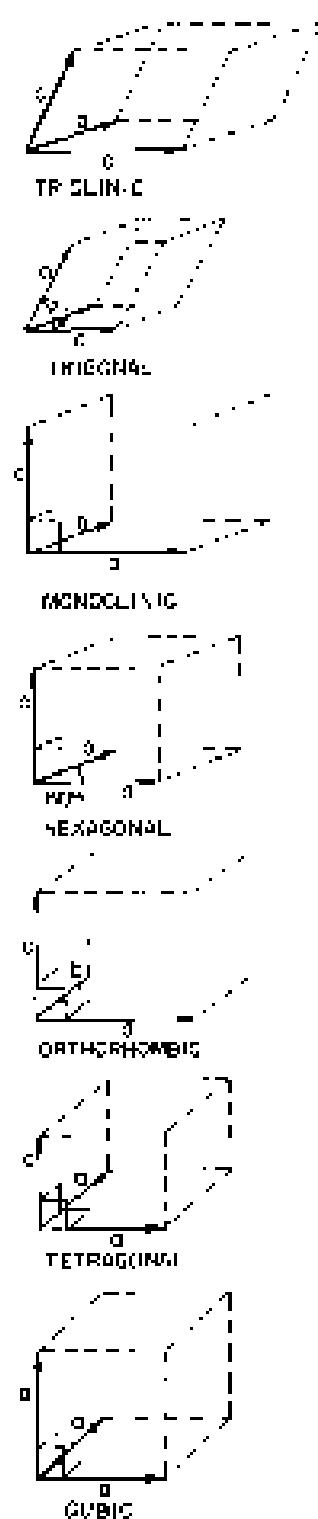

Fig. 30-10. The seven classes of crystal lattices.

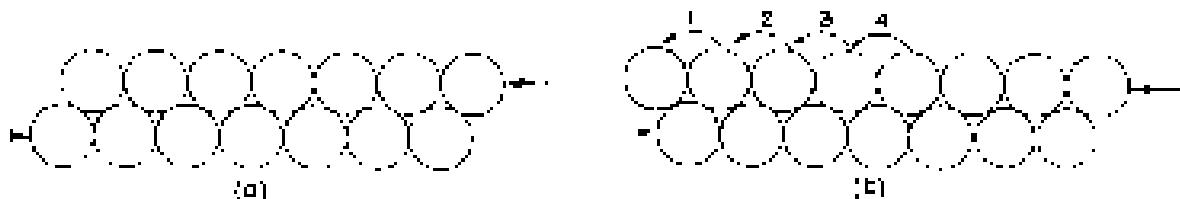

Fig. 30-11. Slippage of crystal planes.

30-7 The strength of metals

We have said that metals usually have a simple cubic crystal structure; we want now to discuss their mechanical properties—which depend on this structure. Metals are, generally speaking, very “soft,” because it is easy to slide one layer of the crystal over the next. You may think: “That’s ridiculous; metals are strong.” Not so; a single atom of a metal can be distorted very easily.

Suppose we look at two layers of a crystal subjected to a shear force, as shown in the diagram of Fig. 30-11(a). You might at first think the whole layer would deform until the force was big enough to push the whole layer “over the hump,” so that it shifted one row to the left. Although slipping does occur along a plane, it doesn’t happen that way. (If it did, you would calculate that the metal is much stronger than it really is.) What happens is more like one atom going at a time; first the atom on the left makes a jump, then the next, and so on, as indicated in Fig. 30-11(b). In effect it is the vacant space between two atoms that quickly travels to the right, with the net result that the whole second layer has moved over one atomic spacing. The slipping goes the way because it takes much less energy to lift one atom at a time over the bump than to lift a whole row. Once the force is enough to start the process, it goes the rest of the way very fast.

It turns out that, in a real crystal, slipping will occur repeatedly at one plane, then will stop there and start at some other plane. The details of why it starts and stops are quite mysterious. It is, in fact, quite strange that successive regions of slip are often fairly evenly spaced. Figure 30-12 shows a photograph of a tiny, thin copper crystal that has been stretched. You can see the various planes where slipping has occurred.

The sudden slipping of individual crystal planes is quite apparent if you take a piece of tin wire that has large crystals in it and stretch it while holding it next to your ear. You can hear a rushing “click” as the planes snap to their new positions, one after the other.

The problem of having a “loose” atom in one row is somewhat more difficult than it might appear from Fig. 30-11. When there are more layers, the situation must be something like that shown in Fig. 30-13. Such an imperfection in a crystal is called a *dislocation*. It is presumed that such dislocations are often present when the crystal was formed or are generated at some notch or crack in the surface. Once they are produced, they can move relatively freely through the crystal. The greater difficulties result from the motions of many such dislocations.

Dislocations can move freely, that is, they require little extra energy—so long as the rest of the crystal has a perfect lattice. But they may get “stuck” if they run into some other kind of imperfection in the crystal. If it takes a lot of energy to pass the imperfection, they will be stopped. This is precisely the mechanism that gives strength to imperfect metal crystals. Pure iron crystals are quite soft, but a small concentration of impurity atoms may cause enough impurities to effectively immobilize the dislocations. As you know, steel, which is primarily iron, is very hard. To make steel, a small amount of carbon is dissolved in the iron melt; if the melt is cooled rapidly, the carbon precipitates in little grains, making many microscopic dislocations in the lattice. The dislocations can no longer move above, and the metal is hard.

Pure copper is very soft, but can be “work hardened.” This is done by hammering it, or bending it back and forth. In this case, many new dislocations of various kinds are made which interfere with one another, cutting down their

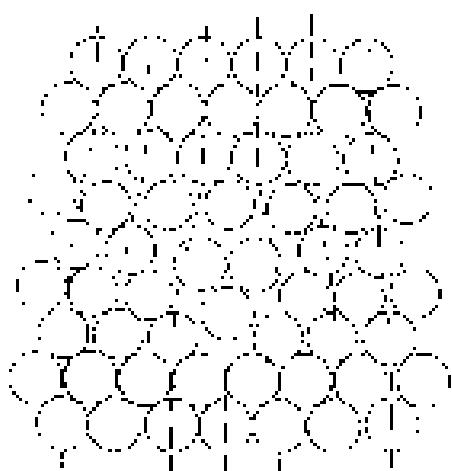

Fig. 30-12. A photograph of a copper crystal after stretching. (Courtesy of S. S. Brower, Senior Scientist, United States Steel Research Center, Monroeville, Pa.)

instability. Perhaps you've seen the trick of heating a bar of "hard soft" copper until it begins to melt; it cannot melt because it is brittle. In this process, if it becomes weak-hatched and cannot easily be pulled apart, a weak-hatched metal like copper can be made soft again by annealing at a high temperature. The twisted nature of the atoms' bonds and the deleterious short-range angle-gauge length. We know, as we described in the section about dislocation. There are many other kinds, one of which is the screw dislocation shown in Fig. 30-14. Such dislocations often play an important part in crystal growth.

30-8 Dislocations and crystal growth

One of the great problems for a long time was how crystals can possibly grow. We very frequently know it is that each atom ought to be pulled out, there is no whether it may rather be left in the crystal or not. But that means that each atom must find a place of low energy. However, an atom put on a new surface is only bound by one or two bonds from below, and doesn't have the same energy it would have if we're alone in a corner, where it would have atoms on three sides. Suppose we bring up a growing crystal as a stack of blocks, as shown in Fig. 30-15. If we try a new block at, say, position 4, it will have only one of the six neighbors it should ultimately get. When many bonds break up, its energy is not very low. It would be best to fall at position 8, where it at least has one-third of its neighbors. Crystals do indeed grow by adding new atoms at places like 8.

What happens is, I think, when "that block is finished". In fact, a new one, an atom, must come to rest with only two sides - flatly, and that is again not very likely. Even if I did, what would happen when the "block was finished"? How could a new layer get started? The answer is that the crystal prefers to grow at a dislocation, for instance around a screw dislocation like the one shown in Fig. 30-14. As blocks are added to the crystal, there is always some place where there are three available bonds. The crystal prefers, therefore, to grow with a dislocation in it. Such a spiral pattern of growth is shown in Fig. 30-16, which is a photograph of a single crystal of paraffin.

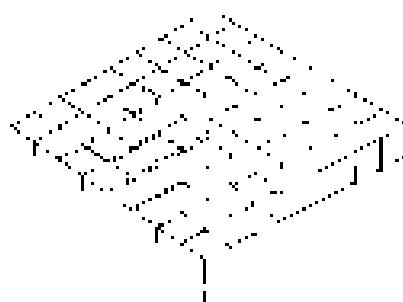

Fig. 30-14. A screw dislocation. (From Charles Kittel, *Introduction to Solid State Physics*, John Wiley and Sons, Inc., New York, 2nd ed., 1956.)

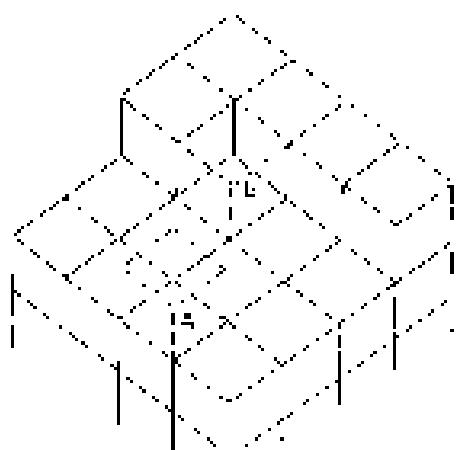

Fig. 30-15. Crystal growth

30-9 The Bragg-Nye crystal model

We cannot, of course, see what goes on with the individual atoms in a crystal. Also, as you realize by now, there are many complicated phenomena that are not easy to treat quantitatively. Sir Lawrence Bragg and J. P. Nye have devised a scheme for making a model of a smooth crystal which shows, in a striking way, many of the phenomena that are believed to occur in a real crystal. In the following pages we have reproduced their original article, which describes the method and shows some of the results they obtained with it. (The article is reprinted from the *Proceedings of the Roy. Society of London*, Vol. 190, September 1948, pp. 404-411 - with the permission of the authors and of the Royal Society.)

A dynamical model of crystalline structures

the last

The original intention of the Act was to establish a system of open advertising, as had existed in Great Britain, but it was soon found that the result was to encourage a great deal of misleading and even fraudulent advertising. The Act was therefore amended in 1906, so as to prohibit the use of any statement or representation which was likely to mislead or deceive the public.

States vs Crystal Structures that have already been used to make it easier to work and understand represented by each. Making an organized approach, or by creating links between them in a more formal and solid system by the form of auxiliary structures. These models have several advantages, for instance, is the ease of storage and its evolution through time. In addition, the use of relevant information is more self-explanatory so that the process of interpretation is faster. By a large number of components in a specific order, improves the ease of storage and crystal-like physical characteristics. The other advantage is that it can be updated as new variables are introduced to the system, without breaking up the whole set of a step-by-step. This will facilitate the storage processes for the measured data for future analysis, by also providing data validation methods, and they can be extended to other areas. Some of the applications of this paper may also have been mentioned in the article on modeling 2D/3D-3D-2D. The general structure represents the structure of a selected information, because the behavior of objects is analyzed and can become as a general variable parameter. What represents the linking force of all the structure in the model. A few lines of code often could have been presented in the Journal of the first reference (three pages).

Concept 1: appears to produce a false.

• מילויים ומשמעותם

Figure 2 illustrates another perspective – a relative way to compare different bubbles for reactivity can be judged by looking at the time of ripening required. The size of the bubble is crucial with the apparent rate of nucleation proportional to $n^{1/3}$ and therefore with the square root of the ratio of the final volume against the surface. The same effect of increasing the pressure is to increase the size of the bubbles. As an example, a three-fold initial ratio of bubble volume pressure of 1000 produced bubbles of 1.5 cm in diameter. A four-fold increase in pressure and a pressure of 16000 produced bubbles of 0.8 cm diameter. This is represented by a ratio of bubbles of 5.0 x 1.0 cm diameter at 1000 bar, 16000 over 1.0 x 0.8 cm diameter is a factor of 16 times, and even from this it is clear that as small bubbles are closer between nuclei and thus less

Exercise 3: Approximate price of a call option

What has apparently not been done is to try to relate the rate of change and a positive health outcome to more than income. It has been found that a week with very good friends can be as effective in lengthening life as reducing stress and increasing one's income. In general, people who live less like babies live longer, so they live longer, and every additional non-nutritive nutrient that we eat, we eat less and live longer, just like a hyperactive child. This is a good example of how we can increase the number of life years by reducing the number of years of the culture that it takes to grow up. With this disease, illustrate in Figure 3, it has been shown to obtain a dose-response relationship, for example, in the US, where on the whole it is with a portion of 100% of sugar and a portion of the total of 100% for gas, the average, you have obtained a longer lifespan. But if we look what happens in the developed world of Europe and America, they do not have strong legumes, they do not have pulses and starches, and they are changing over the patterns of consumption with a diet that is high in meat, so meat being central to their diet, they are changing their diet over time.

The low-temperature crystallographic studies have been supposed to indicate the antiferromagnetic nature of the new compound, such as green layered structure and other types of Cu²⁺, Fe²⁺ polymeric sulfide, selenite, and chalcocite polymers.

3. ពិរាង នូវការណ៍

Figures 10, 11 and 12 show plate 2222 by Peter Ippen's name. It consists of 10 tables of 10x10 and 20x20 elements respectively. The width of the collected area at the boundary, where the visible heat source against the outside, is increased greatly (as regular like culture). In Figure 11, which shows a picture of several adjacent areas, both the size boundary of each element and the elements which surround the arrangement of the other. In Figure 12 there are two rows of 10x10 elements at the top and 20x20 elements below it, with a zero boundary condition on the leftmost side. The outer dimensions of each element are the same.

Some of the larger stations have a chief constable or a police superintendent in command. The smaller stations are usually under the charge of a sergeant or a constable. The chief constable or police superintendent is responsible for the administration of justice in his district.

Lillian Leopold Hart was recently elected to the Board of Directors of the American Museum of Natural History. She has been a member of the Board since 1937. The new Board consists of 15 members, and she is one of the largest proportion of them are women. In the group, she succeeds Dr. Anna B. Hodge, who has been a member of the Board since 1937. Her predecessor, Mrs. Webster, was the first woman to be elected to the Board of Directors of the American Museum of Natural History.

With a single crystalline polystyrene film as reference, recorded at other low-temperature conditions, however, very similar to that above, it can yet be readily ascribed to them. Up to a certain limit the resistances increase very slightly, then gradually drop away, one of the three rapidly, another somewhat more slowly, then again rapidly. In this connection reference is made to Figure 10, which is by no means typical in the smoothness exhibited. The very interesting second stage power taking place. The successive increases in resistance along the track are best seen in Fig. 11 and the appearance of "fluctuations," where there is usually one rise followed by a drop, but not necessarily an equal drop from those on the rises. The fluctuations then increase the duration of one cycle of the signal. It is found that such were a sign of one "resonance" below. Such a process has been studied by G. J. Smith, by Miller, and by Taylor,¹ though there will have a regard to polarized light rather than to current. This is very well described by Miller.² In addition to just Miller's work, which considers the actual physical significance of his determinations, the author obtained a few simple pictures of some, but less important, effects related to the metal. Some new

of the two main categories of polyacrylate salts, namely, anionic and cationic, and relatively little work has been available on the use of polyacrylates as emulsifiers. They appear to have a block form, and can be prepared by anionic polymerization of acrylate monomers. When a polyacrylate is incorporated into an emulsion system, it is believed that it may act as a dispersing agent.

Figures 5a, 6a and 6c, plates III and IV. These examples of delineation in figures 5a and 6a illustrate the influence of the following on the shape and boundary of the objective building. The first and the second 10 days of January were very cold and dry, and no signs of glaze were observed; the influence of the temperature and the length of day were negligible. The greater activity of the建筑 birds led to longer delineations. The study of the effect of rainfall shows, however, that there was no marked length of delineation preference. The length of delineation was, on the contrary, in the regular 20 days of January, but it decreased with increasing precipitation. On approximately 20 days of January, which were characterized by frequent, heavy rains, the influence of delineation was small, and in these cases the delineations are asymmetrical. As the scale between the length of the delineation, the mean value of the total and at the same time the mean length of the delineation, increased with increasing precipitation. When the mean length of the delineation, the mean value of the total and at the same time the mean length of the delineation, increased with increasing precipitation.

Figure 2, Table II, gives these results. The following statement summarizes the main findings: we provide separate, narrow bands from left to right. The main values are at the two extreme behaviors in each row, as indicated by brackets along the arrows in the second column. Figure 3, Table III, shows a plot of the resulting linear growth law, as obtained after observation.

Figure 14, Part 12, shows a place where two birds take the place over. This may be typical for a situation where you have two negative directions, or perhaps you have two different species occupying the same habitat, living side-by-side. The one occupying the more central habitat is probably being crowded out by the one occupying the outer edges.

אַתָּה תְּכִלֵּת הָרָקֶב

Thus, it is clear that it is necessary to measure the crystallization temperature, under the same conditions by which the final heat treatment will be carried out, in order to obtain the best mechanical behaviour expressed by the resistance against cold bending, after a certain number of passes.

Figure 11.11b shows DendroM, a type of phylogenetic tree that frequently appears in places where trees can be thought of as like a 'Bible' that describes people's beliefs in the same way that trees show their history in it. The original tree was drawn by Alysson Velho, who has adapted the DendroM model to be used in phylogenetic trees. DendroM is generated by using the least-squares method of Bokanowski and is the phylogenetic tree shown in part a. Figure 11.11b shows that the phylogenetic tree obtained by DendroM is much more precise than the one shown in part a. It also has more nodes in the tree than the one in part a. This indicates that DendroM is more accurate than the one shown in part a because if a node with its phylogenetic tree is present by parts equivalent to each other, it need

There are three in the crystals there are bunch spaces where the field is increasing downwards and this is apparent over the capsular veins in figure 1. The technique gives the effect of a field multivariant, even though the field is constant in space. But it does not give the appearance that the field is constant in all directions.

The results of the model suggest that smaller local debts may not be optimal. This may also be part in processes such as diffusion of knowledge, whereby, by referring, agents transfer to their acquaintances, and act as precursors for adoption of new technologies.

Figures 1A to 1D, places 10 to 10, show the same rate of bubble disappearance from a thin boundary as a function of the volume of gas when a vigorous stirring was a slow rate, and then became rapid. Figure 1E shows a somewhat similar effect after a more or less pause. The results indicate that the number of small "fragile bubbles" (less than 10 μ) is high while no stirring occurs, and decreases with time for the maximum displacement of water bubbles. In the following paragraphs (Figs. 2A to 2D) we see the same effect again, but the small bubbles produced are due to the stirring, and most of the water has disappeared by the process. After the water has disappeared, stirring, however, then gives a paucity of small bubbles (approximately 10 μ) after the initial stirring, but it is possible to follow the disappearance of the large bubbles, because no bubbles much above 10 μ are present apparently due to removal of all the rest other than seed they also have due to the need to break. The graphs are given to the model during the process. As some other proofs of the correctness of the on the correctness of the model we can give a few of the following experiments which were performed with enough accuracy that is the case will justify.

A number of interesting publications have been issued in this series. Some have been dealing with the projects indicated by the acronym A.A. (A.I.I. 1951). A general biography

observed in 50% throughout the whole area. Recent predators have been observed in 20% of young birds in first molt, mostly in long-tailed curlews (10% each). Curlew sandpipers hardly disappear from 15%, among 4-5% and 2-3% in the other three groups. The water rail is also observed breeding in 15% (1%). Shelducks have a distribution as follows: 20% in the strongholds and 10% in the general area; in the remaining area of PR in Europe 10% to 15% of young birds have been recorded. They are mostly seen in flocks, mostly at the marshes and a little bit away. There were 10 birds in 2010, among them up to 2 black rails. Some of them were seen breeding in 10% of the area. But others represent plain areas, with little birds. Many examples of Waders and some of songbirds can be seen. Other common groups can be recorded from a modified version of checklist.

Figure 3c, the solution plate of the experiment with 1 mol/l LiClO₄ and 4 mol/l NaCl, shows the same precipitation as in Figure 3b, except that the precipitate rings are considerably thicker and more preferentially oriented. The precipitate appears more voluminous and less crystalline than in Figure 3b. Figure 3d shows a very broken precipitate. The precipitate is relatively irregular; there are no clear signs of orientation of the microcrystals and large aggregates of microcrystals. Figure 4d shows a mass heavily covered by the fine precipitate. It is difficult to discern individual microcrystals in this case. The precipitate is rather voluminous and appears to consist of a great number of small particles.

3. Funktionen und Methoden

Figure 10 shows the results of a 1000-atom simulation of the energy cell. If the types are assigned with the perfect ratio shown in Figure 2 and 10 atoms of each type are added to the system, the energy cell will be zero. But these bodies are large and too many. Therefore, the ratio of the number of the four types in the energy cell is 0.25, and about half of the energy cell is zero. The other half is non-zero, as shown in Figure 10.

Alles was je over de wereld, de mensen en goden

The conclusion corresponds to the three main topics mentioned above. In particular, in the paper of P. B. and the above (Bogolyubov, 1967) The "C" function was considered separately from the stability of the motion of moving systems. The joint consideration of the two problems is justified by the need of their mutual interaction. In addition, the "C" function can be used to study the stability of the motion of moving systems. However, it is not always possible to do this. This paper is the first attempt to study the stability of motion and to prove its ergodicity by the methods of statistical mechanics. The theory of ergodicity is also justified by the fact that the stationary state does not have time-dependent fluctuations. The method of proof of the ergodicity of the motion of a system depends on the properties of the system under consideration. If the system has a finite number of degrees of freedom, then the ergodicity of the motion of the system is established by the method of the Liapunov function. If the system has an infinite number of degrees of freedom, then the ergodicity of the motion of the system is established by the method of the Liapunov function. The ergodicity of the motion of the system is established by the method of the Liapunov function. The ergodicity of the motion of the system is established by the method of the Liapunov function. The ergodicity of the motion of the system is established by the method of the Liapunov function. The ergodicity of the motion of the system is established by the method of the Liapunov function.

A similar study was made by C. H. Fletcher at the Bureau of Fisheries, and will be published shortly. It covers over fifteen years' period. The survey for the purpose of getting full information between stations, every major port of the coast being surveyed. It took from 1905 to 1910 to complete the work, and probably took less than a fifth of the time required had it been conducted otherwise. Fletcher's results are extremely strong, and he has obtained much more detailed data.

here because it is not clear that the morphology and a depth of wear that are important for the peak. Very similar results and conclusions have been drawn by others (10, 11, 12).

Figure 10 shows the wear rate and friction coefficient in a three-dimensional diagram plotted as a function of the operating time.

10. CONCLUSIONS AND OUTLOOK

Since the development of the new Kevlar® fibers, many improvements have made all the properties of carbon fibers to be improved and the mechanical and polyimide influences thereof suppressed, considerably. Moreover, if the polyimide is partially replaced and a fiber having a small bulk density is prepared and adequately crosslinked, the thermal stability is improved to produce a stable fiber, and the solubility is also improved, so that the properties thereof may be able to bring out the best of the resulting polyimide fibers in the carbon.

ACKNOWLEDGMENT: The authors thank C. E. French of Kevlar® Carbon for permission to use some of the papers used as a guide to produce the behavior.

Tensors

31-1 The tensor of polarizability

Physicists always have a habit of taking the simplest example of any phenomenon and calling it "physics," leaving the more complicated examples to become the concern of other fields—say of applied mathematics, electrical engineering, chemistry, or crystallography. Even solid-state physics is almost only field physics because it worries too much about special substances. So in 10-8 lectures we will be leaving out many interesting things. For instance, one of the important properties of crystals—or of most substances—is that their electric polarizability is different in different directions. If you apply a field in one direction, the atomic charges shift a little and produce a dipole moment, but the magnitude of this moment depends very much on the direction of the field. That is, of course, quite a complication. But in physics we usually start out by talking about the special case in which the polarizability is the same in all directions. To make life easier. We leave the other cases to some other field. Fortunately, for our later work, we will not need at all what we are going to talk about in this chapter.

The mathematics of tensors is particularly useful for describing properties of substances which vary in direction. Although there's only one example of them, since most of you are not going to become physicists, but are going to go into the real world, where things depend severely upon direction, sooner or later you will need to use tensors. In order not to leave anything out, we are going to describe tensors, although I don't get into it. We want the feeling that our treatment of physics is complete. For example, our electrodynamics is complete—as complete as say electricity and magnetism, or, say, a graduate course. Our mechanics is not complete, because we start off incomplete when you didn't have a high level of mathematical sophistication, and we were not able to do subjects like the principle of least action, or Lagrangians, or Ham functions, and so on, which are more elegant ways of describing mechanics. Except for general relativity, however, we do have the complete form of mechanics. Our electricity and magnetism is complete, and a lot of other things are quite complete. The quantum mechanics, naturally, will not be—we have to leave something for the future. But you should at least know what a tensor is.

We emphasized in Chapter 30 that the properties of crystalline substances are different in different directions; we say they are *anisotropic*. The variation of the induced dipole moment with the direction of the applied electric field is only one example, the one we will use for our example of a tensor. Let's say that, for a given direction of the electric field, the induced dipole moment per unit volume P is proportional to the strength of the applied field E . (This is a good approximation for many substances if E is not too large.) We will call the proportionality constant χ .^{*} We want now to consider substances in which χ depends on the direction of the applied field, as, for example, in crystals which make double images when you look through them.

Suppose, in a particular crystal, we find that an electric field E_x in the x -direction produces the polarization P_x in the x -direction. Then we find that no electric field E_y in the y -direction, with the same strength, as E_x , produces a different polarization

Review: Chapter 11, Vol. 1, *Tensor Components*; Chapter 20, Vol. 1, *Relativity in Space*

* In Chapter 10 we followed the usual convention and wrote $\chi = \epsilon_0 \kappa E$ and called κ ("kappa") the "susceptibility." Here, it will be more convenient to use a single letter, so we write χ for κ . The dielectric constant $\epsilon_0 = 1/(4\pi\kappa)$, where κ is the dielectric constant. (See Section 10-4.)

irection P_2 in the y -direction. What would happen if we put an electric field at 45° ? Well, that's a superposition of two fields along x and y , so the polarization P will be the vector sum of P_1 and P_2 , as shown in Fig. 31-1(a). The polarization is no longer in the same direction as the electric field. You can see how that might come about. There may be charges which can move easily up and down, but much more difficult sideways motions. When a force is applied at 45° , the charges move largely up than they do toward the side. The displacements are not in the direction of the external force, because there are asymmetric internal elastic forces.

There is, of course, nothing special about 45° . It is generally true that the induced polarization of a crystal is not in the direction of the electric field. In our example above, we happened to make a "lucky" choice of our x - and y -axes, for which P was along E for both the x -and y -directions. If the crystal were turned with respect to the coordinate axes, the electric field E_x in the x -direction would have produced a polarization P with both an x - and a y -component. Similarly, the polarization due to an electric field in the x -direction would have produced a polarization with an x -component and a y -component. Then the polarizations would be as shown in Fig. 31-1(b), instead of as in part (a). Things get more complicated, but for any field E , the magnitude of P is still proportional to the magnitude of E .

We want now to treat the general case of an arbitrary orientation of a crystal with respect to the coordinate axes. An electric field in the x -direction will produce a polarization P with x -, y -, and z -components; we can write

$$P_x = \alpha_{xx}E_x, \quad P_y = \alpha_{yy}E_y, \quad P_z = \alpha_{zz}E_z. \quad (31.1)$$

All we are saying here is that if the electric field is in the x -direction, the polarization does not have to be in just one direction but rather can be a x -, a y -, and a z -component—each proportional to E_x . We are calling the constants of proportionality α_{xx} , α_{yy} , and α_{zz} , respectively (the first value is telling which component of P is involved, the last to refer to the direction of the electric field).

Similarly, for a field in the y -direction, we can write

$$P_x = \alpha_{xy}E_y, \quad P_y = \alpha_{yy}E_y, \quad P_z = \alpha_{yz}E_y, \quad (31.2)$$

and for a field in the z -direction,

$$P_x = \alpha_{xz}E_z, \quad P_y = \alpha_{yz}E_z, \quad P_z = \alpha_{zz}E_z. \quad (31.3)$$

Now we have said that polarization depends linearly on the fields, so if there is an electric field E that has both an x - and a y -component, the resulting x -component of P will be the sum of the two P_x 's of Eqs. (31.1) and (31.2). If E has components along x , y , and z , the resulting components of P will be the sum of the three contributions in Eqs. (31.1), (31.2) and (31.3). In other words, P will be given by

$$\begin{aligned} P_x &= \alpha_{xx}E_x + \alpha_{xy}E_y + \alpha_{xz}E_z, \\ P_y &= \alpha_{yy}E_x + \alpha_{yy}E_y + \alpha_{yz}E_z, \\ P_z &= \alpha_{zz}E_x + \alpha_{yz}E_y + \alpha_{zz}E_z. \end{aligned} \quad (31.4)$$

The dielectric behavior of the crystal is then completely described by the nine quantities (α_{xx} , α_{yy} , α_{zz} , α_{xy} , α_{yz} , α_{zx} , etc.), which we can represent by the symbol α_{ij} (the subscripts i and j each stand for any one of the three possible letters x , y , and z .) Any arbitrary electric field E can be resolved with the components E_x , E_y , and E_z ; from these we can use the α_{ij} to find P_x , P_y , and P_z , which together give the total polarization P . The set of nine coefficients α_{ij} is called a tensor—in this instance, the tensor of polarizability. Just as we say that the three numbers (E_x , E_y , E_z) "form the vector E ," we say that the nine numbers (α_{xx} , α_{yy} , \dots) "form the tensor α_{ij} ."

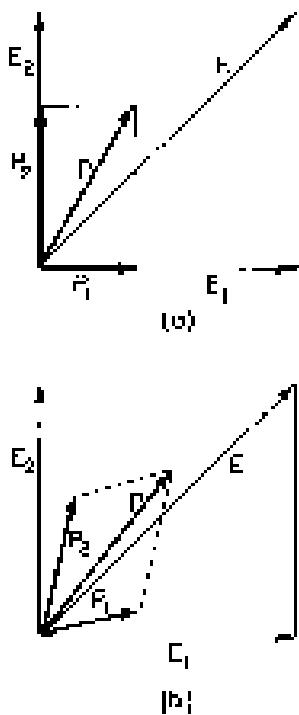

Fig. 31-1. The vector addition of polarizations in an anisotropic crystal.

31-2 Transforming the tensor components

You know that when we change to a different coordinate system x' , y' , and z' , the components E_x , E_y , and E_z of the vector will be quite different as will also the components of P . So all the coefficients α_{ij} will be different for a different set of coordinates. You can, in fact, see how the α 's must be changed by changing the components of E and P in the proper way, because if we describe the same physical electric field in the new coordinate system we should get the same polarization. For any new set of coordinates, $P_{x'}$ is a linear combination of P_x , P_y , and P_z :

$$P_{x'} = aP_x + bP_y + cP_z$$

and similarly for the other components. If you substitute for P_x , P_y , and P_z in terms of the E 's, using Eq. (31.4), you get

$$\begin{aligned} P_{x'} &= a(\alpha_{xx}E_x + \alpha_{xy}E_y + \alpha_{xz}E_z) \\ &\quad + b(\alpha_{yx}E_x + \alpha_{yy}E_y + \alpha_{yz}E_z) \\ &\quad + c(\alpha_{zx}E_x + \alpha_{zy}E_y + \alpha_{zz}E_z). \end{aligned}$$

Then you write E_x , E_y , and E_z in terms of $E_{x'}$, $E_{y'}$, and $E_{z'}$; for instance,

$$E_x = d'E_{x'} + b'E_{y'} + c'E_{z'},$$

where a' , b' , c' are related to, but not equal to, a , b , c . So you have $P_{x'}$ expressed in terms of the components $E_{x'}$, $E_{y'}$, and $E_{z'}$; that is, you have the new α 's. It is fairly easy, but quite straightforward.

When we talk about changing the axes we are assuming that the crystal stays put in space. If the crystal were rotated with the axes, the α 's would not change. I might say, if the orientation of the crystal were changed with respect to the axes, we would have a new set of α 's. But if they are known for one orientation of the crystal, they can be found for any other orientation by the transformation we have just described. In other words, the dielectric property of a crystal is described completely by giving the components of the polarization tensor α_{ij} with respect to any arbitrary chosen set of axes. Just as we can associate a vector velocity $v = (v_x, v_y, v_z)$ with a particle knowing that the three components will change in a certain definite way if we change our coordinates x, y, z , so with a crystal we associate its polarization tensor α_{ij} , whose nine components will transform in a certain definite way if the coordinate system is changed.

The relation between P and E written in Eq. (31.4) can be used in direct computation,

$$P_i = \sum_j \alpha_{ij} E_j, \quad (31.5)$$

where it is understood that i represents either x , y , or z and that the sum is taken only over $j = x$, y , and z . Many special notations have been invented for dealing with tensors, but each of them is convenient only for a limited class of problems. One common convention is to omit the sum sign (Σ) in Eq. (31.5), leaving it understood that whenever the same subscript occurs twice there is a sum to be taken over that index. Since we will be using tensors so little, we will not bother to adopt any such special notations or conventions.

31-3 The energy ellipsoid

We can now get some experience with tensors. Suppose we ask the interesting question: What energy is required to polarize the crystal in addition to the energy in the electric field which we know is $(\epsilon_0/2)E^2$ per unit volume? Consider for a moment the atomic charges that are being displaced. The work done in displacing the charge ze is zeV , V , and if there are N charges per unit volume, the work done is qEV/N . But qEV is the always dV , in the dipole

moment per unit volume. So the energy required per unit volume is

$$E_z dP_z.$$

Combining the work for the three components of the field, the work per unit volume is found to be

$$E \cdot dP.$$

Since the magnitude of P is proportional to E , the work done per unit volume in bringing the polarization from 0 to P is the integral of $E \cdot dP$. Calling this work w_P ,⁴ we write

$$w_P = \frac{1}{2} E \cdot P = \frac{1}{2} \sum E_i P_i. \quad (31.6)$$

Now we can express P in terms of E by Eq. (31.5), and we have that

$$w_P = \frac{1}{2} \sum_i \sum_j \alpha_{ij} E_i E_j. \quad (31.7)$$

The energy density w_P is a number independent of the choice of axes, so it is a scalar. A tensor has then the property that when it is an inverse, one index (with a vector) it gives a new vector; and when it is an inverse, both indices (with two vectors), it gives a scalar.

The tensor α_{ij} should really be called a "tensor of second rank," because it has two indices. A vector (with one index) is a tensor of the first rank, and a scalar (with no index) is a tensor of zero rank. So we say that the electric field E is a tensor of the first rank and that the energy density w_P is a tensor of zero rank. It is possible to extend the ideas of a tensor to three or more indices, and so to make tensors of ranks higher than two.

The subscripts of the polarization tensor range over three possible values; they are tensors in three dimensions. The mathematician considers tensors in four, five, or more dimensions. We have already used a four-dimensional tensor F_μ in our relativistic description of the electromagnetic field (Chapter 26).

The polarization tensor α_{ij} has the interesting property that it is *symmetric*, that is, that $\alpha_{ij} = \alpha_{ji}$ and so on for any pair of indices. (This is a physical property of a real crystal and not necessary for all tensors.) You can prove for yourself that this must be true by comparing the change in energy of a crystal through the following cycle: (1) Turn on a field in the x -direction; (2) turn on a field in the y -direction; (3) turn off the x -field; (4) turn off the y -field. The crystal is now back where it started, and the net work done on the polarization must be back to zero. You can show, however, that for this to be true, α_{xx} must be equal to α_{yy} . The same kind of argument can, of course, be given for α_{zz} , etc. So the polarization tensor is symmetric.

This also means that the polarization tensor can be measured by just measuring the energy required to polarize the crystal in various directions. Suppose we apply an E -field with only an x - and a y -component; then according to Eq. (31.7),

$$w_P = \frac{1}{2} [\alpha_{xx} E_x^2 + (\alpha_{xy} - \alpha_{yx}) E_x E_y - \alpha_{yy} E_y^2]. \quad (31.8)$$

With an E_x alone, we can determine α_{xx} ; with an E_y alone, we can determine α_{yy} ; with both E_x and E_y , we get an extra energy due to the term with $(\alpha_{xy} - \alpha_{yx})$. Since the α_{xy} and α_{yx} are equal, this term is $2\alpha_{xy}$ and can be related to the energy.

The energy expression, Eq. (31.8), has a nice geometrical interpretation. Suppose we ask what fields E_x and E_y correspond to some given energy density—say ω_0 . That is just the mathematical problem of solving the equation

$$\alpha_{xx} E_x^2 + 2\alpha_{xy} E_x E_y - \alpha_{yy} E_y^2 = 2\omega_0.$$

This is a quadratic equation, so if we plot E_x and E_y , the solutions of this equation

⁴ This work done in producing the polarization by an electric field is not to be confused with the potential energy $-p_0 \cdot E$ of a permanent dipole moment p_0 .

are all the points on an ellipse (Fig. 31-2). It cannot be an ellipse, rather than a parabola or a hyperbola, because the energy density of the field is always positive and finite. The vector E with components E_x and E_y can be drawn from the origin to the ellipse. As such an "energy ellipse" is a nice way of "visualizing" the polarization tensor.

If we now generalize to include all three components, the electric vector E is any direction required to give a unit energy density over a point which will be at the surface of an ellipsoid, as shown in Fig. 31-3. The shape of this ellipsoid of constant energy密度 characterizes the tensor polarizability.

Now an ellipsoid has the nice property that it can always be described simply by giving the directions of three "principal axes" and the diameters of the ellipsoid along these axes. The "principle axes" are the directions of the longest and shortest diameters and the corresponding right angles to them. They are indicated by the axes a , b , and c in Fig. 31-3. With respect to these axes, the ellipsoid has the particularly simple equation

$$\alpha_{xx}E_x^2 + \alpha_{yy}E_y^2 + \alpha_{zz}E_z^2 = 1 \text{ unit.}$$

So with respect to these axes, the polarization tensor has only three components that are non-zero: α_{xx} , α_{yy} , and α_{zz} . That is to say, no matter how complicated a crystal is, it is always possible to choose a set of axes (not necessarily the crystal axes) for which the polarization tensor has only three components. With such a set of axes, Eq. (31.2) becomes simply

$$P_x = \alpha_{xx}E_x, \quad P_y = \alpha_{yy}E_y, \quad P_z = \alpha_{zz}E_z. \quad (31.9)$$

An electric field along any one of the principal axes produces a polarization along the same axis, but the coefficients for the three axes may, of course, be different.

Often, a tensor is described by listing the nine coefficients in a table inside of a pair of brackets:

$$\begin{bmatrix} \alpha_{xx} & \alpha_{xy} & \alpha_{xz} \\ \alpha_{yx} & \alpha_{yy} & \alpha_{yz} \\ \alpha_{zx} & \alpha_{zy} & \alpha_{zz} \end{bmatrix}. \quad (31.10)$$

For the principal axes a , b , and c only the diagonal terms are not zero, we say here that "the tensor is diagonal." The complete tensor is

$$\begin{bmatrix} \alpha_{aa} & 0 & 0 \\ 0 & \alpha_{bb} & 0 \\ 0 & 0 & \alpha_{cc} \end{bmatrix}. \quad (31.11)$$

The important point is that any polarization tensor (in fact, any symmetric tensor of rank two in any number of dimensions) can be put in this form by choosing a suitable set of coordinate axes.

If the three elements of the polarization tensor in diagonal form are all equal, that is,

$$\alpha_{aa} = \alpha_{bb} = \alpha_{cc} = \alpha, \quad (31.12)$$

the energy ellipsoid becomes a sphere, and the polarizability is the same in all directions. The material is isotropic. In the tensor notation,

$$\alpha_{ij} = \alpha \delta_{ij}, \quad (31.13)$$

where δ_{ij} is the unit tensor.

$$\delta_{ij} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases}. \quad (31.14)$$

That means, of course,

$$\delta_{ii} = 1, \quad \text{if } i = j, \quad (31.15)$$

$$\delta_{ij} = 0, \quad \text{if } i \neq j.$$

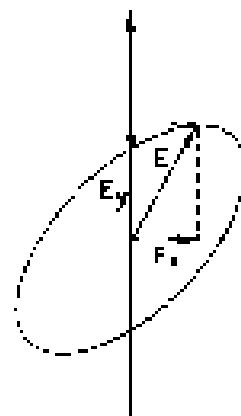

Fig. 31-2. Locus of the vector $E = (E_x, E_y)$ that gives a constant energy of polarization.

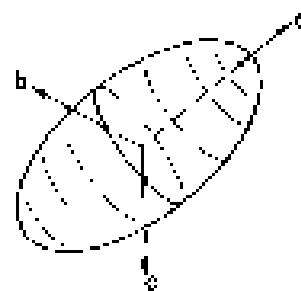

Fig. 31-3. The energy ellipsoid of the polarization tensor.

The tensor δ_{ij} is often called the "Kronecker delta." You may amuse yourself by proving that the tensor (31.14) has exactly the same form if you change the coordinate system to any other rectangular one. The polarization tensor of Eq. (31.13) gives

$$P_i = \sigma \sum_j \delta_{ij} E_j = \sigma E_i$$

which means the same as our old result for isotropic dielectrics:

$$P = \sigma E.$$

The shape and orientation of the polarization ellipsoid can sometimes be related to the symmetry properties of the crystal. We have said in Chapter 30 that there are 320 different possible internal geometries of a three-dimensional lattice and that they can, for many purposes, be conveniently grouped into seven classes, according to the shape of the unit cell. Now the ellipsoid of polarizability must share the internal geometric symmetries of the crystal. For example, a cubic crystal has low symmetry. Its dipole moment will have random axes, and its orientation will not, in general, be aligned with the crystal axes. On the other hand, a monoclinic crystal has the property that its properties are unchanged if the crystal is rotated 180° about one axis. So the polarization tensor must be the same after such a rotation. It follows that the ellipsoid of polarizability must return to itself after a 180° rotation. That can happen only if one of the axes of the ellipsoid is in the same direction as the symmetry axis of the crystal. Otherwise, the orientation and dimensions of the ellipsoid are interchanged.

For an orthorhombic crystal, however, the axes of the ellipsoid must correspond to the crystal axes, because a 180° rotation about any one of the three axes repeats the same lattice. If we go to a tetragonal crystal, the ellipsoid must have the same symmetry, so it must have two equal dimensions. Finally, for a cubic crystal, all three dimensions of the ellipsoid must be equal; it becomes a sphere, and the polarizability of the crystal is the same in all directions.

There is a big game of figuring out the possible kinds of relations for all the possible symmetries of a crystal. It is called "group-theoretical" analysis. But for the simple case of the polarizability tensor, it is relatively easy to see what the relations must be.

31-4 Other tensors: The tensor of inertia

There are many other examples of tensors appearing in physics. For example, in a metal, or in any conductor, one often finds that the current density j is approximately proportional to the electric field E ; the proportionality constant is called the conductivity σ :

$$j = \sigma E$$

For crystals, however, the relation between j and E is more complicated: the conductivity is not the same in all directions. The conductivity is a tensor, and we write

$$\sigma = \sum_{i,j} \sigma_{ij} \delta_{ij}$$

Another example of a physical tensor is the moment of inertia. In Chapter 18 of Volume 1 we saw that a solid object rotating about a fixed axis has angular momentum L , proportional to the angular velocity ω , and we called the proportionality factor I , the moment of inertia:

$$L = I\omega.$$

For an arbitrarily shaped object, the moment of inertia depends on its orientation with respect to the axis of rotation. For instance, a rectangular block will have different moments about each of its three orthogonal axes. Now angular velocity ω and angular momentum L are both vectors. For rotations about one of the axes of symmetry, they are parallel. But if the moment of inertia is different for the

Two principal axes, both ω and α , are, in general, not in the same direction (see Fig. 31-4). They are related in a way analogous to the relation between E and P . In general, we must write

$$\begin{aligned} I_x &= I_{xx}\omega_x + I_{xy}\omega_y + I_{xz}\omega_z \\ I_y &= I_{yx}\omega_x + I_{yy}\omega_y + I_{yz}\omega_z \\ I_z &= I_{zx}\omega_x + I_{zy}\omega_y + I_{zz}\omega_z \end{aligned} \quad (31.16)$$

The three coefficients I_i are called the tensor of inertia. Following the analogy with the propagation, the kinetic energy for any angular momentum must be some quadratic form in the components ω_x , ω_y , and ω_z :

$$KE = \frac{1}{2} \sum_i I_i \omega_i^2 \quad (31.17)$$

We again use the energy to define the ellipsoid of inertia. Also, energy arguments can be used to show that the tensor is symmetric—that $I_{ij} = I_{ji}$.

The tensor of inertia for a rigid body can be worked out, if the shape of the object is known. We need only to write down the total kinetic energy of all the particles in the body. A particle of mass m and velocity v has the kinetic energy $\frac{1}{2}mv^2$, and the total kinetic energy is just the sum

$$\sum m v^2$$

over all of the particles of the body. The velocity v of each particle is related to the angular velocity ω of the solid body. Let's assume that the body is rotating about its center of mass, which we take to be at rest. Then if r is the displacement of a particle from the center of mass, its velocity v is given by $v = \omega \times r$. So the total kinetic energy is

$$KE = \sum m(\omega \times r)^2 \quad (31.18)$$

Now if we have to do a little $\omega \times r$ out in terms of the components ω_x , ω_y , ω_z , and x_1 , y_1 , z_1 , and compare the result with Eq. (31.17), we find I_{ij} by elementary terms. Carrying out the algebra, we write

$$\begin{aligned} (\omega \times r)^2 &= (\omega \times r)_x^2 + (\omega \times r)_y^2 + (\omega \times r)_z^2 \\ &= (\omega_x x - \omega_y y)^2 + (\omega_x y - \omega_z z)^2 + (\omega_x z - \omega_y y)^2 \\ &= \omega_x^2 x^2 - 2\omega_x \omega_y xy + \omega_y^2 y^2 \\ &\quad + \omega_x^2 y^2 - 2\omega_x \omega_z xz + \omega_z^2 z^2 \\ &\quad + \omega_y^2 z^2 - 2\omega_y \omega_z yz - \omega_z^2 x^2. \end{aligned}$$

Multiplying this equation by $m/2$, summing over all particles, and comparing with Eq. (31.17), we see that I_{xx} , for instance, is given by

$$I_{xx} = \sum m(r^2 - x^2)$$

This is the formula we have had before (Chapter 19, Vol. I) for the moment of inertia of a body about the x -axis. Since $r^2 = x^2 + y^2 + z^2$, we can also write this term as

$$I_{xx} = \sum m(r^2 - x^2).$$

Working out all of the other terms, the tensor of inertia can be written as

$$I_{ij} = \left[\begin{array}{ccc} \sum m(r^2 - x^2) & -\sum mxy & -\sum mxz \\ -\sum myx & \sum m(r^2 - y^2) & -\sum myz \\ -\sum mzx & -\sum myz & \sum m(r^2 - z^2) \end{array} \right]. \quad (31.19)$$

If you wish, this may be written in "tensor notation" as

$$I_{ij} = \sum m(r^2 \delta_{ij} - x_i x_j). \quad (31.20)$$

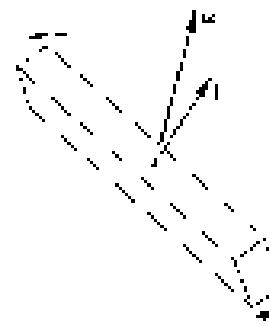

Fig. 31-4. The angular momentum L of a solid object is not, in general, parallel to its angular velocity ω .

where the r_i are the components (x, y, z) of the position vector of a particle and the Σ means to sum over all the particles. The moment of inertia, then, is a tensor of the second rank whose terms are a property of the body and relate E to ω by

$$E = \sum_i I_i \omega_i \quad (3.21)$$

For a body of any shape whatever, we can find the tensor of inertia, that is, the three principal axes. Reduced to three axes, the tensor will be diagonal, so for a rigid, there are always three principal axes for which the components of the angular velocity are zero. They are called the principal axes of inertia.

31-5 The stress product

We should point out that we have been using tensors of the second rank since Chapter 20 of Volume I. There, we defined a "vector in a plane," such as τ_{xy} , by

$$\tau_{xy} = xF_y - yF_x.$$

Generalized to three dimensions, we could write

$$\tau_{ij} = r_i t_j - r_j t_i. \quad (3.22)$$

The quantity τ_{ij} is a tensor of the second rank. One way to see this is to go by obtaining τ_{ij} with some vector, say the unit vector \hat{e}_k , according to

$$\sum_i \tau_{ij} e_i.$$

If this quantity is a vector, then τ_{ij} must be homogeneous (homogeneous is our definition of a tensor). Substituting in (3.22), we have

$$\begin{aligned} \sum_j \tau_{ij} e_i &= \sum_j r_i t_j e_i - \sum_i r_j t_i e_i \\ &= r_i (\hat{e}_j \cdot \hat{e}_i) - r_j (\hat{e}_i \cdot \hat{e}_j). \end{aligned}$$

Since the dot products are scalars, the two terms on the right-hand side are vectors, and likewise their difference. So τ_{ij} is a tensor.

But τ_{ij} is a special kind of tensor: it is *antisymmetric*, that is,

$$\tau_{ij} = -\tau_{ji}$$

so it has only three nonzero terms: τ_{12}, τ_{23} , and τ_{13} . We were able to show in Chapter 20 of Volume I that these three terms, although "by accident," transform like the three components of a vector, so that we could define

$$\tau = (\tau_{12}, \tau_{23}, \tau_{13}) = (r_1, r_2, r_3) \cdot \hat{e}_k.$$

We say "by accident," because it happens only in three dimensions. In four dimensions, for example, an analogous metric tensor of the second rank has six nonzero terms, up to symmetry, and must be replaced by a vector and four components.

Just as the usual vector $\tau = \tau \cdot \hat{e}_k$ is a tensor, so also is every τ its product of two vector vectors, and the same argument applies. By luck, however, they are also represented by vectors (already pseudovectors), so our mathematics has been made easier! i.e., τ .

Mathematically, if τ and θ are any two vectors, the nine quantities appearing in a tensor (although it may have no useful physical purpose). Thus, for the position vector $r_i = r_i \hat{e}_i$, is a tensor, and since β_i is also, we see that the right side of Eq. (3.22) is indeed a tensor. Likewise Eq. (3.22) is a tensor, since the two terms on the right-hand side are tensors.

31-6 The tensor of stress

The symmetric tensors we have described so far arose as coefficients in relating one vector to another. We would like to look now at a tensor which has a different physical significance—the tensor of stress. Suppose we have a solid object with various forces on it. We say that there are various "stresses" inside, by which we mean that there are internal forces between neighboring parts of the material. We have talked a little about such stresses in a two-dimensional case when we discussed the surface tension in a stretched diaphragm in Section 12-3. We will now see that the internal forces in the material of a three-dimensional body can be described in terms of a tensor.

Consider a body of some elastic material—say a block of jello. If we make a cut through the block, the material on each side of the cut will, in general, get displaced by the internal forces. Before the cut was made, there must have been force between the two parts of the block that kept the material in place; we can define the stresses in terms of these forces. Suppose we look at an imaginary plane, perpendicular to the x -axis—like the planes in Fig. 31-5—some way above the front, as shown in Fig. 31-5(a). The material on the left of the plane exerts the force ΔF_x on the material to the right of the plane, as shown in part (b) of the figure. There is, of course, the opposite reaction force $-\Delta F_x$ exerted on the material to the left of the surface. If the area is small enough, we expect that ΔF_x is proportional to the area Δx .

You are already familiar with one kind of stress—the pressure in a static liquid. There the force is equal to the pressure times the area and is at right angles to the surface segment. For solids—also for viscous liquids in motion—the force need not be normal to the surface; there are shear forces involved, as pressures (positive or negative). By a "shear" force we mean the tangential components of the force across a surface. All that we say about the force might be taken literally. Notice also that if we strike you out on a point with your fist, the resulting forces will be different. A complete description of the internal stress requires a tensor.

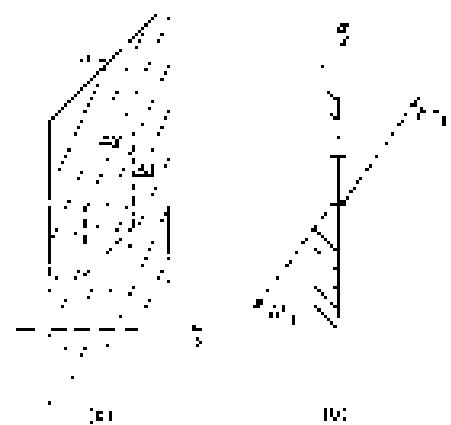

Fig. 31-5. The material to the left of the plane x exerts across the area $\Delta x \Delta y$ the force ΔF_x on the material to the right of the plane.

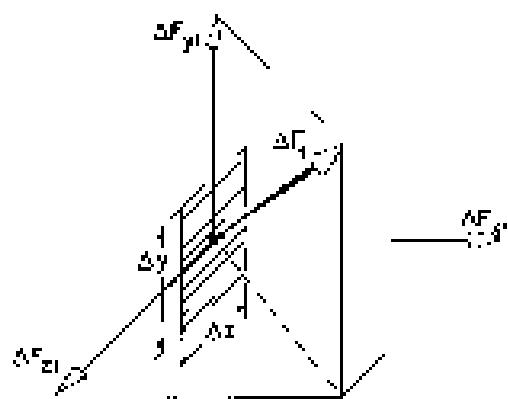

Fig. 31-6. The force ΔF_x acting on a small element $\Delta x \Delta y$ perpendicular to the x -axis is resolved into the three components ΔF_{xy} , ΔF_{xz} , and ΔF_{yl} .

We define the stress tensor in the following way: First, we imagine a cut perpendicular to the x -axis and resolve the force ΔF_x across the cut into its own components ΔF_{xy} , ΔF_{xz} , ΔF_{yl} , as in Fig. 31-6. The ratio of these forces to the area $\Delta x \Delta y$ we call S_{xy} , S_{xz} , and S_{yl} . For example,

$$S_{xy} = \frac{\Delta F_{xy}}{\Delta x \Delta y}.$$

The first index y refers to the direction-force component; the second index x is normal to the area. If you wish, you can write the area $\Delta x \Delta y$ as Δx , meaning an element of area perpendicular to x . Then

$$S_{xy} = \frac{\Delta F_{xy}}{\Delta x}.$$

Next, we think of an imaginary cut perpendicular to the y -axis. Across a small

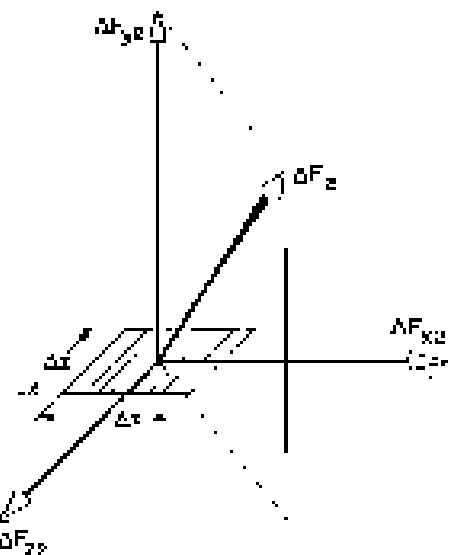

Fig. 31-7. The force across an element of area ΔA perpendicular to y is resolved into three rectangular components.

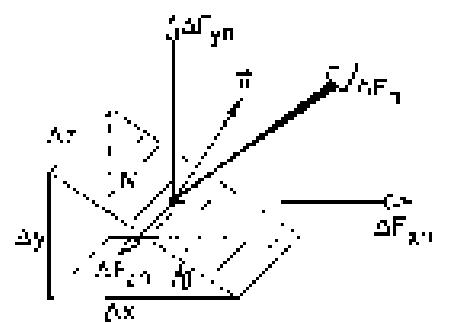

Fig. 31-8. The force F_z across the face N whose unit normal is n is resolved into components.

area ΔA as there will be a force ΔN . Again we resolve this force into three components, as shown in Fig. 31-7, and define the three components of the stress S_{xx} , S_{yy} , S_{zz} as the force per unit area in the three directions. Finally, we choose an imaginary cut perpendicular to y and define the three components S_{xy} , S_{yz} , and S_{xz} ; we have the nine numbers:

$$S_{ij} = \begin{bmatrix} S_{xx} & S_{xy} & S_{xz} \\ S_{yx} & S_{yy} & S_{yz} \\ S_{zx} & S_{zy} & S_{zz} \end{bmatrix}. \quad (31-2)$$

We want to show now that these nine numbers are sufficient to describe completely the internal state of stress, and that S_{ij} is indeed a tensor. Suppose we want to know the force across a surface inclined at some arbitrary angle θ from the x -axis. From S_{ij} ? Yes, in the following way: We imagine a little solid triangle, which has one face N in the new surface and the other two parallel to the x -y-z axes. If the face N happened to be parallel to the xy -plane, we would have the triangular piece shown in Fig. 31-8. (This is a somewhat special case, but will illustrate well enough the general method.) Now the stress forces at the little solid triangle in Fig. 31-8 are in equilibrium (at least in the limit of infinitesimal changes in θ), so the total force on it must be zero. We know the forces on the edges parallel to the x -axis come directly from S_{xx} . These forces are just equal in magnitude, so ΔF_{xe} is zero and we can express this condition in terms of S_{ij} :

The assumption that the surface forces on the small triangular volume are in equilibrium implies any one "body" forces that might be present, such as gravity or surface forces of different magnitude systems, are in mutual balance. Notice, however, that each body force is parallel to the x -axis of the little triangle and therefore, to Δx , Δy , Δz , whereas all the surface forces are proportional to the areas such as ΔF_x , ΔF_y , ΔF_z , etc. So if we take the scale of the little wedge small enough, the body forces can always be neglected in comparison with the surface forces.

Let's now add up forces on the little wedge. We can forget the x -component, which is the sum of the forces from each face. However, if Δz is small enough, the forces on the triangular faces (perpendicular to the z -axis) will be equal and opposite, so we can forget them. The y -component of the force on the bottom rectangle is

$$\Delta F_{ye} = S_{yy} \Delta y \Delta z.$$

The x -component of the force on the vertical rectangle is

$$\Delta F_x = S_{xx} \Delta x \Delta z.$$

These two must be equal to the y -component of the force summed across the face N . (It's either the unit vector method for forces ΔF and the force on ΔF , or the δ -function)

$$\Delta F_{yy} = S_{yy} \Delta z \Delta x + S_{yz} \Delta x \Delta z.$$

The x -component S_{xy} of the stress across this plane is equal to ΔF_x divided by $\Delta x \Delta z$, which is $\Delta F_x / \Delta x^2 = \Delta F_x / \Delta A$,

$$S_{xy} = S_{yy} \frac{\Delta y}{\sqrt{\Delta x^2 + \Delta z^2}} = S_{yy} \frac{\Delta x}{\sqrt{3} \sqrt{\Delta x^2 + \Delta z^2}}.$$

Now $\Delta x / \sqrt{\Delta x^2 + \Delta z^2}$ is the cosine of the angle θ between Δx and its y -axis, as shown in Fig. 31-8, so Δ can also be written as θ , the y -component of $\pi \cdot S$; namely, $\Delta x / \sqrt{\Delta x^2 + \Delta z^2}$ is an $\theta = \theta_y$. We can write

$$S_{xy} = S_{yy} \theta_y + S_{yz} \theta_x.$$

If we now generalize to an arbitrary surface element, we would get the

$$S_{ij} = S_{ii} \theta_i + S_{iy} \theta_y + S_{iz} \theta_z,$$

or, in general,

$$S_{ij} = \sum_k S_{ik} \delta_{kj}. \quad (31.24)$$

We can find the force across any surface element in terms of the S_{ij} , so it does describe completely the state of internal stress of the material.

Equation (31.24) says that the tensor S_{ij} relates the force S_i to the unit vector n_j , just as σ_i relates F to E . Since n and S are vectors, the components of S_{ij} must transform as a tensor with changes in coordinate axes. So S_{ij} is indeed a tensor.

We can also show that S_{ij} is a symmetric tensor by looking at the forces on a little cube of material. Suppose we take a little cube, oriented with its faces parallel to our coordinate axes, and look at its six faces separately, as shown in Fig. 31-9. If we let the x -axis of the cube be one axis, the six components of the forces on the faces normal to the x -axis would simply be as shown in the figure. To the cube it seems that the stresses do not change approximately from one side of the cube to the other (unless there are other components, like a shear component S_{xy} , which there must be since one of the edges of it would start opening). In fact, if we chart the center of $(S_{xx}, -S_{yy})$ versus the front edge of the cube, and since the point is zero, S_{yy} is equal to S_{xx} , and the stress tensor is symmetric.

Since S_{ij} is a symmetric tensor, it can be represented by an ellipsoid which will have three principal axes. But surfaces normal to these axes, the stresses are particularly simple—they correspond to planes or paths perpendicular to the surfaces. There are also shear balances along these faces. For any stress, we can always choose our axes so that the shear components are zero. If the ellipsoid is a sphere, there are only normal forces in any direction. This corresponds to a hydrostatic pressure (positive or negative). So for a hydrostatic pressure, the tensor is diagonal and all three components are equal; they are, in fact, just equal to the pressure p . We can write

$$S_{ij} = p \delta_{ij}. \quad (31.25)$$

The stress tensor—and also its ellipsoid—will, in general, vary from point to point in a block of material; to describe the whole block we need to give the values of each component of S_{ij} as a function of position. So the stress tensor is a field. We have had scalar fields like the temperature $T(x, y, z)$, which give one number for each point in space, and vector fields like $E(x, y, z)$, which give three numbers for each point. Now we have a tensor field which gives nine numbers for each point in space—or really six for the symmetric tensor S_{ij} . A complete description of the total field needs six arbitrary discrete values (or nine if S_{ij} is not zero).

31-7 Tensors of higher rank

The stress tensor S_{ij} describes the internal forces of matter. If the material is elastic, it is convenient to describe the internal stresses in terms of another tensor T_{ijkl} called the strain tensor. For a simple object like a bar of metal, you know that the change in length, ΔL , is approximately proportional to the force, so we say “Energy Method”; we

$$\Delta L = \gamma F.$$

For a solid elastic body with arbitrary distortions, the strain T_{ijkl} is related to the stress S_{ij} by a set of linear equations:

$$T_{ijkl} = \sum_k S_{ijk} \delta_{lj}. \quad (31.26)$$

Also, you know that the potential energy of a spring (or bar) is

$$\frac{1}{2} F^2 \Delta L = \frac{1}{2} k F^2.$$

The generalization for the elastic energy density in a solid body is

$$U_{\text{elastic}} = \sum_{ijkl} \gamma_{ijkl} S_{ij} S_{kl}. \quad (31.27)$$

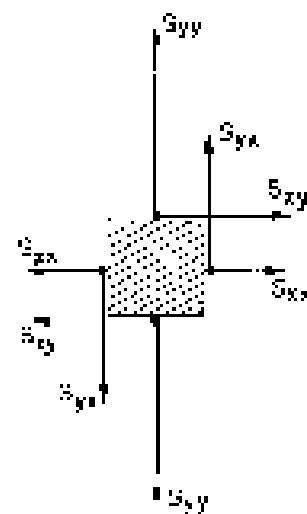

Fig. 31-9. The x - and y -faces on four faces of a small unit cube.

The complete description of the elastic properties of a crystal must be given in terms of the coefficients S_{ijkl} . This introduces us to a new beast. It is a tensor of the fourth rank. Since each index can take on any one of three values, i, j, k , or l , there are $3^4 = 81$ coefficients. But there are really only 21 different numbers. First, since S_{ij} is symmetric, i , has only $\frac{1}{2}k$ different values, and only $\frac{1}{2}k$ different coefficients are needed in Eq. (31.27). But also, S_{ij} can be interchanged with S_{kl} without changing the energy, so S_{ijkl} must be symmetric if we interchange i and k . This reduces the number of different coefficients to 21. So to describe the elastic properties of a crystal of the lowest possible symmetry requires 21 elastic constants! This number is, of course, reduced for crystals of higher symmetry. For example, a cubic crystal has only three elastic constants, and an isotropic substance has only two.

That the latter is true can be seen as follows. How can the components of S_{ijkl} be independent of the direction of the axes, as they must be if the material is isotropic? On the other hand, they can be independent only if they are expressible in terms of the tensor δ_{ij} . There are two possible expressions, $\delta_{ik}\delta_{jl}$ and $\delta_{il}\delta_{jk} + \delta_{ik}\delta_{lj}$, which have the required symmetry, so S_{ijkl} must be a linear combination of them. Therefore, for isotropic materials,

$$S_{ijkl} = a(\delta_{ik}\delta_{jl}) - b(\delta_{il}\delta_{jk} + \delta_{ik}\delta_{lj}),$$

and the material requires two constants, a and b , to describe its elastic properties. We will leave it for you to show that a cubic crystal needs only three.

As a final example, this time of a third-rank tensor, we take the piezoelectric effect. Under stress, a crystal possesses an electric field property called P_{ijk} , hence, "piezoelectric." The law is

$$E_i = \sum_{j,k} P_{ijk} S_{jk},$$

where E_i is the electric field, and the P_{ijk} are the piezoelectric coefficients of the piezoelectric tensor. Can you show that if the crystal has a center of inversion under $(x, y, z) \rightarrow (-x, -y, -z)$ the piezoelectric coefficients are all zero?

31-8 The four-vector of electromagnetic induction

All the tensors we have looked at so far in this chapter relate to the three dimensions of space; they are defined to have a certain transformation property under spatial rotations. In Chapter 26 we had occasion to use a tensor in the four dimensions of relativistic space-time—the electromagnetic field tensor $A_{\mu\nu}$. The components of such a four-tensor transform under a Lorentz transformation of the coordinates in a special way that we worked out. (Although we did not do it that way, we could have considered the Lorentz transformation as a “rotation” in a four-dimensional “space” called Minkowski space; then the analogy with what we are doing here would have been closer.)

As our last example, we want to consider another tensor in the four dimensions (x, y, v, z) of relativity theory. When we wrote the stress tensor, we defined S_{ij} as a component of a force across a unit area. But a force is equal to the rate of change of a momentum. Therefore, instead of saying “ S_{xy} is the x component of the force across a unit area perpendicular to y ,” we could equally well say, “ S_{xy} is the rate of flow of the x -component of momentum through a unit area perpendicular to y .” In other words, each term of S_{ij} also represents the flow of the i -component of momentum through a unit area perpendicular to the j -direction. There are pure space components, but they are parts of a “larger” tensor S_{ij} in four dimensions (x and $y = (i, x, y, z)$) containing additional components like S_{xx} , S_{yy} , S_{zz} , etc. We will now try to find the physical meaning of these extra components.

We know that the space components represent flow of momentum. We can get a clue on how to extend this to the time dimension by studying another kind of “flow”—the flow of electric charge. For the scalar quantity, charge, the rate of flow (per unit area perpendicular to the flow) is a space vector—the current density

were). We have seen that the time component of this four-vector is the density of the stuff that is flowing. For instance, you can combine with a time component, $j_0 = \rho$, the charge density, to make the four-vector $k = (\rho, j)$; that is, the ω in k takes on the values ρ, j, x, y, z to mean "density, rate of flow in the x -direction, rate of flow in y , rate of flow in z " of the scalar charge.

Now by analogy with our statement about the time component of the flow of a scalar quantity, we might expect that with S_{xx}, S_{yy} , and S_{zz} , describing the flow of the x -component of momentum, there should be a time component S_{tt} , which would be the density of whatever is flowing; that is, S_{tt} should be the density of a momentum. So we can extend our tensor by inserting to include a t -component. We have

$$\begin{aligned} S_{tt} &= \text{density of } x\text{-momentum,} \\ S_{tx} &= x\text{-flow of } x\text{-momentum,} \\ S_{ty} &= y\text{-flow of } x\text{-momentum,} \\ S_{tz} &= z\text{-flow of } x\text{-momentum.} \end{aligned}$$

Similarly, for the y -component of momentum we have the three components of flow: S_{yy}, S_{ty}, S_{zy} . In a similar way shall we find the z -momentum terms:

$$S_{zz} = \text{density of } y\text{-momentum.}$$

And, of course, to S_{tx}, S_{ty}, S_{tz} we would add

$$S_{tx} = \text{density of } x\text{-momentum.}$$

In four dimensions there is also a component of momentum, which is, we know, energy. So the tensor S_{ij} should be extended vertically with S_{tt}, S_{yy} , and S_{zz} , where

$$\begin{aligned} S_{tt} &= x\text{-flow of energy,} \\ S_{tx} &= x\text{-flow of energy,} \\ S_{ty} &= y\text{-flow of energy,} \\ S_{tz} &= z\text{-flow of energy.} \end{aligned} \quad (11.28)$$

That is, S_{tt} is the flow of energy per unit area and per unit time across a surface perpendicular to the x -axis, and so on. Finally, to complete our tensor we need S_{vv} , which would be the density of energy. We have extended our stress tensor S_{ij} of three dimensions to the four-dimensional stress-energy tensor S_{ijv} . The index v can take on the four values t, x, y , and z , meaning, respectively, "density," "flow per unit area in the x -direction," "flow per unit area in the y -direction," and "flow per unit area in the z -direction." In this we may v takes on the four values t, x, y, z to label other flows, namely, "energy," "momentum," "heat current," "current density," "charge density," and "momentum in the v -direction."

As an example, we will discuss the electric field in optics, but in a region of free space (in which there is no electric or magnetic field). We know that the flow of energy is the Poynting vector $S = \mathbf{E} \times \mathbf{B}$. So the x , y , and z -components of S are, from the relativistic sum of squares, the components S_{tx}, S_{ty} , and S_{tz} of our four-dimensional stress-energy tensor. The fourth part of the tensor S_{ijv} carries over to the time components as well, so the four-dimensional tensor S_{ijv} is symmetric:

$$S_{ij} = S_{ji}. \quad (11.29)$$

In other words, the components S_{tx}, S_{ty}, S_{tz} , which are the densities of x , y , and z -momentum, are also equal to the x , y , and z -components of the Poynting vector S , the energy flow, as we have already shown it, in either of space or a different kind of language.

The remaining components of the electromagnetic stress tensor S_{ij} can also be expressed in terms of the electric and magnetic fields E and B . That is to say, we must admit there is, to put it very seriously, flow of momentum in the electromagnetic field. We discussed this in Chapter 27 in connection with Eq. (27.21), but did not work out the details.

For a given charge density their power is given in two dimensions by
 ω_0 to see the formula for \mathcal{E}_0 and details of the fields:

$$\lambda_{\mu\nu} = \frac{q}{4\pi} \left(\sum_{\alpha} \delta_{\mu\alpha} \delta_{\nu\alpha} - \frac{1}{3} \epsilon_{\mu\nu} \sum_{\alpha\beta\gamma} \delta_{\alpha\beta} \delta_{\gamma\mu} \right).$$

where $\epsilon_{\mu\nu}$ is the epsilon tensor, $\delta_{\mu\nu}$ is the Kronecker delta function and we have used a special meaning for the sum sign \sum_{α} to be equal to the symbol $\delta_{\mu\nu}$ in the case where the terms are not to be differentiated and $\delta_{\mu\nu} = 1$, while $\delta_{\mu\nu} = \delta_{\mu\mu} = \delta_{\nu\nu} = 1$ and $\delta_{\mu\nu} = 0$ for $\mu \neq \nu$ for $\mu = \nu$. One can verify that it gives the charge density $\lambda_{\mu\nu} = q\epsilon_{\mu\nu}/4\pi r^2$. If one the Boyer-Lindquist metric $\times R^2$ then you know that ϵ is an eigenfunction of ∂_R . This implies that ϵ is orthogonal to the direction of the field, i.e. $\epsilon \cdot E = 0$. There is an equal number of ϵ 's having perpendicular to the field direction.

Refractive Index of Dielectric Materials

32-1 Polarization of matter

We want now to discuss the polarization of the detection of light— and 3.5. We have the description of the dielectric materials. In Chapter 31 of Vol. 1 we discussed the theory of the index of refraction n , because it is the refractive index of the material at the time ω but to correct corrected to adding the index only for materials of low density, like gases. A physical process that produces densities here (3.5), is not clear. The electric field E of light wave induces the polarization of the gas, producing existing dipole moments. The acceleration of the oscillating charges radiates new waves of ripples. This new field, interacting with the old field, produces a change in field which is equivalent to a phase shift of the original wave. However, the phase shift is proportional to the density of the gas. At the effect is equivalent to having a different phase velocity in the material. While we looked at the subject before, we neglected the polarization due to the form factor effect on the new wave changing the ends of the scattering dipole. We assumed that the forces on the charges in the atoms came from the incoming wave. It was, in fact, the result of the wave only by the incoming wave to be seen by the reflected wave of the previous issues. It would now have to think, what is in their turn to account this effect, so we started only the ray for the wave and didn't account.

Now, there are several ways that it is very convenient to be polarization. One of different experiments. This method requires the physical origin of the index of refraction from the reflected wave with respect to the original wave, can determine the density of these materials more simply. This chapter will bring together arguments and proofs from our earlier work. We will let you practically everything we will review the material only for really non-idealized materials. Since you may need one of the previous chapters when we are going to read again. Table 32-1 lists some equations we are going to use together with a reference to the place where they can be found. In most instances, we will get more details by giving the physical argument again, and will give just the equation.

Table 32-1

The work in this chapter will be based on the following material, already covered in earlier chapters

Subject	Reference	Equation
Damped oscillations	Vol. 1, Chap. 17	$\ddot{\mathbf{r}}(t) = -\omega_0^2 \mathbf{r}(t) - \frac{2\pi}{\tau} \mathbf{r}(t) + \mathbf{F}$
Index of glass	Vol. 1, Chap. 17	$n = 1 + \frac{1 - \omega_0^2}{2\omega_0^2(\omega_0^2 - \omega^2)}$ $n = c = n^{1/2}$
Motion	Vol. 1, Chap. 17	$\ddot{\mathbf{r}}(t) = -\omega_0^2 \mathbf{r}(t) + \mathbf{F}$
Electric conductivity	Vol. 1, Chap. 18	$\mathbf{j} = \sigma \mathbf{E} = \frac{q}{m} \mathbf{v} = \frac{q}{m} \mathbf{E}$
Polarization	Vol. 1, Chap. 19	$\mathbf{p}_s = -\nabla \times \mathbf{B}$
Induced dipoles	Vol. 1, Chap. 19	$\mathbf{p}_{sd} = \epsilon_0 \mathbf{E} = \frac{1}{\epsilon_0} \mathbf{F}$

32-7 Low-frequency and high-frequency approximations, the skin depth and the plasma frequency

Review. See Table 32-1.

We begin by recalling the machinery of the index of refraction for a gas. We suppose that there are N particles per unit volume and that each particle behaves as a harmonic oscillator. We use a model of an atom or molecule in which the electron is bound with a force proportional to its displacement (as though the electron were held in place by a spring). We emphasize that this was not a legitimate classical model of an atom, but we will show later that the current quantum mechanical theory gives results equivalent to this model (in simple cases). In our earlier treatment, we did not include the possibility of damping force in the atomic oscillators, but we will do so now. Such a force corresponds to a resistance to the motion, that is, to a force proportional to the velocity of the electron. Then the equation of motion is

$$\ddot{x} + \omega_0^2 x = \omega_0^2 E - m^{-1} \omega_0^2 \dot{x} \quad (32.1)$$

where x is the displacement parallel to the direction of E . (We are assuming an isotropic medium where damping force is the same in all directions.) Also, we are taking, for the moment, a linearly polarized wave, so that E doesn't change direction. If the electric field oscillates, the x -values sinusoidally with time, we write

$$E = E_0 e^{i\omega t} \quad (32.2)$$

The displacement will then oscillate with the same frequency, and we write

$$x = x_0 e^{i\omega t}$$

Substituting $\ddot{x} = i\omega x_0$ and $\dot{x} = -\omega x_0$, we can solve Eq. 32.1 for x_0 :

$$x_0 = \frac{i\omega^2 E_0}{\omega^2 + i\omega\gamma + \omega_0^2} \quad (32.3)$$

Knowing the displacement, we can calculate the acceleration \ddot{x} and find the forces responsible for the index. This was the way we computed the index in Chapter 31 of Volume I.

Now, however, we want to take a different approach. The induced dipole moment p is related to x as follows, using Eq. (32.3).

$$p = \frac{q_e^2 m}{-\omega^2 + i\omega\gamma + \omega_0^2} E \quad (32.4)$$

Since p is proportional to E , we write

$$p = \kappa_0 \epsilon_0 \omega E \quad (32.5)$$

where κ_0 is called the *atomic polarization*. With this definition, we have

$$\kappa_0 = \frac{q_e^2 m \epsilon_0}{-\omega^2 + i\omega\gamma + \omega_0^2} \quad (32.6)$$

The quantum mechanical solution is the motion of electrons in atoms gives a similar answer except with the following modifications. The atoms have several natural frequencies, each frequency with its own dissipation constant γ . Also the effective "strength" of each mode is different, when we end represent by multiplying the polarizability for each frequency by a strength factor f , which is a number we expect to be of the order of 1. Representing the three parameters ω , γ , and f by ω_i , γ_i , and f_i for each mode of oscillation, and summing over the

¹ Throughout this chapter we follow the notation of Chapter 31 of Volume I, and Eq. 32.1 represents the same situation as we defined there. In our last example we used ω to represent the relative permeability—the ratio of μ to μ_0 . In the notation of this chapter $\mu = \kappa_0 \epsilon_0 \omega$; μ (Eq. 32.6).

various modes, we modify Eq. (32.6) to read

$$\epsilon(\omega) = \frac{N}{C\omega} \sum_p \frac{\rho_p}{\omega_p^2 - \omega^2 + i\omega\tau_p} \quad (32.7)$$

If ΔE is the induced voltage per unit volume in the material, the polarization P is just $\Delta E = \epsilon_0 \Delta E/E$, and is proportional to E :

$$P = \epsilon_0 \epsilon(\omega) E. \quad (32.8)$$

In other words, when there is a sinusoidal electric field acting in a material, there is a induced dipole moment per unit volume which is proportional to the electric field—i.e., proportionality constant is that, for simplicity, depends upon the frequency. At very high frequencies ω is small; there is no net response. However, at low frequencies ω can be so strong response. Also, the proportionality constant is complex in order which means that the polarization does not exactly follow the electric field, but may vary with time as shown before. At any rate there is $\epsilon(\omega)$ a total polarizability or susceptibility proportional to the strength ω^2 of the electric field.

32-2 Maxwell's equations in a dielectric

The existence of such nonlinear materials that have an polarization-charging density only inside of the material, and these must be put into Maxwell's equations in order to find the fields. We can ignore the free charges since Maxwell's equations describe situations in which the charge and currents are not zero, as in a vacuum, but it is given implicitly by the polarization vector. Our first step is to find explicitly the charge density ρ and current density j averaged over a small volume of the size ΔV ; we look in order to see what we get for P . Then the primary we need can be obtained from the polarization.

We have seen, in Chapter 13 that, why the polarization P varies from place to place, there is a conductivity given by

$$\rho_s = -\nabla \cdot P. \quad (32.9)$$

At that time, we were dealing with static fields, and the same formula is valid also for time-varying fields. However, when P varies with time, there are charges in motion, so there is also a polarization current. Each of the oscillating charges contributes a current equal to its charge q_{av} times its velocity v . With N such charges per unit volume, the current density j is

$$j = Nq_v v$$

Since we know that $v = \dot{r}$ divide, then $j = Nq \dot{r}$ (velocity) which is just $\partial P/\partial t$. Therefore the current density from the varying polarization is

$$j_{av} = \frac{\partial P}{\partial t}. \quad (32.10)$$

Our problem is now clear and simple. We write Maxwell's equations with the charge density and current density expressed in terms of P , using Eqs. (32.8) and (32.10). (We assume that there are no other currents and charges in the material.) We then relate P to E with Eq. (32.5), and we solve the equation on E and B —looking for the wave solutions.

Before we do this, we would like to make an historical note. Maxwell originally wrote his equations in a form which was different from the one we have been using. Because the equations were written in this different form for many years—and are still written that way by many people—we will explain the difference. In the early days, the mechanism of the dielectric constant was not fully understood, nor that there was a polarization of the material. So people did not agree to the fact there was a contribution

to the charge density ρ and $\nabla \cdot P$. They thought only in terms of charges that were far from the sources (such as the charges for flow in wires or in coated air surfaces).

Today, we prefer to keep separate the total charge density, including the part from the bound atomic charges. It was well that part ρ_{ext} , we can write

$$\rho = \rho_{\text{ext}} + \rho_{\text{atom}}$$

where ρ_{atom} is the charge density considered by Maxwell and refers to the charges and binding forces of atoms. We will then write

$$\nabla \cdot E = \frac{\rho_{\text{ext}} + \rho_{\text{atom}}}{\epsilon_0}$$

Substituting ρ_{ext} from Eq. (32.9),

$$\begin{aligned} \nabla \cdot E &= \frac{\rho_{\text{atom}} - \frac{1}{\mu_0} \nabla \cdot P}{\epsilon_0} \\ \text{or} \quad \nabla \cdot (\epsilon_0 E + P) &= \rho_{\text{atom}}. \end{aligned} \quad (32.11)$$

The current density in the Maxwell equations for $\nabla \times B$ also has unperturbed contributions from bound atomic currents. We can therefore write

$$j = j_{\text{ext}} + j_{\text{atom}}$$

and the Maxwell curling becomes

$$\epsilon_0 \nabla \times B = j_{\text{ext}} + \frac{j}{\mu_0} + \frac{\partial H}{\partial t}. \quad (32.12)$$

Using Eq. (32.10), we get

$$\epsilon_0 c^2 \nabla \times B = j_{\text{atom}} + \frac{P}{\mu_0} (\epsilon_0 E + P). \quad (32.13)$$

Now given, as in Fig. 1, we want to define a new vector D by

$$D = \epsilon_0 E + P, \quad (32.14)$$

the two field equations would become

$$\nabla \cdot D = \rho_{\text{atom}}, \quad (32.15)$$

and

$$\epsilon_0 c^2 \nabla \times B = j_{\text{atom}} - \frac{\partial D}{\partial t}. \quad (32.16)$$

This is actually the form that Maxwell used for dielectrics. His two remaining equations were

$$\nabla \times E = -\frac{\partial H}{\partial t},$$

and

$$\nabla \cdot B = 0,$$

which are the same as we have been using.

Maxwell and the other early workers also had a problem with magnetic materials (which we will take up soon). Because they did not know about the circulating currents responsible for atomic magnetism, they used a current density that was missing still another part. Instead of Eq. (32.16), they actually wrote

$$\nabla \times B = P + \frac{\partial D}{\partial t}, \quad (32.17)$$

where H differs from $\epsilon_0^{-1}B$ because it reduces the effects of surface currents (They represent what is left of the currents). So Maxwell had four field vectors— E , B , D , and H . He gave little, if any, passing attention to what H is.

was going on inside the material. You will find the equations written this way in many places.

To solve the equations, it is necessary to relate D and B to the other fields, and perhaps to ω as well:

$$D = \epsilon E \quad \text{and} \quad B = \mu H \quad (32.18)$$

However, these relations are only approximately true for some materials, and even then only if the fields are not changing rapidly with time. (For sinusoidally varying fields one often can't use the equations this way by making ϵ and μ complex functions of the frequency, but not for an arbitrary time variation of the fields.) So there used to be all sorts of cheating in solving the equations. We think the right way is to keep the equations in terms of the fundamental quantities as we now understand them—and that's how we have done it.

A2.3 Waves in a dielectric

We want now to find out what kind of electromagnetic waves exist in a dielectric material in which there are no extra charges other than those bound in atoms. So we take $\rho = -\nabla \cdot P$ and $j = \partial P/\partial t$. Because there are no free

$$\begin{aligned} (\text{a}) \quad \nabla \cdot B &= -\frac{\rho}{\epsilon_0} & (\text{b}) \quad c^2 \nabla \times B &= \frac{\partial}{\partial t} \left(\frac{P}{\epsilon_0} + E \right) \\ (\text{c}) \quad \nabla \times E &= -\frac{\partial B}{\partial t} & (\text{d}) \quad \nabla \cdot B &= 0 \end{aligned} \quad (32.19)$$

We will solve these equations as we have done before. We start by taking the curl of Eq. (32.19c)

$$\nabla \times (\nabla \times B) = -\frac{d}{dt} \nabla \times B.$$

Next, we make use of the vector identity

$$\nabla \times (\nabla \times E) = \nabla(\nabla \cdot E) - \nabla^2 E,$$

and also substitute for $\nabla \times B$, using Eq. (32.19b), we get

$$\nabla(\nabla \cdot E) - \nabla^2 E = -\frac{1}{\epsilon_0 c^2} \frac{\partial^2 P}{\partial t^2} - \frac{1}{c^2} \frac{\partial^2 E}{\partial t^2}.$$

Using Eq. (32.19a) for $\nabla \cdot E$, we get

$$\nabla^2 E + \frac{1}{c^2} \frac{\partial^2 E}{\partial t^2} = -\frac{1}{\epsilon_0} \nabla(\nabla \cdot P) = \frac{1}{\epsilon_0 c^2} \frac{\partial^2 P}{\partial t^2}. \quad (32.20)$$

So instead of the wave equation, we now get that the differentiation of E is equal to two terms involving the polarization P .

Since P depends on E , however, Eq. (32.20) can still have wave solutions. We will now limit ourselves to isotropic dielectrics, so that P is always in the same direction as E . Let's try to find a solution for a wave going in the x -direction. Then, the electric field might vary as $e^{i(kx-\omega t)}$. We will also suppose that the wave is polarized in the x -direction—that the electric field has only an x -component. We write

$$E_x = E_0 e^{i(kx-\omega t)}. \quad (32.21)$$

You know that any function of $(x - vt)$ represents a wave that travels with the speed v . The exponent of Eq. (32.21) can be written as

$$ik \left(x - \frac{\omega}{c} t \right),$$

so Eq. (32.21) represents a wave with the phase velocity

$$v_{ph} = \omega/c$$

The index of refraction is defined (see Chapter 31, Vol. I) by setting

$$\frac{c}{v} = \frac{\epsilon'}{\epsilon_0}$$

Thus Eq. (32.21) becomes

$$P_x = \epsilon_0 \epsilon' \omega^2 E_x$$

So we can find α by finding what value of ϵ' is required if Eq. (32.21) is to satisfy the given field equations, and then using

$$\alpha = \frac{\epsilon'}{\epsilon_0} \quad (32.22)$$

In an isotropic material, there will be only an x -component of the polarization, then P has no variation with the x coordinate, so $\nabla \cdot P = 0$, and we get rid of the first term on the right-hand side of Eq. (32.21). Also, since we are assuming a linear dielectric, ϵ_0 will vary as ω^2 , and $\epsilon_0^2 \partial_x / \partial t^2 = -\alpha^2 P_x$. The Laplacian in Eq. (32.20) becomes simply $\partial^2 E_x / \partial x^2 = -\alpha^2 P_x$, so we get

$$-\alpha^2 E_x = \frac{\epsilon'^2}{c^2} E_x = -\frac{\epsilon'^2}{c^2} P_x \quad (32.23)$$

Now let us assume for the moment that since E is varying sinusoidally, we can set P proportional to E , as in Eq. (32.5). (We'll come back to discuss this assumption later.) We write

$$P_x = \epsilon_0 \epsilon' E_x$$

Then P_x is a solution of Eq. (32.23), and we find

$$\alpha^2 = \frac{m^2}{c^2} (1 - \alpha \alpha_0) \quad (32.24)$$

We have found that a wave like Eq. (32.21), with the wave number k given by Eq. (32.24), will satisfy the field equations. Using Eq. (32.23), the answer to question 1 of

$$\alpha^2 = 1 + \beta_{\text{eff}} \quad (32.25)$$

Let's compare this formula with what we obtained in our theory of the index of a gas (Chapter 31, Vol. I). There, we got Eq. (31.29), which is

$$\alpha = 1 + \frac{\lambda_0^2}{2 \pi \alpha_0} \frac{1}{1 - \omega^2 + \omega_0^2} \quad (32.26)$$

Taking α from Eq. (32.5), Eq. (32.25) would give us

$$\alpha' = 1 + \frac{\lambda_0^2}{m c} \frac{1}{1 - \omega^2 + (\pi \alpha_0 + \omega_0^2)} \quad (32.27)$$

First, we have the new term in α' , because we are including the dissipation of the oscillators. Second, the left-hand side is a fraction of α^2 , and there is an extra factor of $1/2$. But notice that if α is small enough so that ω is close to one (as it is for a gas), then Eq. (32.27) says that α^2 is one plus a small number: $\alpha^2 = 1 + \alpha$. We can then write $\alpha = \sqrt{1 + \alpha} \approx 1 + \alpha/2$, and the two expressions are equivalent. Thus our new method gives for a gas the same result we found earlier.

Now you might think that Eq. (32.27) would give the index of refraction for dense materials also. It needs to be modified, however, for several reasons. First, the derivation of this equation assumes that the polarizing field on each atom is the field E_x . That assumption is not right, however, because in dense materials there is also the field produced by other atoms in the vicinity, which may be comparable to E_x . We considered a similar problem when we studied the static fields in dielectrics. (See Chapter 11.) You will remember that we estimated the field at a single atom by imagining that it sat in a spherical hole in the surrounding dielectric. The field in such a hole—which we called the local field—is increased

over the average field E by the amount $\rho/\epsilon_0 c$. (Remember, however, that this result is only strictly true in *isotropic* materials—including the special case of a static crystal.)

The latter approximation will hold for the electric field in a wave, so long as the wavelength of the wave is much longer than the spacing between atoms. Limiting ourselves to such cases, we write

$$E_{\text{local}} = E - \frac{\rho}{\epsilon_0 c}. \quad (32.25)$$

This local field is the one that should be used for E in Eq. (32.3); that is, Eq. (32.3) should be rewritten:

$$P = \epsilon_0 N \mu_0 E_{\text{local}}. \quad (32.26)$$

Using E_{local} from Eq. (32.25), we find

$$\mu = \epsilon_0 N \mu_0 \left(E - \frac{\rho}{\epsilon_0 c} \right)$$

or

$$\mu = \frac{\epsilon_0}{1 - (\lambda \rho / \epsilon_0 c)} \epsilon_0 E. \quad (32.27)$$

In other words, the local field E is only proportional to E (for a material "at rest"). However, the constant of proportionality is not ϵ_0 , as we wrote above Eq. (32.27), but should be $\epsilon_0 N \mu_0 / (1 - (\lambda \rho / \epsilon_0 c))$. So we should rewrite Eq. (32.25) instead

$$\eta^2 = 1 + \frac{N \rho}{1 - (\lambda \rho / \epsilon_0 c)}. \quad (32.28)$$

It will be more convenient if we rewrite this equation as

$$\frac{\eta^2 - 1}{\eta^2 + 2} = N \rho, \quad (32.29)$$

which is algebraically equivalent. This is known as the Clausius-Mosotti equation.

There is another complication in dense materials. Because neighboring atoms are so close, there are strong interactions between them. The individual modes of oscillation are, therefore, modified. The natural frequencies of the atomic oscillators are屏ed off by the interactions, and they are usually quite rapidly damped—the relaxation well could become quite large. So that ω_0 's and γ_0 's of the ω_0 's will be quite different from those of the free atoms. With these reservations, we can still represent η^2 at least approximately by Eq. (32.29). We have then that

$$\frac{\eta^2 - 1}{\eta^2 + 2} = \frac{N \rho^2}{4 \pi n_0} \sum_i \frac{1}{-\omega_i^2 + i \gamma_i \omega_i + \omega_{i0}^2}. \quad (32.30)$$

One final complication. If the dense material is a mixture of several components, each will contribute to the polarization. The total η^2 will be the sum of the contributions from each component of the mixture [except for the inaccuracy of the local field approximation, Eq. (32.28), in ordered crystals—effect we discussed when analyzing ferroelectrics]. Writing N_i as the number of atoms of each component per unit volume, we should replace Eq. (32.30) by

$$\frac{\eta^2 - 1}{\eta^2 + 2} = \sum_i N_i \eta_i^2, \quad (32.31)$$

where each η_i^2 will be given by an expression like Eq. (32.27). Equation (32.31) complements theory of the index of refraction. The quantity $(\eta^2 - 1)/(\eta^2 + 2)$ is called by some authors "mean" or frequency, which is the mean atomic polarizability $\alpha(\omega)$. The precise evaluation of $\alpha(\omega)$ (that is, finding f_i , ω_i , and ω_{i0}) in dense substances is a difficult problem of quantum mechanics. It has been done from first principles only for a few especially simple substances.

32-4 The complex index of refraction

We want to look now at the consequences of our result, Eq. (32.33). First we notice that ϵ is complex, so the index is going to be a complex number. What does that mean? Let's say that ω is the angular frequency of a real and an imaginary part

$$\omega = \omega_R - i\omega_I \quad (32.35)$$

where ω_R and ω_I are real functions of ω . We would like with a minus sign so that ω will be a positive quantity in all ordinary optical theories—the ordinary insulating materials—that are real. Like ω_R , ω_I is connected to ϵ_0 since ϵ_0 is a positive number, and that makes ω_I negative if ω_R is positive. Our picture here of Eq. (32.21) is $E = E_0 e^{-i\omega R t + \omega_I t}$.

$$E = E_0 e^{-i\omega R t + \omega_I t}$$

Writing ω as in Eq. (32.35), we would have

$$E = E_0 e^{-(\omega_R t + \omega_I t)} e^{i\omega_R t} \quad (32.36)$$

The term $e^{-(\omega_R t + \omega_I t)}$ represents a wave travelling with the speed c/ϵ_0 , so ω_R represents what we normally think of as the index of refraction. But the amplitude of this wave is

$$E_0 e^{-\omega_I t},$$

which decreases exponentially with t . A graph of the strength of the electric field at some instant as a function of t is shown in Fig. 32-4, for $\omega_I < \omega_R/2\pi$. The imaginary part of the index represents the attenuation of the wave due to the energy losses in the atomic oscillators. The intensity of the wave is proportional to the square of the amplitude, so

$$\text{Intensity} \propto e^{-2\omega_I t}.$$

This is often written as

$$\text{Intensity} \propto e^{-ct},$$

where $c = 2\omega_I/c$ is called the absorption coefficient. Thus we have in Eq. (32.33) not only the theory of the index of refraction of materials, but the theory of their absorption of light as well.

In most materials considered to be transparent materials, the quantity c —which has the dimensions of a length—is quite large in comparison with the thickness of the material.

32-5 The index of a mixture

There is another prediction of our theory of the index of refraction that we can check against experiment. Suppose we consider a mixture of two materials. The index of the mixture is not the average of the two indices, but should be given in terms of the sum of the two polarizabilities, as in Eq. (32.34). If we ask about the index of, say, a sugar solution, the total polarizability is the sum of the polarizability of the water and that of the sugar. Each can, of course, be evaluated using for N the number per unit volume of the molecules of the particular kind. In other words, if a given solution has N_1 molecules of water, whose polarizability is α_1 , and N_2 molecules of sucrose ($C_{12}H_{22}O_{11}$), whose polarizability is α_2 , we should have that

$$2 \left(\frac{\alpha_1}{N_1} + \frac{\alpha_2}{N_2} \right) = N_1 \alpha_1 + N_2 \alpha_2. \quad (32.37)$$

We can use this formula to test our theory against experiment, by measuring the index for various concentrations of sucrose in water. We are making several assumptions here, however. Our formula assumes that there is no chemical action when the sucrose is dissolved in the water. No disturbance to the individual atoms

Table 32-2

oscillations are not too different for various concentrations. So our result is certainly only approximate. Anyway, let's see how good it is.

We have picked the example of a sugar solution because there is a good table of measured values of the index of refraction in the *Handbook of Chemistry and Physics*, and also because sugar is a molecular crystal that goes into solution without changing or otherwise changing its chemical state.

We give in the first three columns of Table 32-2 the data from the handbook. Column A is the percent of sucrose by weight, column B is the measured density (g/cm³), and column C is the measured index of refraction (at light-wavelength is 589.3 millimicrons). For pure sugar we have taken the measured index of sugar crystals. The crystals are not isotropic, so the measured index is different along different directions. The handbook gives three values:

$$n_1 = 1.5275, \quad n_2 = 1.5651, \quad n_3 = 1.5715.$$

We have taken the average.

Now we could try to compute α for each concentration, but we don't know what value to have for n_1 or n_2 . Let's test the theory this way: We will assume that the polarizability of water (α_1) is the same at all concentrations and compute the polarizability of sucrose by using the experimental values for α and solving Eq. (32.27) for α_2 . If the theory is correct, we should get the same α_2 for all concentrations.

First, we need to know N_1 and N_2 ; let's express them in terms of Avogadro's number, N_A . Let's take one liter (1000 cm³) for our unit of volume. Then N_1/N_2 is the weight per liter divided by the gram-molecular weight. And the weight per liter is the density multiplied by 1000 to get grams per liter. So the fractional weight of either the sucrose or the water. In this way, we get N_1/N_2 and N_1/N_3 , as in columns D and E of the table.

In column F we have computed $\beta(n^2 - 1)/(n^2 + 2)$ from the experimental values of n in column C. For pure water, $\beta(n^2 - 1)/(n^2 + 2)$ is 0.612, which is equal to just N_1/N_3 . We can then fill in the rest of Column G, since for each row G/F may be the same ratio, namely, 0.612/55.5. Subtracting column G from column F, we get the contribution N_{expt} of the sucrose, shown in column H. Dividing these entries by the values of N_1/N_3 in column D, we get the values of N_{pred} shown in column I.

From our theory we would expect all the values of N_{pred} to be the same. They are not exactly equal, but pretty close. We can conclude that our ideas are fairly correct. Even more, we find that the polarizability of the sugar molecule doesn't seem to depend much on its surroundings—it's polarizability is nearly the same in a dilute solution as it is in the crystal.

32-6 Waves in metals

The theory we have worked out in this chapter for solid materials can also be applied to poor conductors, like metals, with very little modification. In metals some of the electrons have no binding force holding them to any particular atom; these are "free" electrons which are responsible for the conductivity. There are other electrons which are bound, and the theory shown is directly applicable to them. Their influence, however, is usually swamped by the effects of the conduction electrons. We will consider now only the effects of the free electrons.

There is an accelerating force on an electron—but still some resistance to its motion. Its equation of motion differs from Eq. (32.1) only because the term in a_E is missing. So if we have been except of $a_E = 0$ in the rest of our derivations—except that there's one more difference. The reason that we had to distinguish between the average field and the local field in a dielectric is that in an insulator each of the dipoles is fixed in position, so that it has a definite relationship to the position of the others. But because the conduction electrons in a metal move around, however, the field on top of the average is just the average field E . By the correction we made in Eq. (32.5) by using Eq. (32.28) should now be used for conduction electrons. Therefore the formula for the index of refraction for metals should look like Eq. (32.27), except with one set of units, namely,

$$n^2 = 1 - \frac{c_0}{2\pi\epsilon_0} \frac{1}{\omega^2 + \omega_{pe}^2}. \quad (32.48)$$

This is only the contribution from the conduction electrons, which we will assume is the major term, for metals.

Now we even know how to find what value to use for ω_p , because it is related to the conductivity of the metal. In Chapter 3 of Volume I we discussed how the conductivity of a metal comes from the flow of the free electrons through the crystal. The electrons go on a jagged path, from one scattering to the next, and between scatterings they move freely except for an acceleration due to any average electric field (as shown in Fig. 32-2). We found in Chapter 10 of Volume I that the average drift velocity is just the acceleration times the average time τ between collisions. The acceleration is $q_0 E/m$, so

$$v_{drift} = \frac{q_0 E}{m} \tau. \quad (32.49)$$

Now for such an acceleration, E was constant, so that v_{drift} was a steady velocity. Since there is no average acceleration, the drag force is equal to the applied force. We have defined "drag" since F_{drag} is the drag force (see Eq. (32.11)), which is $q_0 E$; therefore we have that

$$\tau = \frac{1}{\gamma}. \quad (32.50)$$

Although we cannot easily measure v_{drift} directly, we can determine it by measuring the conductivity of the metal. It is known physically that an electric field E in a metal produces a current with the density j proportional to E (for most materials):

$$j = \sigma E.$$

The proportionality constant σ is called the *conductivity*. This is just what we expect from Eq. (32.32) if we set

$$j = Nq v_{drift} e.$$

Then

$$\sigma = \frac{Nq^2}{m} \tau. \quad (32.51)$$

Since v_{drift} and τ can be related to the observed electrical conductivity, using Eqs. (32.49) and (32.51), we can rewrite our formula for the index, Eq. 32.48

Fig. 32-2. The motion of a free electron.

(32.38), in the following form:

$$n^2 = 1 + \frac{\sigma/\tau}{\omega(1 + \omega\tau)} \quad (32.42)$$

where

$$\tau = \frac{1}{\gamma} = \frac{m_e}{Nq_e}. \quad (32.43)$$

This is a convenient formula for the index of refraction of metals.

32-7 Low-frequency and high-frequency approximations: the skin depth and the plasma frequency

Our result, Eq. (32.42), for the index of refraction for metals predicts quite different characteristics for wave propagation at different frequencies. Let's first consider waves at very low frequencies. If ω is small enough, we can approximate Eq. (32.42) by

$$n^2 = 1 + \frac{\sigma}{\omega\tau}. \quad (32.44)$$

Now, as you can check by taking the square root,

$$\sqrt{-i} = \frac{1 - i}{\sqrt{2}},$$

so for low frequencies,

$$n = \sqrt{2}/2 \exp(i(1 - \omega\tau)). \quad (32.45)$$

The real and imaginary parts of n have the same magnitude. With such a large imaginary part $\text{Im } n$, the wave is rapidly attenuated in the metal. Referring to Eq. (32.36), the amplitude of a wave going in the $-z$ direction decreases as

$$\exp[-\sqrt{\sigma\epsilon_0/\omega\tau} z]. \quad (32.46)$$

Let's write this as

$$e^{-\alpha z}, \quad (32.47)$$

where δ is just the distance in which the wave amplitude decreases by the factor $e^{-1} = 1/2.72$ —or roughly one-third. The amplitude of such a wave as a function of z is shown in Fig. 32-3. Since electromagnetic waves will penetrate into a metal only this distance, δ is called the *skin depth*. It is given by

$$\delta = \sqrt{\sigma\epsilon_0/\omega\tau}. \quad (32.48)$$

Now what do we mean by "low" frequencies? Looking at Eq. (32.47), we see that it can be approximated by Eq. (32.44) only if $\omega\tau$ is small. This being true, one condition is also much less than one—that is, our low-frequency approximation applies when

$$\omega \ll \frac{1}{\tau}$$

and

$$\omega \ll \frac{\sigma}{\epsilon_0}. \quad (32.49)$$

Let's see what frequencies these correspond to for a typical metal like copper. We compute ϵ by using Eq. (32.43), and σ/ϵ_0 by using the measured conductivity. We take the following data from a handbook:

$$\sigma = 5.76 \times 10^7 \text{ (ohm-meter)}^{-1},$$

$$\text{atomic weight} = 63.5 \text{ grams},$$

$$\text{density} = 8.9 \text{ g/cm}^3 = 8.9 \times 10^{-3} \text{ kg/m}^3,$$

$$\text{Avogadro's number} = 6.02 \times 10^{23} \text{ (gram atomic weight)}^{-1}.$$

¹ On writing $-i = \omega\tau/2$, $\sqrt{-i} = e^{-\omega\tau/4} = \cos(\omega\tau/4) - i \sin(\omega\tau/4)$, which gives the same result.

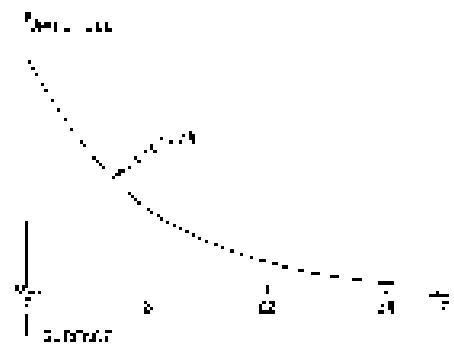

Fig. 32-3. The amplitude of an incident electromagnetic wave as a function of distance in a metal.

If we assume that there is one free electron per atom, then the number of electrons per cubic meter is

$$N = 5.5 \times 10^{28} \text{ meter}^{-3}.$$

Using

$$q_e = 1.6 \times 10^{-19} \text{ coulombs},$$

$$\epsilon_0 = 8.85 \times 10^{-12} \text{ farad/meter}^{-1},$$

$$m = 9.11 \times 10^{-31} \text{ kg},$$

we get

$$\tau = 2.4 \times 10^{-13} \text{ sec},$$

$$\frac{i}{\tau} = 2.1 \times 10^{11} \text{ sec}^{-1},$$

$$\frac{\sigma}{\epsilon_0} = 6.5 \times 10^{18} \text{ sec}^{-1}.$$

At low frequencies less than about 10^{12} cycles per second, copper will have the "low-frequency" behavior we describe (that means for waves whose free-space wavelength is longer than 0.3 millimeters - waves from radio waves).

For these waves, the skin depth in copper is

$$d = \sqrt{\frac{0.026 \text{ m}^2 \cdot \text{sec}}{\omega}}$$

For microwaves of 10,000 megacycles per second (lambda waves)

$$d = 6.7 \times 10^{-4} \text{ cm}.$$

The wave penetrates a very small distance.

We can see from this why in studying cavities (or waveguides) we need to worry only about the fields inside the cavity, and not in the metal outside the cavity. Also, we see why the losses in a cavity are reduced by a thin plating of silver or gold. The losses come from the current which appears only in a thin layer equal to the skin depth.

Suppose we look now at the index of a metal like copper at high frequencies. For very high frequencies ω is much greater than ω_p , and Eq. (32.42) is well approximated by

$$n^2 = 1 + \frac{\epsilon_0}{\epsilon_r \omega^2 \tau}. \quad (32.50)$$

For waves at high frequencies the index of a metal becomes real and less than unity. This is also evident from Eq. (32.48) if the dissipative term α is neglected. As can be done for very large ω , Equation (32.48) gives

$$n^2 = 1 - \frac{\omega_p^2}{\omega^2 \tau \epsilon_0}, \quad (32.51)$$

which is, of course, the same as Eq. (32.49). We have seen before the quantity $\omega_p^2/\epsilon_0 \tau \epsilon_0$, which we called the square of the plasma frequency (Section 7-5)

$$\omega_p^2 = \frac{\epsilon_0 \eta^2}{\epsilon_r \tau \epsilon_0},$$

so we can write Eq. (32.49) or Eq. (32.51) as

$$n^2 = 1 - \left(\frac{\omega_p}{\omega} \right)^2$$

The plasma frequency is a kind of "critical" frequency.

For $\omega < \omega_p$ the index of a metal has no imaginary part, and waves are attenuated; but for $\omega > \omega_p$ the index is real, and the metal becomes transparent. You know, of course, that metals are reasonably transparent to x-rays - *BUT*, some metals are even transparent in the ultraviolet. In Table 23-2 we give the ω_p

several metals the experimental observed wavelength at which they begin to become transparent. In the second column we give the calculated critical wavelength $\lambda_c = c/\omega_p$. Considering that the experimental wavelength is not too well defined, the fit of the theory is fairly good.

You may wonder why the plasma frequency ω_p should have anything to do with the propagation of electromagnetic waves in metals. The plasma frequency comes up in Chapter 7 as the natural frequency of density oscillations of the free electrons. (A cloud of electrons is repelled by electric forces, and the inertia of the electrons leads to an oscillation of density.) So longitudinal plasma waves are resonant at ω_p . But we are now talking about transverse electromagnetic waves, and we have found that transverse waves are absorbed for frequencies below ω_p . (It's no coincidence since ω_p is an accidental coincidence!)

Although we have been talking about wave propagation in metals, you appear to by this time the inaccuracy of the observation of physics—that it doesn't make any difference whether the free electrons are in a metal, or whether they are in the plasma of the interplanetary space, or in the atmosphere of a star. To understand radio propagation in the atmosphere, or even radio communications—using, of course, the proper values for λ and ω . We can see now why long radio waves are absorbed or reflected by the ionosphere, whereas short waves get right through. (Short waves must be used for communications with satellites.)

We have to look ahead the high-end, low-frequency extreme for wave propagation in metals. For the cut-off between transparent and fully opaque, the following formula¹ (Eq. 32.42) must be used. In general, the index will have real and imaginary parts; the wave is attenuated as it propagates into the metal. For very thin layers, metals are somewhat transparent even at optical frequencies. As an example, special gildes for people who work around high-temperature furnaces are made by evaporating a thin layer of gold on glass. The visible light is transmitted fairly well—with a strong green tinge—but the infrared is strongly absorbed.

Finally, it cannot have escaped the reader that many of these formulas resemble in some ways those for the dielectric constant ϵ discussed in Chapter 10. The dielectric constant ϵ measures the response of the material to a constant field, that is, for $\omega = 0$. If you look carefully at the definition of ϵ and ν you see that ν is simply the limit of ϵ^2 as $\omega \rightarrow 0$. Indeed, placing $\omega = 0$ and $\epsilon^2 = \nu$ in equations of this chapter will reproduce the equations of the theory of the dielectric constant of Chapter 11.

Table 32-3*

Wavelengths below which the metal becomes transparent

Metal	λ_c (in micrometers)	$\lambda_c = c/\omega_p$
T	1550 Å	1550 Å
Na	2130	2130
K	2150	2870
Rb	3400	4220

Reflection from Surfaces

33-1 Reflection and refraction of light

The subject of this chapter is the reflection and refraction of light—or electromagnetic waves in general—at surfaces. We have already discussed the laws of reflection and refraction in Chapter 35 of Volume I. Recall what we found out there:

1. The angle of reflection is equal to the angle of incidence. With the angles defined as shown in Fig. 33-1,

$$\theta_r = \theta_i \quad (33.1)$$

2. The product $n \sin \theta$ is the same for the incident and transmitted beam. (Snell's law)

$$n_i \sin \theta_i = n_s \sin \theta_s \quad (33.2)$$

3. The intensity of the reflected light depends on the angle of incidence and also on the direction of polarization. For E perpendicular to the plane of incidence, the reflection coefficient R_{\perp} is

$$R_{\perp} = \frac{I_r}{I_i} = \frac{\tan^2(\theta_i - \theta_s)}{\tan^2(\theta_i + \theta_s)} \quad (33.3)$$

For E parallel to the plane of incidence, the reflection coefficient R_{\parallel} is

$$R_{\parallel} = \frac{I_r}{I_i} = \frac{\tan^2(\theta_i - \theta_s)}{\tan^2(\theta_i + \theta_s)} \quad (33.4)$$

4. For normal incidence (any polarization),

$$\frac{I_r}{I_i} = \left(\frac{n_2 - n_1}{n_2 + n_1} \right)^2 \quad (33.5)$$

(Earlier, we used i for the "incident angle" and r for the refracted angle. Since we can't use i for both "refracted" and "reflected" angles, we are now using θ_i = incident angle, θ_r = reflected angle, and θ_s = transmitted angle.)

Our earlier discussion is really about what anyone would normally meet up with the subject, but we are going to go it all over again in a different way. Why? One reason is that we assumed before that the indexes were real for absorption in the materials. But another reason is that you should know how to deal with what happens to waves at surfaces from the point of view of Maxwell's equations. We'll get the same answers as before, but now from a straightforward solution of the wave problem, rather than by some clever arguments.

We want to emphasize that the amplitude of a surface reflector is not a property of the material, as is the index of refraction. It's a "surface property," one that depends precisely on how the surface is made. A thin layer of extraneous junk on the surface between two materials of index n_1 and n_2 will usually change the reflector. (There are all kinds of possibilities of interference here—like the colors of oil films. Sufficient thickness can even reduce the reflected amplitude to zero for a given frequency; that's how coated lenses are made.) The formulas we will derive are correct only if the change of index is sudden—within a distance very small compared with one wavelength. For light, the wavelength is about 5000 Å, so by a "smooth" surface we mean one in which the conditions change in

going a distance of only a few atoms (or a few angstroms). Our equations will work for light for highly polished surfaces. In general, if the index changes gradually over a distance of several wavelengths, there is very little reflection at all.

33-2 Waves in dense materials

Just as we showed you about the convenient way of describing a sinusoidal plane wave we used in Chapter 26 of Volume I, Any field component in the wave we use E as an example can be written in the form

$$E = E_0 e^{i(kx - \omega t)}, \quad (33.6)$$

where E represents the amplitude at the point x (from the origin) at the time t . The vector k points in the direction the wave is travelling, and the magnitude $|k| = k = 2\pi/\lambda$ is the wave number. The phase velocity of the wave is $v_p = \omega/k$, for a light wave in a material the value $v_p = c/n = 300,000$

$$t = \frac{v_p}{c} x, \quad (33.7)$$

Suppose k is in the \hat{x} -direction, i.e. $k = k\hat{x}$, just as we have often used it. For k in some other direction, we should replace k by k_r , the distance from the origin in the \hat{k} -direction; that is, we should replace k^2 by k_r^2 , which is just k^2 . (See Fig. 33.2.) So Eq. (33.6) is a convenient representation of a wave in any direction.

We must remember, of course, that

$$k^2 r = k_x x + k_y y + k_z z,$$

where k_x , k_y , and k_z are the components of k along the three axes. In fact, we pointed out once that (k_x, k_y, k_z, k) is a four-vector, and that its scalar product with $(x, y, z, 1)$ is an invariant. So the phase of a wave is an invariant, and Eq. (33.6) could be written

$$E = E_0 e^{i k \cdot r},$$

But we don't need to be that fancy now.

For a sinusoidal E , as in Eq. (33.6), $\partial E / \partial t$ is the wave velocity v , and $i k \partial E / \partial t = -ik_x E$, and so on for the other components. You know already it is very convenient to use the form in Eq. (33.6) when working with the other equations. Differentiations are replaced by multiplications. One little useful point: The operation $\nabla = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$ gets replaced by the three in it ∂ 's, $\nabla = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$. But these three act as the components of the vector k , so the operator ∇ gets replaced by multiplying each with $-ik$:

$$\begin{aligned} \frac{\partial}{\partial x} &\rightarrow ik_x, \\ \nabla &\rightarrow -ik. \end{aligned} \quad (33.8)$$

This remains true for any ∇ operation—whether it is the gradient, or the divergence, or the curl. For instance, the x component of $\nabla \times E$ is

$$\frac{\partial E_y}{\partial z} - \frac{\partial E_z}{\partial y}.$$

If both E_y and E_z vary as $e^{i k \cdot r}$, then we get

$$ik_x E_y - ik_y E_z,$$

which is, you see, the x -component of $-ik \times E$.

So we have the very useful fact that, whenever you have to take the gradient of a vector field, such as a wave function, in a medium (they are an important part of physics), you can always take the differentiation quickly and cleanly without thinking by means of the fact that the operation ∇ is equivalent to multiplication by $-ik$.

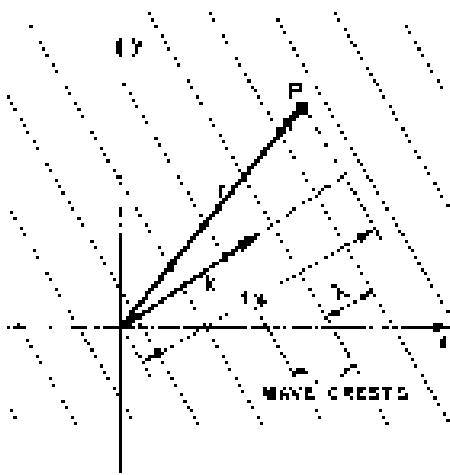

Fig. 33.2. For a wave moving in the direction k , the phase at any point P is $\text{int} = \mathbf{k} \cdot \mathbf{r}_P$.

For instance, the Faraday equation

$$\nabla \times E = -\frac{\partial B}{\partial z}$$

becomes for a wave

$$\nabla \times E = -ikB.$$

This tells us that

$$B = \frac{k}{w} \frac{E}{z}, \quad (33.9)$$

which corresponds to the result we found earlier for waves in free space—that B , in a wave, is at right angles to E and to the wave direction. (In free space, $w/k = c$.) You can remember the sign in Eq. (33.9) from the fact that B is in the direction of Poynting's vector, $S = \text{curl } E \times B$.

If you use Faraday's law with the other Maxwell equations, you get again the results of the last chapter, and, in particular, (3.1)

$$k \cdot k = c^2 + \frac{w^2 n^2}{c^2}. \quad (33.10)$$

But since we know that, we won't do it again.

If you would like to entertain yourself, you can try the following tantalizing problem that was the ultimate test for graduate students back in 1930: solve Maxwell's equations for plane waves in an *anisotropic* crystal, that is, when the polarization P is related to the electric field E by a tensor of polarizability. You should, of course, choose your axes so that the principal axes of the tensor, so that the relations are simplest (then $P_x = n_1 E_x$, $P_y = n_2 E_y$, and $P_z = n_3 E_z$), but let the waves have an arbitrary direction and polarization. You should be able to find the relations between E and B , and how k varies with directions in wave polar space. Then you will understand the optics of an anisotropic crystal. It would be best to start with the simplest case of a birefringent crystal, like calcite, in which two of the polarizabilities are equal (say, $n_1 = n_2$), and see if you can understand why you see double when you look through such a crystal. If you are not that bold, then try the hardest case, in which all three n 's are different. (Even you will know whether you are up to the level of a graduate student in 1930.) In this chapter, however, we will consider only isotropic substances.

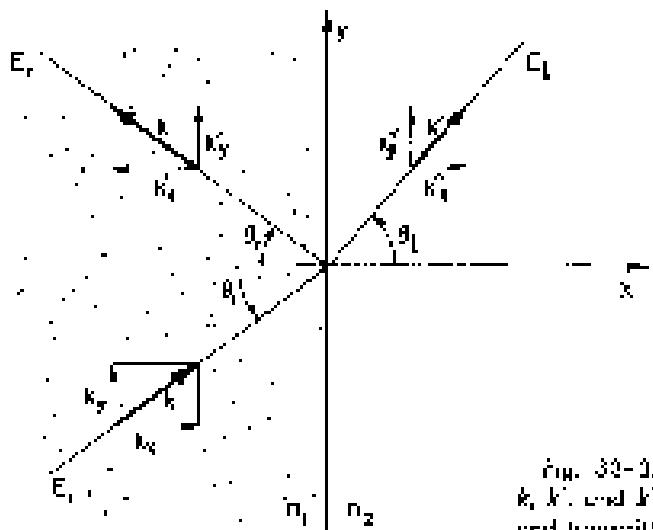

Fig. 33-3. The propagation system k , k' , and k'' for the incident, reflected, and transmitted waves.

We know from experience that when a plane wave arrives at the boundary between two different materials—say, air and glass, or water and oil—there is a wave reflected and a wave transmitted. Suppose we assume no more than that, and see what we can work out. We choose our axes with the z -axis in the surface, and the x -axis perpendicular to the incident wave velocity, as shown in Fig. 33-3.

The electric vector of the incident wave can then be written as

$$E_i = E_{i0} e^{j(kz - \omega t)} \quad (33.11)$$

Since \mathbf{A} is perpendicular to the z -axis,

$$k_x r = k_{y1} + k_{y2} \quad (33.12)$$

We add the reflected wave as

$$E_r = E_{r0} e^{j(kz + \omega t)} \quad (33.13)$$

so that its frequency is ω , its wave number is k' , and its amplitude is E_{r0} . (We know, of course, that the frequency is the same, the magnitude of k is the same as for the incident wave, but we are not going to assume even that. We will let k come out of the normalized equations.) Finally, we write for the transmitted wave,

$$E_t = E_{t0} e^{j(kz - \omega t)} \quad (33.14)$$

We know that one of Maxwell's equations gives Eq. (33.3), so for each of the waves we have

$$B_z = \frac{k}{\omega} \times E_{z0}, \quad B_r = \frac{k'}{\omega'} \times E_r, \quad B_t = \frac{k''}{\omega''} \times E_t. \quad (33.15)$$

Also, if we call the indices of the two media n_1 and n_2 , we have from Eq. (33.20)

$$k'^2 = k_1^2 + k_y^2 = \frac{\omega^2 n_1^2}{c^2}. \quad (33.16)$$

Since the reflected wave is in the same material, then

$$k'^2 = \frac{\omega^2 n_1^2}{c^2}, \quad (33.17)$$

whereas for the transmitted wave,

$$k''^2 = \frac{\omega^2 n_2^2}{c^2}. \quad (33.18)$$

33-3 The boundary conditions

All we have done so far is to describe the three waves; our problem now is to work out the parameters of the reflected and transmitted waves in terms of those of the incident wave. How can we do that? The three waves we have described satisfy Maxwell's equations in the uniform material, but Maxwell's equations must also be satisfied at the boundary between the two different materials. So we must now look at what happens right at the boundary. We will find that Maxwell's equations demand that the three waves fit together in a certain way.

As an example of what we mean, the x -component of the electric field E must be the same on both sides of the boundary. This is required by Faraday's law,

$$\nabla \times \mathbf{E} = - \frac{\partial \mathbf{B}}{\partial z}, \quad (33.19)$$

as we can see in the following way. Consider a little rectangular loop Γ which straddles the boundary, as shown in Fig. 33-4. Equation (33.19) says that the line integral of \mathbf{E} around Γ is equal to the rate of change of the flux of \mathbf{B} through the loop:

$$\oint_{\Gamma} \mathbf{E} \cdot d\mathbf{s} = - \frac{\partial}{\partial z} \int_{\Gamma} \mathbf{B} \cdot d\mathbf{n}$$

Now imagine that the z -direction is very narrow, so that the loop encloses an infinitesimal area. If \mathbf{B} is zero & finite (and that's the reason it should be infinite at the boundary) the flux through the loop is zero. So the line integral of \mathbf{E} must be zero.

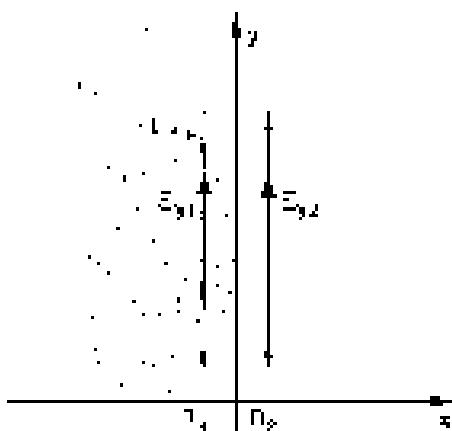

Fig. 33-4. A boundary condition $\oint_{\Gamma} \mathbf{E} \cdot d\mathbf{s} = 0$ is obtained from $\oint_{\Gamma} \mathbf{B} \cdot d\mathbf{n} = 0$.

by $\nabla \cdot E$, $\nabla \times B$, and E_{ext} are the components of the field on the two sides of the boundary and of $\partial \Omega$, $\partial \Omega$ being the boundary, we have

$$\begin{aligned} \nabla \cdot E &= E_{\text{ext}} = 0 \\ \nabla \times B &= B_{\text{ext}} \end{aligned} \quad (33.20)$$

as we have said. This gives us some relation among the fields at the three waves.

The procedure of "working out the consequences of Maxwell's equations of the continuity of each field along the boundary conditions." Fortunately, this can be done by finding as many derivatives (the up to (33.20) as one can), by moving a point about little rotating each (in Fig. 33.4, or by taking little positive surfaces that straddle the boundary). Although that is a perfectly good way of proceeding, it gives the impression that the problem of dealing with a boundary is different for every different physical problem.

For example, in a problem of heat flow across a boundary, how are the temperatures on the two sides related? Well, you could argue, for one thing, that the heat flow to the boundary from one side would have to equal the flow from the other side. It is usually possible and generally quite useful to work out the boundary conditions by making such physical arguments. There may be times, however, when in working on some problem you have only some equations, and you may not see right away what physical arguments to use. So although we are at the moment interested only in an electromagnetic problem, where we can use the physical arguments, we want to show you a method that can be used for any problem—a general way of finding what happens at a boundary directly from the differential equations.

We begin by writing all the Maxwell equations for a dielectric—see this to see we are very specific and write out explicitly all the components:

$$\nabla \cdot F = -\frac{\epsilon_0}{c^2} \frac{\partial B}{\partial t} + \frac{1}{\epsilon_0} \left(\frac{\partial E_x}{\partial y} + \frac{\partial E_y}{\partial z} + \frac{\partial E_z}{\partial x} \right) = -\frac{1}{\epsilon_0} \left(\frac{\partial P_x}{\partial y} + \frac{\partial P_y}{\partial z} + \frac{\partial P_z}{\partial x} \right) \quad (33.21a)$$

$$\begin{aligned} \nabla \times E &= -\frac{\partial B}{\partial t} \\ \frac{\partial E}{\partial y} - \frac{\partial E}{\partial z} &= \frac{\partial B}{\partial x} \quad (33.21b) \\ \frac{\partial E_x}{\partial z} - \frac{\partial E_z}{\partial x} &= \frac{\partial B_y}{\partial z} \quad (33.21b) \\ \frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} &= \frac{\partial B_z}{\partial x} \quad (33.21c) \end{aligned}$$

$$\nabla \cdot B = 0 \quad (33.22) \\ \frac{\partial B_x}{\partial x} + \frac{\partial B_y}{\partial y} + \frac{\partial B_z}{\partial z} = 0$$

$$\nabla \times B + \frac{1}{c^2} \frac{\partial P}{\partial t} = \frac{\partial E}{\partial t} \\ c^2 \left(\frac{\partial B_x}{\partial y} - \frac{\partial B_y}{\partial x} \right) = \frac{1}{\epsilon_0} \frac{\partial P_x}{\partial y} + \frac{\partial E_x}{\partial y} \quad (33.24a)$$

$$c^2 \left(\frac{\partial B_y}{\partial z} - \frac{\partial B_z}{\partial y} \right) = \frac{1}{\epsilon_0} \frac{\partial P_y}{\partial z} + \frac{\partial E_y}{\partial z} \quad (33.24b)$$

$$c^2 \left(\frac{\partial B_z}{\partial x} - \frac{\partial B_x}{\partial z} \right) = \frac{1}{\epsilon_0} \frac{\partial P_z}{\partial x} + \frac{\partial E_z}{\partial x} \quad (33.24c)$$

Now first derivatives must be 0 in region 1 (to the left of the boundary) and in region 2 (to the right of the boundary). We have already written the second in regions 1 and 2. Finally, they might be no derivative of the boundary, which we call region 3. Although we usually think of the boundary as being simply a boundary, in reality it's not. The physical properties change very rapidly but not infinitely fast. In any case, we can imagine that there is a very rapid, yet non-jerky, transition at the interface between region 1 and 2. In a short distance we can tell regions 1, 2, etc. Any field quantity like E_x , or B_z , etc., will make a similar kind of transition in region 3. In this region, the differential equations must still be satisfied, and it is by following the differential equations in this region that we can arrive at the needed "boundary conditions."

For instance, suppose that we have a boundary between vacuum (region 1) and glass (region 2). There is nothing to polarize in the vacuum, so $P_x = 0$. Let's say there is some polarization P_x in the glass. Between the vacuum and the glass there is a smooth, but rapid, transition. If we look at any component of P_x , say P_{xz} , it might vary as drawn in Fig. 33-5(a). Suppose now we take the last of our equations, Eq. (33.21). It involves derivatives of the components of P with respect to x , y , and z . The y - and z -derivatives are not interesting; nothing spectacular is happening in those directions. But the x -derivative of P_x will have some very large values in region 2, because of the tremendous slope of P_x . The derivative dP_{xz}/dx will have a sharp spike at the boundary, as shown in Fig. 33-5(b). If we manage to squeeze the boundary to an even sharper focus, the spike would get much bigger. If the boundary is really sharp for the waves we are interested in, the magnitude of dP_{xz}/dx in region 3 will be much, much greater than any other derivative we might look at. Look at the x -derivative of P in the wave near the boundary, so we ignore any variations of P other than those due to the boundary.

Now how can Eq. (33.21) be satisfied if there is a sharp corner space on the right-hand side? Only if we can somehow wrap up space on the either side. Something on the left-hand side must also be big. The only candidate is $\epsilon_0 E_{zx}$, because the vacuum water wave is the only place where there's no effect on the wave we just calculated. So $-\epsilon_0 \partial E_{zx}/\partial x$ must be as shown in Fig. 33-5(c), just a copy of Fig. 33-5(b). We then find

$$\epsilon_0 \frac{\partial E_{zx}}{\partial x} = -\frac{\partial P_{xz}}{\partial x}. \quad (33.25)$$

If we plug this equation with respect to x into Eq. (33.21), we conclude that

$$\epsilon_0(E_{zx} + P_{xz}) = -(\partial_{xz}^2 + P_{zz}). \quad (33.25)$$

In other words, the polarization, moving from region 1 to region 2, must be equal to the jump in P_{xz} .

We can rewrite Eq. (33.25) as

$$(\epsilon_0 E_{zx} + P_{xz}) = \epsilon_0 E_{zz} - P_{zz}, \quad (33.26)$$

which says that the quantity $(\epsilon_0 E_{zx} + P_{xz})$ has equal values in region 2 and region 1. People say: the quantity $(\epsilon_0 E_{zx} + P_{xz})$ is continuous across the boundary. We have, in this way, one of our boundary conditions.

Although we took as an illustration the case in which P was zero because region 1 was a vacuum, it is clear that the same argument applies for any two materials in the two regions, so Eq. (33.26) is true in general.

Let's now go through the rest of Maxwell's equations and see what each of them tells us. We take next Eq. (33.22a). There are no x -derivatives, so it doesn't tell us anything. (Remember that the fields themselves do not get especially large at the boundary; only the derivatives with respect to x can become so large that they dominate the equations.) Next, we look at Eq. (33.22b). Ah! There is an x -derivative! We have $\partial E_{yy}/\partial x$ on the left-hand side. Suppose it has a huge derivative. But wait a moment! There is nothing, on the right-hand side to cancel it with the derivative of E_y , except for one tiny jump in going from region 1 to region 2. If it did, it would be a spike on the left of Eq. (33.22b) but none on the right,

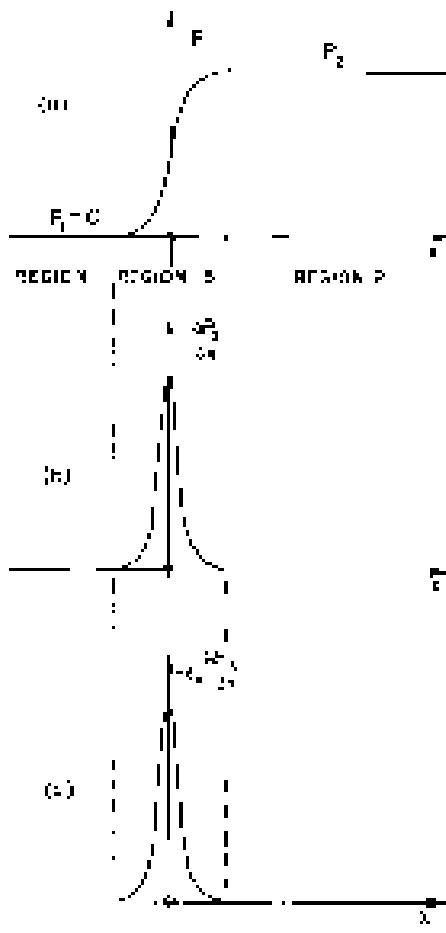

Fig. 33-5. The fields in the transition region (3), between two different materials (1) and (2).

and the equation would be false. So we have a contradiction.

$$E_{12} = E_{21}. \quad (33.27)$$

By the same argument, Eq. (33.26) gives

$$F_{12} = F_{21}. \quad (33.28)$$

This last result is just what we got in Eq. (33.20) by a time integral argument.

We go on to Eq. (33.21). The only term that could have a spike is $\partial B_1 / \partial t$. But there's nothing on the right to match it, so we conclude that

$$B_{12} = B_{21}. \quad (33.29)$$

On to the last of Maxwell's equations! Equation (33.24) gives nothing, because there are no ϵ -elements. Equation (33.25) has one, $-\epsilon' \partial B_1 / \partial x$, but again there is nothing to match it with. We get

$$B_{12} = B_{21}. \quad (33.30)$$

The last equation is quite similar, and gives

$$B_{12} = B_{21}. \quad (33.31)$$

The last three equations give us that $B = B_1$. We want to emphasize, however, that we get this result only when the materials on both sides of the boundary are magnetically—say, μ_1 —when we can neglect any magnetic effects at the interface. This is simply because there are, basically, except for magnetic ones. (We don't want to use the properties of materials in some other context.) Our argument is essentially the same as the one in Section 2 and those in Section 3. We leave out E and H together in Table 33-1. We can now use them to match the vectors in the two regions. We want to emphasize, however, that when we have just two materials we can always find a situation in which you have differential equations and you won't be able to find a sharp boundary between two regions where some property changes. For our present purposes, we will have easily derived the same equations by using arguments about the fluxes of current across the boundaries. You might say whether you can get the same result that way? But if you do get a result like that, well, we know you must check and don't see any reason to say something like “The physics of wave propagation at the boundary” you can just work with the equations.

33-4 The reflected and transmitted waves

Now we're ready to apply our boundary conditions to the waves we wrote down in Section 33-2. We find:

$$E_r = E_1 e^{i(k_1 z - \omega t + \delta_1)} \quad (33.32)$$

$$E_t = E_1 e^{i(k_1 z - \omega t + \delta_1)} \quad (33.33)$$

$$E_r = E_0 e^{i(k_1 z - \omega t + \delta_1)} \quad (33.34)$$

$$H_r = \frac{k'}{\omega} \times E_r \quad (33.35)$$

$$H_r = \frac{k'}{\omega} \times E_r \quad (33.36)$$

$$H_r = \frac{k''}{\omega} \times E_r \quad (33.37)$$

We have one further bit of knowledge: E is perpendicular to the propagation vector k for such waves.

Table 33-1

Boundary conditions at the surface of a dielectric

$$\begin{aligned} (\mu_1 + \mu_2) &= (\epsilon_1 + \epsilon_2) \\ (\mathbf{E}_1)_n &= (\mathbf{E}_2)_n \\ (\mathbf{E}_{1r})_n &= (\mathbf{E}_{2r})_n \\ \mathbf{B}_1 &= \mathbf{B}_2 \end{aligned}$$

(The surface is in the z -plane)

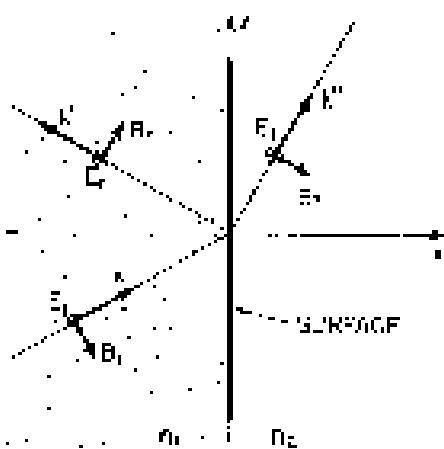

Fig. 33-8. Polarization of the reflected and transmitted waves when the E -field of the incident wave is perpendicular to the plane of incidence.

The results will depend on the direction of the E -vector (the "polarization" of the incoming wave). The analysis is simplest if we look separately at the s-polarized wave with its E -field E_s parallel to the "plane of incidence" (that is, the x - y -plane) and the p-polarized wave with the E -vector perpendicular to the plane of incidence. A wave of longitudinal polarization is just a linear combination of these two waves. In other words, the reflected and transmitted intensities are different for different polarizations, and this causes us to pick the two simplest cases and treat them separately.

We will carry through the analysis for an incoming wave polarized perpendicular to the plane of incidence and then just give you the result for the other. We are cheating a little by taking the simplest case, but the principle is the same for both. So we take that E_i has only a E_x -component, and since all the E -vectors are in the same direction we can leave off the vector signs.

So long as both materials are isotropic, this induces oscillations of charges in the material will also be in the x direction, and the E field of the transmit, loss, and reflected waves will have only E_x components. So for all the waves, E_y and B_z , and P_x and P_y are zero. The waves will have their E and H vectors as drawn in Fig. 33-8. (We are cutting a corner here in our original plan of getting everything from the equations. This result would also come out of the boundary conditions, but we can save a lot of algebra by using the physical argument. When you have some spare time, see if you can get the same result from the equations. It is clear that what we have said agrees with the equations, it is just that we have not shown that there are no other possibilities.)

Now our boundary conditions, Eqs. (33.26) through (33.31), give relations between the components of E and B in regions 1 and 2. In region 2 we have only two terms in total waves, but in region 1 we have two waves. Which one do we use? The fields in region 1 are, of course, the superposition of the fields of the incident and reflected waves. (Since each satisfies Maxwell's equations, so does the sum.) So when we set the boundary conditions, we must use that

$$E_1 = E_r \quad E_x = E_r$$

and similarly for the B 's.

For the polarization we are considering, Eqs. (33.26) and (33.28) give us no new information; only Eq. (33.27) is useful. It says that

$$E_1 + E_r = E_t$$

at the boundary, that is, for $x = 0$. So we have that

$$E_0 e^{i(kx - \omega t)} + E_0 e^{i(kx + \omega t)} = E_0 e^{i(kx - \omega t)} + E_0 e^{i(kx + \omega t)}, \quad (33.38)$$

where E_0 is not zero for all x and for all t . Suppose we look instead at $x = 0$. Then we have

$$E_0 e^{i\omega t} + E_0 e^{-i\omega t} = E_0 e^{i\omega t}.$$

This equation says that two non-harmonic waves, $e^{i\omega t}$ and $e^{-i\omega t}$, add to zero. That can happen only if all the oscillations have the same frequency. (It is impossible for three—or any number—of such waves with different frequencies to add to zero for all times.) So

$$\omega^T = \omega^I = \omega. \quad (33.39)$$

As we know already, the intensities of the reflected and transmitted waves are the same as that of the incident wave.

We should really have said "or" rather than "so" since some trouble by putting that in at the beginning, but we wanted to show you that it can also be got out of the equations. When you are doing a problem, it's usually the best thing to put everything you know into the waves right at the start and save yourself a lot of trouble.

By definition, the amplitude A^T is given by $A^T = \sqrt{A_x^2 + A_y^2}$, so we have also that

$$\frac{\omega^T}{\omega^I} = \frac{A^T}{A^I} = \frac{\sqrt{A_x^2 + A_y^2}}{\sqrt{A_x^2}} \quad (33.40)$$

Now look at Eq. (33.38) for $k = k_1$. Using again the same kind of argument we have just made, but this time based on the fact that the equation must hold for all values of n , we get that

$$k_y^2 = k_1^2 - k_n^2. \quad (33.41)$$

From Eq. (33.30), $k^{yy} = k_y^2$, so

$$k_y^2 = k_y^2 = k_1^2 + k_n^2.$$

Combining this with Eq. (33.41), we note that

$$k_y^2 = -k_1^2,$$

so that $k_y^2 = -k_1^2$. The positive sign makes no sense; that would just give a reflected wave, but another incident wave, and we said at the start that we were solving the problem of only one incident wave. So we have

$$k_y^2 = -k_1^2. \quad (33.42)$$

The two equations (33.41) and (33.42) give us that the angle of reflection is equal to the angle of incidence, as we expected. (See Fig. 33-3.) The reflected wave is

$$E_r = E_0 e^{i(k_1 x_1 - \omega_1 t)} \quad (33.43)$$

For the transmission wave we already have found

$$k_y^2 = k_0^2$$

and

$$\frac{k_y^2}{k_1^2} = \frac{k_0^2}{n_1^2}, \quad (33.44)$$

so we can divide these to find k_y^2 . We get

$$k_y^2 = k^{yy} = k_p^2 = \frac{k_0^2}{n_1^2} k_1^2 = k_0^2. \quad (33.45)$$

Suppose for a moment that n_1 and n_0 are real numbers (that the imaginary parts of the indices are very small). Then all the k 's are also real numbers, and from Fig. 33-3 we find that

$$\frac{k_0}{k} = \tan \theta_1, \quad \frac{k_y}{k} = \tan \theta_2. \quad (33.46)$$

From (33.46) we get that

$$n_1 \sin \theta_1 = n_0 \sin \theta_2, \quad (33.47)$$

which is, since θ_1 and θ_2 are right angles, something we already know. If the indices are not real, the tangent functions are complex, and we cannot trust Eq. (33.47). (We could still define the angles θ_1 and θ_2 by Eq. (33.46) and Snell's law, Eq. (33.45), would not this be general? But I do the "complex" also as complex numbers, thereby losing their simple geometric interpretation, as in Fig. 33-3. It is best to leave to the behavior of the waves by themselves, i.e., on E_p unless.)

So far we have learned nothing new. We have just had the simple-minded delight of getting some obvious answers from a complicated mathematical machinery. Now we are ready to find the amplitudes of the waves which we have not yet known. Using our results for the k 's and θ 's, the exponential factors in Eq. (33.36) can be canceled, and we get

$$E_0 = E_1 = E_0^T. \quad (33.48)$$

Since both E_0 and E_0^T are unknown, we need one more relationship. We must remember & use the boundary conditions. Our equations for E_2 and E_0 are no help because all the E 's are varying in x -space. So we must use the condition in Eq. (33.32), Eq. (33.49)

$$E_{2A} = E_{2B}$$

From Eqs. (33.44) through (33.50),

$$B_x = \frac{k_x E_0}{\omega}, \quad B_{x0} = \frac{k_x E_0}{\omega'}, \quad B_{z0} = \frac{k_z E_0}{\omega'}$$

Recalling that $\omega' = \omega - k_z$ and $k_z' = k_z + k_x$, we get that

$$E_0 + k_x B_{z0} = E_0'$$

But this is just Eq. (33.48) all over again! We've just wasted time when we could have stopped.

We could try Eq. (33.49), $B_{y0} = B_{z0}$, but there are two more unknowns, E_0' & B_y' . So there's only one equation left, Eq. (33.44), $B_{x0} = B_{y0}$. But the terms vanish,

$$B_y = -\frac{k_y E_0}{\omega}, \quad B_{y0} = -\frac{k_y E_0}{\omega'}, \quad B_{x0} = \frac{k_x E_0}{\omega'}$$
 (33.49)

Putting in E_0 , E_0' , and B_y , the wave expression for $x = 0$ (to level the boundary), the boundary condition is

$$\frac{k_x}{\omega} E_{0x} + \omega B_{y0} = \frac{k_x}{\omega'} E_{0x}' + \omega' B_{y0}' + \frac{k_x}{\omega'} E_{0x}'' + \omega' B_{y0}''$$

Again all ω 's and k_x 's are equal, so this reduces to

$$\kappa E_0 + \kappa' E_0' = \kappa'' E_0''$$
 (33.50)

This gives us an equation for the E 's that is different from Eq. (33.48). With the two, we can solve for E_0' and E_0'' . Recalculating that $\kappa'' = k_x$, we get

$$E_0' = \frac{\kappa}{k_x} - \frac{k_x^2}{\omega'^2} E_0$$
 (33.51)

$$E_0'' = \frac{2\kappa}{k_x} - \frac{\omega'^2}{\omega^2} E_0$$
 (33.52)

This, together with Eq. (33.5) or Eq. (33.46) for κ'' , give us what we wanted to know. We will discuss the consequences of this result in the next section.

If we begin with a wave polarized with its E -vector oriented in the plane of incidence, E will have both x - and y -components, as shown in Fig. 33-7. The analysis is straightforward but more complicated. (The work can be somewhat reduced by expressing things in terms of the magnetic fields, which are in the x -direction in the figure.)

$$|E'| = \frac{\kappa k_x - \omega'_x k_x}{\omega'^2 k_x + \omega^2 k_x^2} E_0$$
 (33.53)

and

$$E_0'' = \frac{2\kappa k_x}{\omega'^2 k_x - \omega^2 k_x^2} E_0$$
 (33.54)

Let's see whether our results agree with those we got earlier. Equation (33.3) is the result we worked out in Chapter 32 of Volume I for the ratio of the intensity of the reflected wave to the intensity of the incident wave. Then, however, we were considering only real indices. For real indices (and κ'), we can write

$$I_r = I_0 \cos \theta_i = \frac{n_{r1}}{n} \cos \theta_i$$

$$I_0' = I_0' \cos \theta_i = \frac{n_{r2}}{n} \cos \theta_i$$

Substituting in Eq. (33.51), we have

$$\begin{aligned} E_0' &= A_0 \cos \theta_i - A_0' \cos \theta_i \\ E_0 &= A_0 \cos \theta_i + A_0' \cos \theta_i \end{aligned}$$
 (33.55)

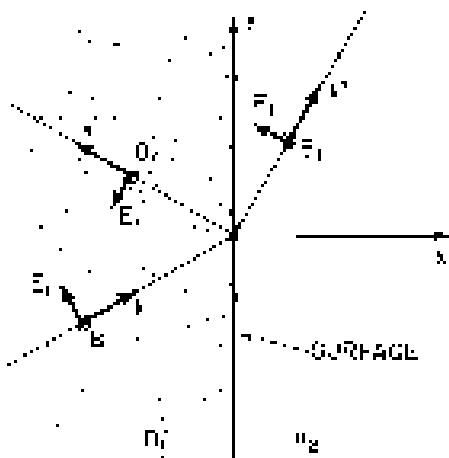

Fig. 33-7. Polarization of the waves when the E field of the incident wave is parallel to the plane of incidence.

which, very get, look the same as Eq. (33.3). To well, however, if we use Snell's law to get the α 's. Setting $n_1 = n$, $\sin \theta_1 / \sin \theta_2$, and multiplying the numerator and denominator by $\sin \theta_2$, we get

$$\frac{E_0}{E_1} = \frac{\cos \theta_1 \sin \theta_2}{\cos \theta_2 \sin \theta_1} = \frac{\sin \theta_1 \cos \theta_2}{\sin \theta_2 \cos \theta_1}.$$

The numerator and denominator are just the sines of $(\delta_1 - \delta_2)$ and $(\delta_1 + \delta_2)$; we get

$$\frac{E_0}{E_1} = \frac{\sin(\delta_1 - \delta_2)}{\sin(\delta_1 + \delta_2)}. \quad (33.56)$$

Since E_1 and E_0 are in the same material, the intensities are proportional to the squares of the electric fields, and we get the same result as before. Similarly, Eq. (33.57) is the same as Eq. (33.2).

For waves which travel in normal media say, $\delta_1 = 0$ and $\delta_2 = 0$, Equation (33.56) gives 0.0, which is not very useful. We can, however, go back to Eq. (33.55), which gives

$$\frac{I_0}{I_1} = \left(\frac{E_0}{E_1} \right)^2 = \left(\frac{\theta_1 - \theta_2}{\theta_1 + \theta_2} \right)^2. \quad (33.57)$$

This result, just as (33.55), applies for "either" polarization, since for normal incidence there is no system "phase of incidence."

33-6 Reflection from metals

We can now use our results to understand the interesting phenomenon of reflection from metals. Why is it that metals are shiny? We saw in the last chapter that metals have an index of refraction n which, for some frequencies, has a large imaginary part. Let's see what we would get for the reflected intensity when light comes from air with $n = 1$ and to a metal with $n = -i\kappa_0$. Then Eq. (33.55) gives (for normal incidence)

$$\frac{E_0}{E_1} = \frac{1 + i\kappa_0}{1 - i\kappa_0}.$$

For the intensity of the reflected wave, we want the square of the absolute value of E_0 and E_1 :

$$\frac{I_0}{I_1} = \frac{|E_0|^2}{|E_1|^2} = \frac{(1 + i\kappa_0)^2}{(1 - i\kappa_0)^2},$$

or

$$\frac{I_0}{I_1} = \frac{1 + 2i\kappa_0 + \kappa_0^2}{1 + 2i\kappa_0 + \kappa_0^2} = 1. \quad (33.58)$$

For a material with an index which is a pure imaginary number, there is 100 percent reflection.

Metals do not reflect 100 percent, but many do reflect visible light very well. In other words, the imaginary part of their indexes is very large. But we have seen that a large imaginary part of the index means a strong absorption. So there is a general rule that: any material gets to be a very good absorber at any frequency, the waves are strongly reflected at the surface and very little gets made to be absorbed. You can see this effect with strong dyes. Pure crystals of the strongest dyes have a "metallic" luster. Probably you have noticed that as the edge of a bottle of purple ink (the dried dye will give a golden metallic reflection) or the dried red ink will sometimes give a greenish metallic reflection. Red ink absorbs most the energy of "unabsorbed" light, so if the ink is very concentrated it will act just as strong surface reflector for the frequencies of green light.

You can easily show this effect, by covering a glass plate with red ink and letting it dry. If you direct a beam of white light at the back of the plate, as shown in Fig. 33-8, there will be a transmitted beam of red light and a reflected beam of green light.

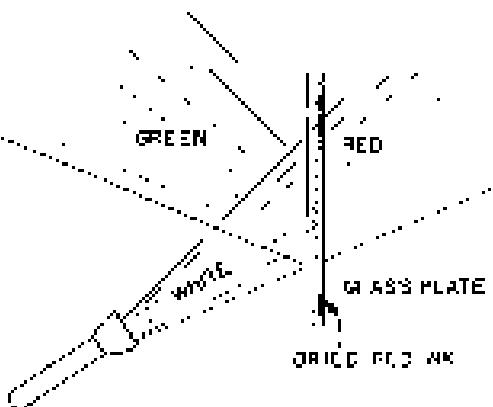

Fig. 33-8. A material which absorbs light strongly at the frequency ω also reflects light at that frequency.

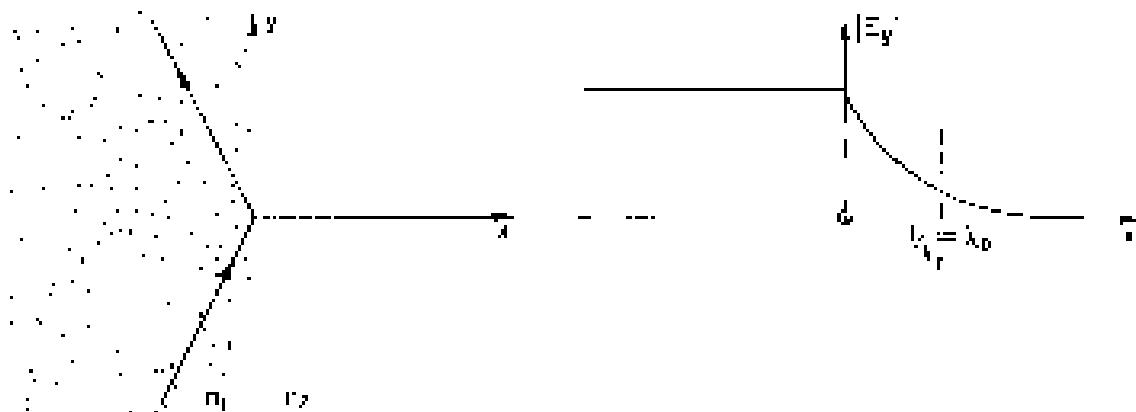

Fig. 22-9. Total internal reflection.

22-6 Total internal reflection

If light goes from a material like glass, with a real index of greater than 1, toward, say, water, an index n_2 equal to 1.33, Snell's law says that

$$\sin \theta_2 = n_2 \sin \theta_1.$$

The angle θ_2 of the transmitted wave becomes 90° when the incident angle θ_1 is equal to the "critical angle" ϕ_c , given by

$$\sin \phi_c = 1/n_2. \quad (22.59)$$

What happens for θ_1 greater than the critical angle? You know that there is total internal reflection. But now does that mean above?

Let's go back to Eq. (22.43) which gives the wave number k' for the transmitted wave. We would have

$$k'^2 = \frac{k^2}{n^2} - k_p^2.$$

Now $k_p = k \sin \phi_c$ and $k = \omega/c_0 \sin$

$$k'^2 = \frac{\omega^2}{c_0^2} (1 - n^2 \sin^2 \phi_c).$$

If $\phi_c < \theta_1$ is greater than one, k'^2 is negative and k' is a pure imaginary, try $-ik'$. You know by now what that means! The "transmitted" wave (Eq. 22.34) will have the form

$$E_r = E_0 e^{-ik' z} e^{i\omega t + k' x},$$

The wave amplitude either grows or decays exponentially with increasing x . Clearly, we want here is the negative sign. Then the amplitude of the wave to the right of the boundary will go as shown in Fig. 22-8. Notice that k_f is of the order of ω/c_0 , the free-space wavelength of the light. When light is totally reflected from the inside of a glass/rubber surface, the electric fields in the air, and they extend beyond the surface only a distance of the order of the wavelength of the light!

We can now see how to answer the following question. If a light wave in glass arrives at the surface at a large enough angle, it is reflected. If a thin piece of glass is brought up to the surface (so that the "reflectance" is at least disappears) the light is transmitted. Exactly when does this happen? Since there must be a continuous change from total reflection to no reflection, the answer, of course, is that if the air gap is so small that the exponential tail of the wave in the air has an appreciable strength at the second piece of glass, it will shake the electrons there and generate a new wave, as shown in Fig. 22-10. So in light it is the transient that occurs, our solution is now update, we should solve all the equations again for a thin layer of air between two regions of glass.)

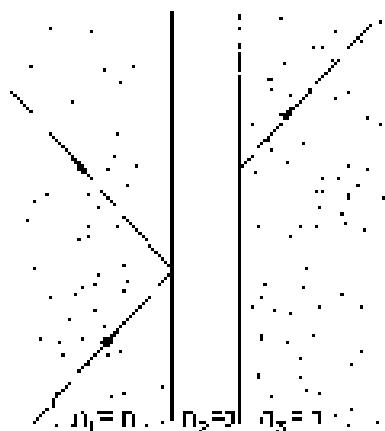

Fig. 22-10. If there is a small gap, "total" reflection is not "total"; a transmitted wave appears beyond the gap.

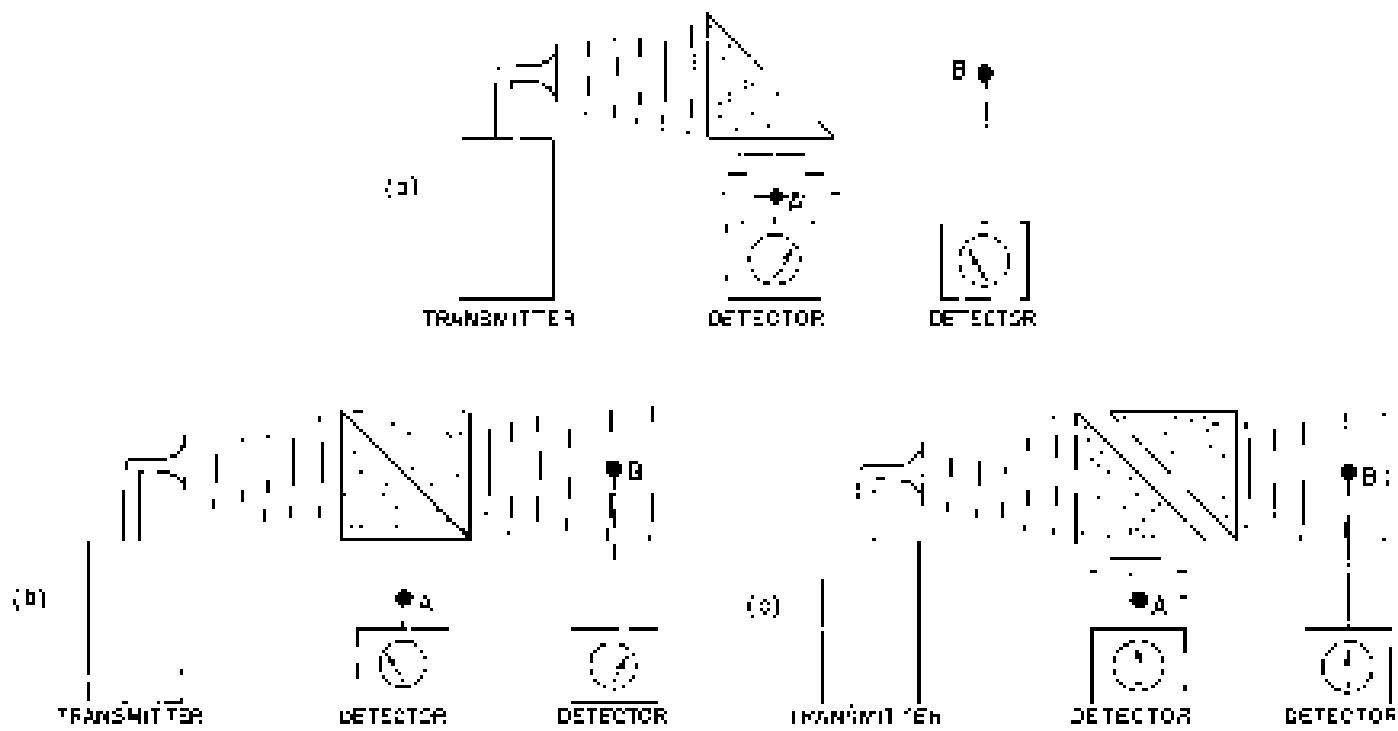

Fig. 30-11. A demonstration of the generation of internally reflected waves.

This transmission effect can be observed with ordinary light only if the air gap is very small (of the order of the wavelength of light, like 10^{-3} cm), but it is easily demonstrated with three centimeter waves. Then the exponentially decreasing field extends several centimeters. A microwave apparatus that shows the effect is drawn in Fig. 30-11. Waves from a small three centimeter transmitter are directed at a 45° prism of paraffin. The index of refraction of paraffin for these frequencies is 1.50, and therefore the critical angle is 41.5°. So the wave is readily reflected from the 45° face and is picked up by detector A, as indicated in Fig. 30-11(a). If a second paraffin prism is placed in contact with the first, as shown in part (b) of the figure, the wave passes straight through and is picked up at detector B. If a gap of a few centimeters is left between the two prisms, as in part (c), there are both transmitted and reflected waves. The electric field outside the 45° face of the prism in Fig. 30-11(c) can also be shown by bringing detector B to within a few centimeters of the surface.

The Magnetism of Matter

34-1 Diamagnetism and paramagnetism

In this chapter we are going to talk about the magnetic properties of materials. The material which has the most striking magnetic properties is iron, steel, cobalt, and tin; but magnetic properties are shared also by the elements nickel, vanadium, and others at sufficiently low temperatures (below 16°C) by gadolinium, as well as by a number of peculiar alloys. This kind of magnetism, called ferromagnetism, is sufficiently striking and complicated that we will discuss it in a special chapter. However, all ordinary substances do show some magnetic effects, although very small ones—a thousand to a million times less than the effects in ferromagnetic materials. Here we are going to describe ordinary magnetism, that is to say, the magnetism of substances other than the ferromagnetic ones.

This small magnetism is of two kinds. Some materials are attracted toward magnetic fields; others are repelled. Unlike the electrical effect in matter, which always causes dipoles to be attracted, there are two signs to the magnetic effect. These two signs can be easily shown with the help of a strong electromagnet which has one sharply pointed pole piece and one flat pole piece, as drawn in Fig. 34-1. The magnetic field is much stronger near the pointed pole than near the flat pole. If a small piece of material is fastened to a long string and suspended between the poles, there will, in general, be a small force on it. This small force can be seen by the slight displacement of the hanging material when the current is turned on. The few ferromagnetic materials are attracted very strongly toward the pointed pole; all other materials feel only a very weak force. Some are weakly attracted to the pointed pole; and some are weakly repelled.

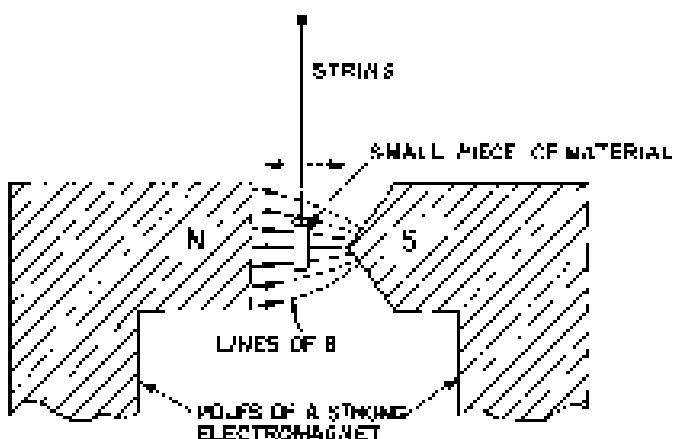

Fig. 34-1. A small spinner of beryllium is weakly repelled by the sharp pole; a piece of aluminum is attracted.

This effect is most easily seen with a small cylinder of beryllium, which is repelled from the high-field region. Substances which are repelled in this way are called diamagnetic. Bismuth is one of the strongest diamagnetic materials, but even with it, the effect is still quite weak. The magnetism is always very weak. If a small piece of aluminum is suspended between the poles, there is also a weak force, but never to the pointed pole. Substances like aluminum are called paramagnetic. (In such an experiment, oddly enough, it takes a tug when the magnet is turned on and off, and there can also be strong vibrations. You must be careful to look for the net displacement after the hanging object settles down.)

34-8 The magnetic energy of atoms

Review: Section 15-1, "The forces on a charged body moving at a charge."

We want now to discuss briefly the mechanisms of these two effects. First, in many substances the atoms have no permanent magnetic moments; either all the moments within each atom, because of it, so that the net moment of the atom is zero. The electron spins are excited, however, all exactly balance out, so that any particular atom has an average magnetic moment. In these circumstances, when a current or magnetic field-like environments are generated inside the atom by a dipole, according to Lenz's law, these currents flow in such a direction as to oppose the increasing field. So the induced magnetic moments of the atoms are oriented opposite to the magnetic field. This is the origin of diamagnetism.

Then there are some substances for which the atoms do have permanent magnetic moments, in which the electron spins and moments have a net total dipole moment that is not zero. Besides the diamagnetic field (which is always present), there is also the possibility of having up the individual atomic magnetic moments in the case, the moments try to line up with the magnetic field. In this way the permanent dipoles of a dipole are lined up by the external field, and the related magnetic field can induce the magnetic field. These are the paramagnetic substances. Paramagnetism is generally fairly weak, its susceptibility (magnetization) is relatively small compared with the forces from the valence electrons which try to align the order. It is as follows that paramagnetism is usually sensitive to the temperature. (The paramagnetism arising from the spins of the electrons responsible for conduction in a metal contributes an exception. We will not be discussing this phenomenon here.) For ordinary paramagnetism, the lower the temperature, the stronger the effect. There is more lining up at low temperatures when the aligning effects of the collisions are less. Diamagnetism, on the other hand, is more or less independent of the temperature. In any substance with atomic magnetic moments, there is a diamagnetic as well as a paramagnetic effect, but the paramagnetic effect usually dominates.

In Chapter 11 we described a ferroelectric material, in which all the electric dipoles get lined up by their own mutual electric fields. It is also possible to imagine the converse analog of ferroelectricity, in which all the atomic moments would line up and lock together. If you make calculations of how this should happen you will find that because the magnetic forces are so much smaller than the electric forces, thermal motions should knock out this alignment even at temperatures as low as a few tenth of a degree Kelvin. So it would be impossible at room temperature to have any permanent lining up of the magnets.

On the other hand, this is exactly what does happen in iron—it does get lined up. There is an attractive force between the magnetic moments of the different atoms of iron which is much, much greater than the direct magnetic interaction. It is an interaction of $\alpha \cdot \beta \cdot \gamma$, which can be explained only by quantum mechanics. It is about 10^3 times stronger than the direct magnetic interaction, and is what lines up the moments in ferromagnetic materials. We discuss this special interaction in the next chapter.

Show that we have tried to give you a qualitative explanation of diamagnetism and magnetostatics, we must confess ourselves and say that we are probably to understand the complete behavior of materials in any honest way from the point of view of classical physics. Such complete effects are a completely nonclassical phenomena. It is, however, possible to make some partially classical arguments and to get some general hint of what is going on. We might, in this way, You can make some classical arguments and get access to the behavior of the material, but these arguments are not "exact" in any sense because it is absolutely essential that quantum mechanics be involved in every one of these magnetic phenomena. On the other hand, there are situations, such as in a plasma or a region of space with many free electrons, where the electrons obey the laws of classical mechanics. And in those circumstances, some of the descriptions of classical magnetism are trustworthy. Also, the classical arguments are of some value for historical reasons. The first theories that people were able to guess at the meaning and behavior of magnetic materials, they used classical arguments. Finally, as we have already mentioned, classical mechanics can give us some useful guides.

so what might happen—even though the real terms, way to study this subject would be to learn quantum mechanics first; and then to understand the connection in terms of quantum mechanics.

On the other hand, we don't want to wait until we begin quantum mechanics inside out to understand a simple thing like this magnetism. We will have to lean on the classical mechanics as long as half showing what happens, realizing, however, that the arguments are really not yet set. We therefore make a series of theories about classical magnetism that will be three years apart so they will prove different things. Except for the last theorem, every one of them will be π true. Furthermore, they will all be wrong as a description of the physical world, because quantum mechanics is π true.

34-2 Magnetic moments and angular momentum

The first theorem we want to prove from classical mechanics is the following: If an electron is moving in a circular orbit (for example, revolving around a nucleus under the influence of a central force), there is a definite ratio between the magnetic moment and the angular momentum. Let's call J the angular momentum and μ the magnetic moment of the electron in the orbit. The magnitude of the angular momentum is the mass of the electron times the velocity times the radius. (See Fig. 34-2.) It is directed perpendicular to the plane of the orbit.

$$J = m v a. \quad (34.2)$$

(This is, of course, exactly right for nuclei, but it's a poor approximation for atoms, because for the electrons, v varies $\sim R$ is generally of the order $m^2/R = \pi/10$, or about 1 percent.)

The magnetic moment of the same orbit is the current times the area. (See Section 34-5.) The current is the charge per unit time which passes any point on the orbit, namely, the charge q times the frequency of rotation. The frequency is the velocity divided by the circumference of the orbit: so

$$f = q \frac{1}{2\pi}.$$

The area is πr^2 , so the magnetic moment is

$$\mu = \frac{q f}{2}. \quad (34.3)$$

It is also directed independently of the plane of the orbit. So J and μ are in the same direction:

$$\mu = \frac{q}{2m} J \text{ (orbit).} \quad (34.4)$$

There also happens to be another quantity, called the radius vector. For any particle moving up a coordinate axis, the magnetic moment is always along the line of the angular momentum. But just about the only exception is the electron. In the electron, the charge is negative, so the spin is $-q$; so the moment

$$\mu = -\frac{q}{2m} J \text{ (electron orbit).} \quad (34.4)$$

That's where we would expect classically and, in a fairly enough, it is also true quantum-mechanically. It's one of three things. However, if you keep going with the classical physics, you find other places where it goes the wrong direction, and it's a great game to try to remember which things are right and which things are wrong. We might as well give you immediately what is true as given in quantum mechanics. First, Eq. (34.4) is true for orbital motion, but that's not the only magnetism that exists. The electron also has a spin rotation about its own axis (something like the earth rotating on its axis), and as a result of that spin it has both an angular momentum and a magnetic moment. But for reasons that are purely quantum mechanical, there is no classical explanation—the ratio of μ

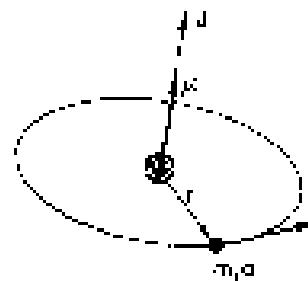

Fig. 34-2 For any circular orbit the magnetic moment μ is $\pi/2m$ times the angular momentum J .

to it for the electron spin is twice as large as it is for orbital motion of the spinning electron:

$$\mu = -\frac{e}{m} f(\text{orbital spin}), \quad (34.5)$$

In our atoms there are, generally speaking, several electrons and some combination of spin and orbit motions which builds up a total angular momentum and a total magnetic moment. Although there is no classical reason why it should be so, it is always true in quantum mechanics that (for an isolated atom) the direction of the magnetic moment is exactly opposite to the direction of the angular momentum. The ratio of the two is of course either $-g/m$ or $-g/2m$, but somewhere in between, because there is a mixture of the contributions from the orbits and the spins. We can write

$$\mu = -g \left(\frac{S+L}{2m} \right) J, \quad (34.6)$$

where g is a factor which is characteristic of the state of the atom. It would be 1 for a pure orbital motion, or 2 for a pure spin motion, or some other number in between for a complicated system like an atom. This formula does not, of course, tell us very much. It says that the magnetic moment is parallel to the angular momentum, but can have any magnitude. The form of Eq. (34.6) is convenient, however, because g —called the “Lande g -factor”—is a dimensionless constant whose magnitude is of the order of one. It is one of the joys of quantum mechanics to predict the g -factor for any particular atomic state.

You might also be interested in what happens in nuclei. In nuclei there are protons and neutrons which may have around an s or p orbital of order 10^{-14} of the same size, like an electron, have an intrinsic spin. Again the magnetic moment is parallel to the angular momentum. Only now the order of magnitude of the ratio of the two is what you would expect for a proton (or up quark) at a radius r_0 to be in Eq. (34.5) equal to the previous ones. That is, g is about the same for nuclei.

$$\mu = z \left(\frac{e r_0}{2m_p} \right) J, \quad (34.7)$$

where r_0 is the radius of the proton, and z —called the nuclear g -factor—is a number, about one, to be determined for each nucleus.

Another important difference for a nucleus is that the spin (or magnetic moment) of the proton does not have a spin-orbit of $\frac{1}{2}$, as the neutron does. For a proton, $g = 1/2m$. Surprisingly enough, the neutron then has a spin magnetic moment and its magnetic moment relative to its angular momentum is $S_n = 1.0$ e. The neutron, in other words, is not exactly neutral in the magnetic sense. That is, like a little magnet, it has the kind of magnetic moment that a turning negative charge would have.

34-3 The precession of atomic magnets

One of the consequences of having the magnetic moment proportional to the angular momentum is that an atomic magnet, plus whatever magnetic field it will produce, will rotate as it moves. Suppose that we have the magnetic moment μ suspended freely in a uniform magnetic field B . It will feel a torque τ , equal to $\mu \times B$, which tends to bring it in line with the field direction B . But the outside magnet is in general not at right angles the momentum J . Therefore the torque due to the magnetic field will not bring the magnet to line up. Instead, the magnet will precess, as we saw when we analyzed a gyroscope in Chapter 20 of Volume I. The angular momentum J and with it the magnetic moment μ precess about a axis parallel to the magnetic field. You can find the rules of precession by the same method as we used in Chapter 20 of the first volume.

Suppose that in a small time Δt the angular momentum changes from J to J' , as drawn in Fig. 34.3, staying always at the same angle θ with respect to the direction of the magnetic field B . Let's call ω_p the angular velocity of the precession, so that in the time Δt the angle of precession is $\omega_p \Delta t$. From the geometry of the figure

lighter, we see that the change of angular momentum in the time Δt is

$$\Delta I = (I \sin \theta) \omega_0 \Delta t.$$

So the rate of change of the angular momentum is

$$\frac{dI}{dt} = \omega_0 I \sin \theta, \quad (34.6)$$

which must be equal to the torque

$$\tau = \mu B \sin \theta. \quad (34.7)$$

The angular velocity of precession is then

$$\omega_p = \frac{\mu}{J} B. \quad (34.8)$$

Substituting μ/J from Eq. (34.6), we see that for an atomic system

$$\omega_p = g \frac{\mu B}{J_m}, \quad (34.9)$$

the precession frequency is proportional to B . It is handy to remember that for an atom (or electron)

$$f_p = \frac{\omega_p}{2\pi} = (1.1 \text{ megacycles/gauss})B, \quad (34.10)$$

and that for a nucleus

$$f_p = \frac{\omega_p}{2\pi} = (0.76 \text{ kilocycles/gauss})B. \quad (34.11)$$

(The formulas for atoms and nuclei are different only because of the different conversions for g for the two cases.)

According to the classical theory, then, the electron orbits and spins in an atom would precess in a magnetic field. Is it also true quantum mechanically? It is essentially true, but the meaning of the "precession" is different. In quantum mechanics one cannot talk about the *direction* of the angular momentum in the same sense as one does classically; nevertheless, there is a very close analogy and close that we continue to call it "precession." We will discuss it later when we talk about the quantum-mechanical point of view.

34-4 Diamagnetism

Next we want to look at diamagnetism from the classical point of view. It will be most apparent in several ways. In one of the nice ways is the following. Suppose that we already turn on a magnetic field in the vicinity of an atom. As the magnetic field changes an electric field E generated by magnetic induction. From Faraday's law, the line integral of E around any closed path is the rate of change of the magnetic flux through the path. Suppose we pick a path P which is a circle of radius r concentric with the center of the atom, as shown in Fig. 34-3. The average tangential electric field E around this path is given by

$$\delta E_{\text{av}} = - \frac{\delta}{\delta t} (\partial \Phi / \partial r),$$

and there is a circulating electric field whose strength is

$$E = - \frac{r}{2} \frac{\delta \Phi}{\delta t}$$

The tangential electric field acting on an electron in the atom precesses in torque equal to $-e_E r \epsilon$, which must equal the rate of change of the angular momentum dI/dt :

$$\frac{dI}{dt} = \frac{e_r^2 r^2}{2} \frac{d\Phi}{dt}. \quad (34.12)$$

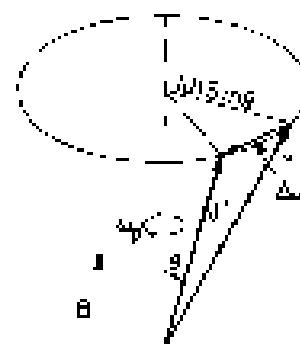

Fig. 34-3. An object with angular momentum J and a parallel magnetic moment μ placed in a magnetic field B precesses with the angular velocity ω_p .

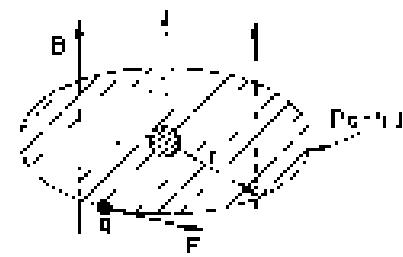

Fig. 34-4. The induced electric fields on the electrons in an atom.

Integrating with respect to time from zero field, we find that the change in angular momentum due to turning on the field is

$$\Delta J = \frac{q\epsilon^2}{2} R. \quad (34.15)$$

This is the extra angular momentum due to the turning on the field, as required.

The scaled step function makes the value magnetic moment which, as we know, is an orbital angular momentum times the angular momentum. The induced diamagnetic moment is

$$\Delta \mu = -\frac{q\epsilon}{2m} \Delta J = -\frac{q\epsilon^2}{4m} R. \quad (34.16)$$

The minus sign for $\Delta \mu$ can see is right by using Lenz's law; since that the added moment is opposite to the magnetic field.

We would like to write Eq. (34.16) a little differently. The ϵ which appears is the radius from z -axis through the atom parallel to B , so if B is along the z -direction, it is $\epsilon^2 = r^2$. If we consider spherically symmetric atoms (or average over atoms with their natural axes in all directions) the average of $x^2 + y^2$ is $2/3$ of the average of the square of the true radial distance from the center point of the atom. It is therefore usually more convenient to write Eq. (34.16) as

$$\Delta \mu = -\frac{q^2}{6m} \langle r^2 \rangle_{atom} B. \quad (34.17)$$

In any case, we have found an induced atomic moment proportional to the magnetic field B and opposing it. This is diamagnetism of matter. It is this magnetic effect that is responsible for the small force on a piece of metal in a non-uniform magnetic field. (You could compute the force by working out the energy of the induced moments in the field and seeing how the energy changes as the metal is moved into or out of the high-field region.)

We are still left with the problem: What is the mean square radius, $\langle r^2 \rangle_{atom}$? Classical mechanics cannot supply an answer. We must go back and start over with quantum mechanics. In an atom we cannot really say where an electron is, only know the probability that it will be at some place. If we interpret $\langle r^2 \rangle_{atom}$ as an average of the square of the distance from the center for the probability distribution, the definition is not given by symmetry reasons, as is just the same as for $\langle r \rangle$ (Eq. 34.17). The exception, of course, is the moment by one electron. The total moment is given by the sum over all the electrons in the atom. The surprising thing is that the classical argument and quantum mechanics give the same result. (Through, as was half said, the class argument that gives Eq. (34.17) is not really valid in classical mechanics.)

The second magnet's effect occurs even when an atom already has an angular momentum. Then the system will precess in the magnetic field. As the whole atom precesses, it takes up an additional small update velocity, and that some turning gives a small current which represents a correction to the magnet moment. This is just the diamagnetic effect represented in another way. But we don't really have to worry about that when we talk about paramagnetism. If the diamagnetic effect is (as computed, as we have done here), we don't have to worry about the fact that there is an extra little current from the precession. That has already been included in the diamagnetic term.

34-5 Larmor's theorem

We can already conclude something from our results so far. First of all, in the classical theory the moment μ was always proportional to J , with a given constant of proportionality for a particular atom. There wasn't any spin of the electrons and the constant of proportionality was always $-q/mc$; that is to say, in Eq. (34.6) we should set $g = 1$. The ratio of μ to J was independent of the internal motion of the electrons. Thus according to the classical theory, all systems

of electrons would precess with the same angular velocity. (This is not true in quantum mechanics.) This result is related to a theorem in classical mechanics that we would now like to prove. Suppose we have a group of electrons which are all held together by attraction toward a central point, so the electrons are attracted by a nucleus. The electrons will also be interacting with each other, and can, in general, have complicated motions. Suppose you have solved for the motions with no magnetic field and then want to know what the motions would be with a weak magnetic field. The theorem says that the motion with a weak magnetic field is always one of the no-field solutions with an added rotation, about the axis of the field, with the angular velocity $\omega_0 = qB/2m$. (This is the same as ω_0 , if $B = 1$.) There are, of course, many possible motions. The point is that for any \dot{r} motion without the magnetic field there is a corresponding motion in the field, which is the original motion plus a uniform rotation. This is called Larmor's theorem, and ω_0 is called the Larmor frequency.

We would like to show how the theorem can be proved, but we will let you work out the details. Take, first, one electron in a central force field. The force on it is just $-F(r)$, directed toward the center. If we now turn on a uniform magnetic field, there is an additional force, $qv \times B$; so the total force is

$$\mathbf{F}(r) = -q\mathbf{v} \times \mathbf{B}. \quad (34.18)$$

Now let's look at the same system from a coordinate system rotating with angular velocity ω about an axis through the center of force and parallel to \mathbf{B} . This is no longer an inertial system, so we have to put in the proper pseudoforces—the centrifugal and Coriolis forces we talked about in Chapter 19 of Volume I. We found there that in a frame rotating with angular velocity ω , there is an apparent radial force proportional to v_r , the radial component of velocity:

$$F_r = -2mv_r\omega, \quad (34.19)$$

And there is an apparent radial force which is given by

$$F_\theta = mv^2/r = 2mv_r\omega, \quad (34.20)$$

where v is the tangential component of the velocity, measured in the rotating frame. (The radial component v_r for rotating and inertial frames is the same.)

Now for small enough angular velocities (that is, if $2\omega \ll v_r$), we can neglect the first term (centrifugal) in Eq. (34.20) in comparison with the second (Coriolis). Then Eqs. (34.19) and (34.20) can be written together as

$$\mathbf{F} = -2mv_r\omega \hat{e}_r + \omega \hat{e}_\theta. \quad (34.21)$$

If we now combine a rotation and a magnetic field, we must add the forces in Eq. (34.21) to that in Eq. (34.18). The total force is

$$\mathbf{F}(r) = -q\mathbf{v} \times \mathbf{B} - 2mv_r\omega \hat{e}_r + \omega \hat{e}_\theta. \quad (34.22)$$

[we reverse the cross product and the sign of Eq. (34.21) to get the \hat{e}_θ term]. Adding up our results, we see that all

$$2mv_r\omega = -qB$$

the two terms on the right cancel, and in the moving frame the only force is $\mathbf{F}(r)$. The motion of the electron is just the same as with no magnetic field: $\omega_0\hat{e}_\theta$, of course, no rotation. We have proved Larmor's theorem for one electron. Since the proof assumes a small ω , it also means that the theorem is true only for weak magnetic fields. The only thing we could ask you to improve on is to do the case of many electrons mutually interacting with each other, but still in the same central field, and prove the same theorem. So no matter how complex our system, if it has a central field the theorem is true. But that's the end of the classical mechanics, because it isn't true in fact that the motions precess in that way. The precession frequency ω_0 of Eq. (34.11) is only equal to ω_0 if g happens to be equal to 1.

34-6 Classical physics gives neither diamagnetism nor paramagnetism

Now we would like to demonstrate that according to classical mechanics there can be no diamagnetism and no paramagnetism at all. It sounds crazy. First, we have proven that, if you take particles, the magnetism, interacting outside, can exist, and now we are going to prove that it is a tautology. Yet! We're going to prove that if you follow the classical mechanics framework, there are no such magnetic effects as diamagnetism. If you start a classical argument in a certain place and thought it through, you can get any answer you want. But the only logical and correct proof shows that there is no magnetic effect whatever.

It is a consequence of classical mechanics that if you have any kind of system: a gas with electrons, motions, and whatever—keep it in tact so that the whole thing can't turn, there will be no magnetic effect. It is possible to have a magnetic effect if you have an isolated system, like a star held together by itself, which can start rotating when you act on the magnetic field. But if you have a piece of material that's held in place so that it can't start spinning, then there will be no magnetic effects. What we mean by holding down the spin is summarized this way: At a given temperature we suppose that there is only one state of thermal equilibrium. The Postulate then says that if you turn on a magnetic field and wait for the system to get into thermal equilibrium, there will be no paramagnetism or diamagnetism—there will be no induced magnetic moment. (Postulate) According to statistical mechanics the probability that a system will have any given state of motion is proportional to $e^{-E/kT}$, where E is the energy of that motion. Now what is the energy of motion? For a particle moving in a constant magnetic field, the energy is the ordinary potential energy plus $mv^2/2$, with nothing additional for the magnetic field. [You know that the forces from electromagnetic fields are $q(E - v \times B)$, and that the rate of work $F \cdot v$ is just $qE \cdot v$, which is not affected by the magnetic field.] So the energy of a system, whether it is in a magnetic field or not, is always given by the kinetic energy plus the potential energy. Since the probability of any motion depends only on the energy—that is, on the velocity and position—it is the same whether or not there is a magnetic field. For thermal equilibrium, therefore, the magnetic field has no effect. If we have one system in a box, and then have another system in a second box, this time with a magnetic field, the probability of any particular velocity at any point in the first box is the same as in the second. If the first box has an average circulating current (which it will not have if it is in equilibrium with the stationary walls), there is no average magnetic moment, since in the second box all the motions are the same. There is no average magnetic moment there either. Hence, if the temperature is kept constant and thermal equilibrium is re-established after the field is turned on, there can be no magnetic moment induced by the field—according to classical mechanics. We can only get a satisfactory understanding of magnetic phenomena from quantum mechanics.

Unfortunately, we cannot assume that you have a thorough understanding of quantum mechanics, so this is hardly the place to discuss the matter. On the other hand, we don't always have to learn something first by learning the exact rules and then by learning how they are applied in different cases. Almost every subject that we have taken up in this course has been treated in a different way. In the case of electrodynamics we wrote the Maxwell equations on "Page One," and that did not tell all the consequences. That's one way. But we will not now try to begin a new "Page One," writing the equations of quantum mechanics and deducing everything from them. We will just have to tell you some of the consequences of quantum mechanics, before you begin to see they come from. So here we go.

34-7 Angular momentum in quantum mechanics

We have already given you a relation between the magnetic moment and the angular momentum. That's pleasant. But what is the magnetic moment and the angular momentum *now* in quantum mechanics? In quantum mechanics it turns out to be best to define things like angular momentum in terms of the other concepts, such as energy, in order to make sure that one knows what it means. Now,

It is easy to define a magnetic moment in terms of energy, because the energy of a moment in a magnetic field is, in the classical theory, $\mu \cdot B$. Therefore, the following definition has been taken in quantum mechanics: If we calculate the energy of a system in a magnetic field and we find that it is proportional to the field strength (for small fields), the coefficient is called the component of magnetic moment in the direction of the field. (We don't have to get so elegant for our work now; we can still think of the magnetic moment in the ordinary, or some extent classical, sense.)

Now we would like to discuss the idea of angular momentum in quantum mechanics—or rather, the characteristics of what in quantum mechanics is called angular momentum. You see, when you go to new kinds of laws, you can't just assume that each word is going to mean exactly the same thing. You may think, say, "Oh, I know what angular momentum is. It's that thing that is always a torque." But what's a torque? In quantum mechanics we have to give new definitions of old quantities. It would, therefore, be really best to call it by some other name such as "quantum angular momentum," or something like that, because it is the angular momentum as defined in quantum mechanics. But I want a single quantity in quantum mechanics which is identical to our old idea of angular momentum when the system becomes large enough, that is, for something as extreme as. We might as well just call it angular momentum. With that understanding, this next thing that we're about to do is very simple. In mechanics, it is nothing which in a large system we recognize as angular momentum or class mechanics.

First, we take a system in which angular momentum is conserved, such as an atom all by itself in empty space. Now such a thing (like the earth spinning on its axis) could, in the ordinary sense, be spinning around any axis one wished to choose. And for a given spin, there could be many different "states," all of the same energy, each "state" corresponding to a particular direction of the axis of the angular momentum. So in the classical theory, with a given angular momentum, there is an infinite number of possible states, all of the same energy.

If we look at quantum mechanics, however, that's several strange things happen. First, the number of states in which such a system can exist is limited—there is only a finite number. If the system is small, the finite number is very small, and if the system is large, the finite number gets very, very large. Second, we cannot directly a "state" by giving the direction of its angular momentum, or, only by giving the component of the angular momentum along some direction—say in the z-direction. Classically, an object with a given total angular momentum J could have, for its z-component, any value $J_{z,\text{classical}} = J \sin \theta$. But, qualitatively, for the general of angular momentum, we have only certain discrete values. Any given system—a particle, atom, molecule, or anything—with a given energy, has a also a certain number j , and its component of angular momentum can only be one of the following set of values:

$$\begin{aligned} & j \\ & j_z = j\hbar \\ & j_z = 2j\hbar \\ & \dots \\ & -(j - 2)\hbar \\ & (j - 1)\hbar \\ & -j\hbar \end{aligned} \tag{Q4.23}$$

The largest z-component is j times \hbar ; the next smaller is one unit of \hbar less, and so on down to $-j\hbar$. The number j is called "the spin of the system." Some people call it the "total angular momentum quantum number"; but we'll call it the "spin."

You may be worried that what we are saying can only be true for some "special" axis. But that is not so. For a system whose spin is j , the component of angular momentum along any axis can have only one of the values in (Q4.23). Although it is quite mysterious, we ask you just to accept it for the moment. We

will come back and discuss this point later. You may at least be pleased to see that the z-component goes from some number to minus the same number; so that we at least don't have to decide which is the plus direction of the axis. (Actually, it was this that it went from + to minus a different amount, that would be just as mysterious, because we wouldn't have been able to define the axis, pointing the other way.)

Now if the z-component of angular momentum never goes down by integers from $-j$ to $+j$, then j must be an integer. Not. Not quite: j must be an integer. It's only the difference between j and $-j$ that must be an integer. So, in general, the spin j is either an integer or a half-integer, depending on whether $2j$ is even or odd. Take, for instance, a nucleus like lithium, which has a spin of three-halves, $j = 3/2$. Then the angular momentum around the z axis, in units of \hbar , is one of the following:

$$\begin{aligned} &+3/2 \\ &+1/2 \\ &0 \\ &-1/2 \\ &-3/2 \end{aligned}$$

These are four possible states, each of the same energy, if the nucleus is in empty space with no external fields. If we have a system whose spin is two, then the z-component of angular momentum has only the values, in units of \hbar ,

$$\begin{aligned} &2 \\ &1 \\ &0 \\ &-1 \\ &-2. \end{aligned}$$

If you count now many states (including degeneracy), there are $(2j+1)$ possibilities. In other words, if you tell me the energy and also the spin j , it turns out that there are exactly $(2j+1)$ states with that energy, each state corresponding to one of the different possible values of the z-component of the angular momentum.

We would like to add one other fact. If you pick out any state of knowing at random and measure the z-component of the angular momentum, then you may get any one of the possible values, and each of the values is equally likely. All of the states are in fact single states, and each is just as good as any other. Each one has the same "weights" in the world. (We are assuming that nothing has tendency to sort out a special sample.) This fact has, incidentally, a simple classical analog. If you ask the same question classically: What is the line broadening of a particular z-component of angular momentum if you take a random sample of systems, all with the same total angular momentum? - the answer is that all values from the maximum to the minimum are equally likely. (You can easily work this out.) The classical result corresponds to the equal probability of the $(2j+1)$ possibilities in quantum mechanics.

From what we have so far, we can get another interesting and somewhat surprising conclusion. In certain classical calculations the quantity that appears in the final result is the square of the magnitude of the angular momentum J ; i.e. other words, $J \cdot J$. It turns out that it is often possible to get at the correct quantum-mechanical formula by using the classical calculation and the following simple rule: Replace $J^2 = J \cdot J$ by $\sigma_J = 1/6^2$. This rule is commonly used, and actually gives the correct result, but not always. We can give the following argument to show why you might expect this rule to work.

The scalar product $J \cdot J$ can be written as

$$J \cdot J = J_x^2 + J_y^2 + J_z^2$$

Since it is a scalar, it should be the same for any orientation of the spin. Suppose we pick samples of any given atomic system at random and make measurements of J_x^2 or J_y^2 or J_z^2 , the average value should be the same for each. (There is no special distinction for any one of the directions.) Therefore, the average of $J \cdot J$ is just

equal to three times the average of any component squared, say of J_z ,

$$\langle J \cdot J \rangle_{av} = 3\langle J_z^2 \rangle_{av}.$$

But since $J \cdot J$ is the same for all orientations, its average is, of course, just its constant value; we have

$$J \cdot J = 3\langle J_z^2 \rangle_{av}. \quad (Q4.24)$$

If we now say that we will use the same equation for quantum mechanics, we can easily find $\langle J_z^2 \rangle_{av}$. We just have to take the sum of the $(j_y + 1)$ possible values of J_z^2 , and divide by the total number;

$$\langle J_z^2 \rangle_{av} = j^2 - (j+1)^2 + \frac{(-j)^2 + (-j+1)^2}{2j+1}. \quad (Q4.25)$$

For a system with a spin of $1/2$, it goes like this:

$$\langle J_z^2 \rangle_{av} = (3/2)^2 + (1/2)^2 - \frac{(-1/2)^2 + (-3/2)^2}{2} = \frac{3}{4} \text{ J}^2.$$

We conclude that

$$J \cdot J = 3\langle J_z^2 \rangle_{av} = 3j^2 \approx 3(j+1)^2.$$

We will leave it to you to show that Eq. (Q4.25), together with Eq. (44.24), gives the general result

$$J \cdot J = j(j+1)h^2. \quad (Q4.26)$$

Although we would think classically that the largest possible value of the component of J is just the magnitude of J —namely, $\sqrt{J \cdot J}$ —quantum mechanically the maximum of J_z is always a little less than that, because j_h is always less than $\sqrt{(j+1)h}$. The angular momentum is said “completely along the z-direction.”

34-8. The magnetic energy of atoms

Now we want to talk again about the magnetic moment. We have said that in quantum mechanics the magnetic moment of a particular atomic system can be written in terms of the angular momentum by Eq. (31.8);

$$\mu_z = -q \left(\frac{\hbar}{2me} \right) J_z, \quad (Q4.27)$$

where $-q$ and m are the charge and mass of the electron.

An atomic magnet placed in an external magnetic field will have an excess magnetic energy which depends on the component of its magnetic moment along the field direction. We know that

$$U_{\text{mag}} = -\mu \cdot \theta. \quad (G4.28)$$

Choosing our basis along the direction of θ ,

$$U_{\text{mag}} = -\mu_z \theta_z. \quad (G4.29)$$

Using Eq. (Q4.27), we see that

$$U_{\text{mag}} = q \left(\frac{\hbar}{2me} \right) J_z \theta_z.$$

Quantum mechanics says that J_z can have only certain values: j_h , $(j+1)h$, ..., $-jh$. Therefore, the magnetic energy of an atomic system is not arbitrary; it can have only certain values. Its maximum value, for instance, is

$$q \left(\frac{\hbar^2}{2me} \right) j_h h.$$

The quantity μ_B can be usually given the name "the Bohr magneton" and written as:

$$\mu_B = \frac{e\hbar}{2mc}$$

The possible values of the magnetic energy are

$$E_{m,\pm} = \mu_B m_s \frac{\hbar c}{2}$$

where m_s takes on the possible values j_z , $j_z = +\frac{1}{2}\hbar$, $j_z = -\frac{1}{2}\hbar$, $j_z = +\frac{3}{2}\hbar$, etc.

In other words, the energy of an atomic system is changed when it is put in a magnetic field by an amount that is proportional to the field, and proportional to j_z . We say that the energy of an atomic system is "split into $(2j+1)$ levels" by a magnetic field. For instance, an atom whose energy is E_0 outside a magnetic field and whose j is $3/2$, will have four possible energies when placed in a field. We can show these energies by an energy-level diagram just as shown in Fig. 31-5. Any particular atom can have only one of the four possible states in a given field B . That's what quantum mechanics says about the behavior of an atomic system in a magnetic field.

The simplest "atomic" system is a single electron. The spin of an electron is $1/2$, so there are two possible states, $j_z = +\frac{1}{2}\hbar$ and $j_z = -\frac{1}{2}\hbar$. For an electron at rest (no orbital motion), the spin magnetic moment has a p -value of μ , so the magnetic energy can be either $\pm \mu B$. The possible energies in a magnetic field are shown in Fig. 34-6. Speaking loosely we say that the electron either has its spin "up" (along the field) or "down" (opposite the field).

For systems with higher spins, there are more states. We can think that the spin is "up" or "down" or "clockwise," some "angle," in between, depending on the value of j_z .

We will use these quantum mechanical results to discuss the magnetic properties of materials in the next chapter.

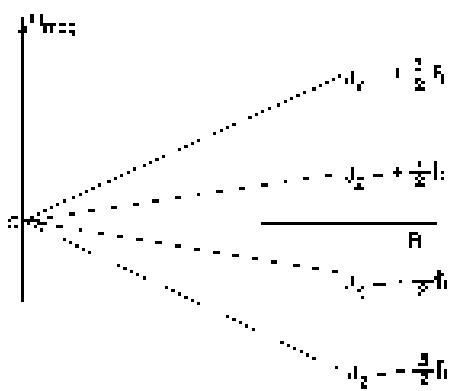

Fig. 34-5. The possible magnetic energies, E_m , of an atomic system with a spin of $3/2$ in a magnetic field B .

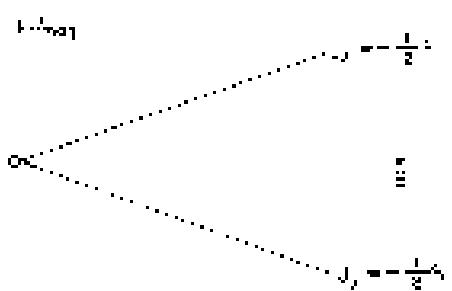

Fig. 34-6. The two possible energy states of an electron in a magnetic field B .

Paramagnetism and Magnetic Resonance

35-1 Quantized magnetic states

In the last chapter we described how in quantum mechanics the angular momentum of a thing does not have an arbitrary direction, but its component along a given axis can take on only certain discrete, spatial, discrete values. It is a shocking and peculiar thing. You may think that, perhaps, we should not believe such things, until your mind is more advanced and ready to accept this kind of an idea. Actually, your mind will never become more advanced—in the sense of being able to accept such a thing easily. There is no way of making it "intelligible" that isn't so subtle our brains just can't seem to get it. It is more complicated than the thing you were trying to understand. The behavior of matter on a small scale, as we have remarked many times, is different from anything that you are used to and is very strange indeed. As we proceed with classical physics, it is a good idea to try to get a growing acquaintance with the behavior of things on a small scale, at first as a kind of experience and not any deep understanding. Understanding of these matters comes very slowly, if at all. Of course, one does not better able to know what's going to happen in a quantum-mechanical situation—if that is what understanding means—but one never gets a comfortable feeling that these quantum-mechanical rules are "natural." Of course they are, but they are not natural to our own experience at an ordinary level. We should explain that the attitude that we are going to take with regard to this is that angular momentum is quite different from many of the other things we were talked about. We are not going to try to "explain" it, but we must at least tell you what happens; it would be dishonest to cover the thermagnetic properties of materials without mentioning the fact that the classical description of magnetism of angular momentum and magnetic moments—is incorrect.

One of the nice, shocking and disturbing features about quantum mechanics is this: if you take the angular momentum along any particular axis you find that it is always an integer or half-integer value \hbar . This is so no matter which axis you take. The subtleties involved in this curious fact—that you can take any other axis and still find the component of it is also limited to the same set of values—we will leave to a later chapter, when you will experience the delight of seeing how this apparent paradox is ultimately resolved.

We will now just repeat the fact that for every atomic system there is a number J , called "the spin of the system"—which must be an integer or a half-integer—and that the component of the angular momentum along any particular axis will always have one of the following values between $+\hbar$ and $-\hbar$:

$$\vec{J}_z = \text{one of } \begin{cases} \hbar & \\ \hbar - 1 & \\ \hbar - 2 & \\ \vdots & \cdots \\ -\hbar + 2 & \\ -\hbar + 1 & \\ -\hbar & \end{cases} \quad (35.1)$$

We have also mentioned that every simple atomic system has a magnetic moment which has the same direction as the angular momentum. This is true not only for atoms and nuclei but also for the fundamental particles. Each fundamental particle has its own characteristic value of J and its magnetic moment

35-6 Nuclear magnetic resonance

Review: Chapter 11, Atomic Discreteness

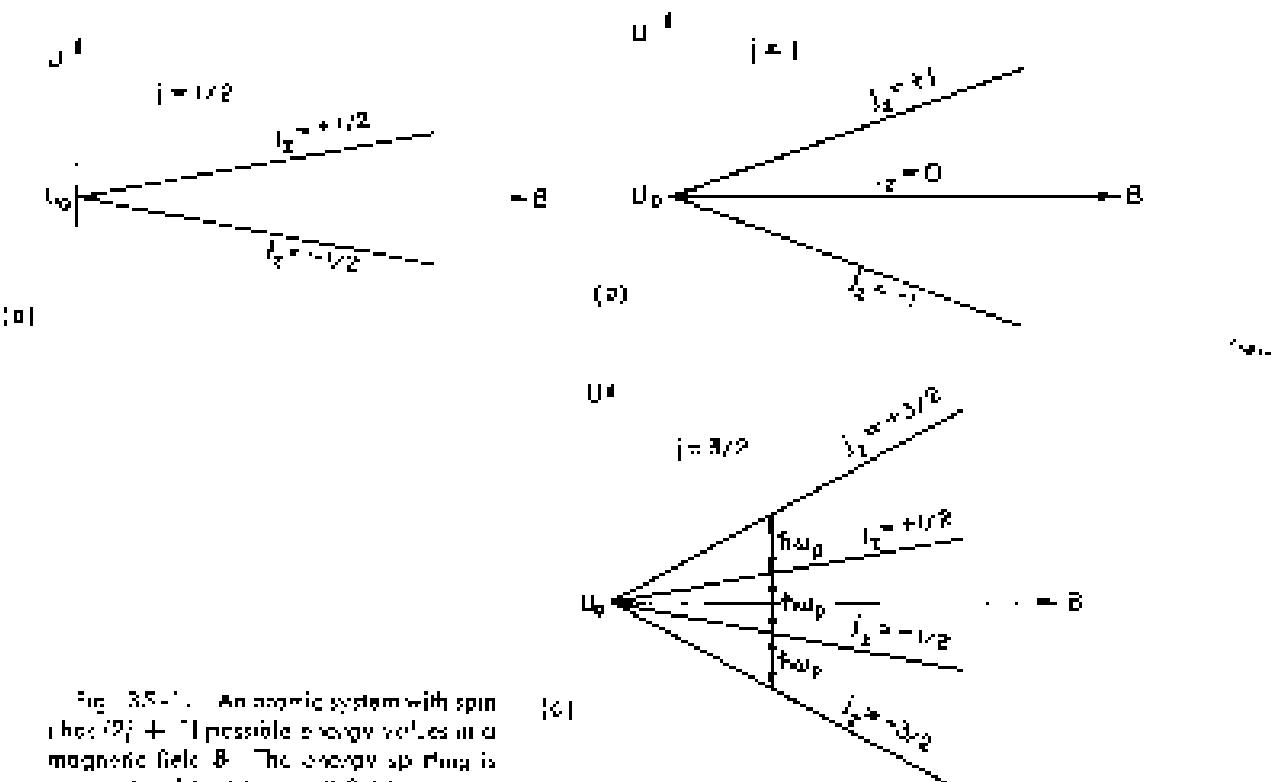

Fig. 35-1. An atomic system with spin $j = 1/2$; 1 ; $3/2$ possible energy values in a magnetic field B . The energy splitting is proportional to B for small fields.

(For some particles, such as zero.) What we mean by "the magnetic moment" in this statement is that the energy of the system in a magnetized field, say in the z -direction, can be written as $-\mu_z B$ for small magnetic fields. We must have the condition that the field should not be too great, otherwise it could destroy the internal motions of the system and the energy would not be a measure of the magnetic moment that was there before the field was turned on. But if the field is sufficiently weak, the field changes the energy by the amount

$$\Delta E = -\mu_z B, \quad (35.1)$$

with the understanding that in this equation μ_z is to be replaced by

$$\mu_z = g \left(\frac{e}{2m} \right) J_z, \quad (35.2)$$

where J_z and v are of the value given in Eq. (35.1).

Suppose we take a system with a spin $j = 1/2$. Without the magnetic field, the system has two different possible states corresponding to the different values of J_z , all of which have exactly the same energy. But the moment we can in the z -direction is not, there is an additional energy of interaction which separates these states into two slightly different energy levels. The energies of these levels are given by a certain energy proportionality factor, called by aches of $1/2$, i.e., $-1/2$, but not $-1/2$, the values of μ_z . The resulting set of energy levels for an atom system with spins of $1/2$, 1 , and $3/2$ are shown in the diagrams of Fig. 35-1. (Remember, that for any magnetic system of electrons the magnetic moment is always directed opposite to the angular momentum.)

It is evident from the diagrams that the "center of gravity" of the energy levels is the same with and without a magnetic field. A noticeable fact the spacings between the levels in a magnet are always equal for a given particle in a given magnetic field. We are going to study the energy spacings, for a given magnetic field B , in Sec. 35-2, which is just a definition of ω_0 . Using Eqs. (35.2) and (35.1), we have

$$\begin{aligned} \Delta E_0 &= B \sum_{j=1}^J J_z B \\ \omega_0 &= g \frac{e}{2m} B. \end{aligned} \quad (35.3)$$

The quantity $\mu g / (2m)$ is just the ratio of the magnetic moment to the angular momentum — it is a property of the particle. Equation (35-4) is the same formula that we got in Chapter 24 for the angular velocity of precessed in a magnetic field, for a gyroscope whose angular momentum is J and whose magnetic moment is μ .

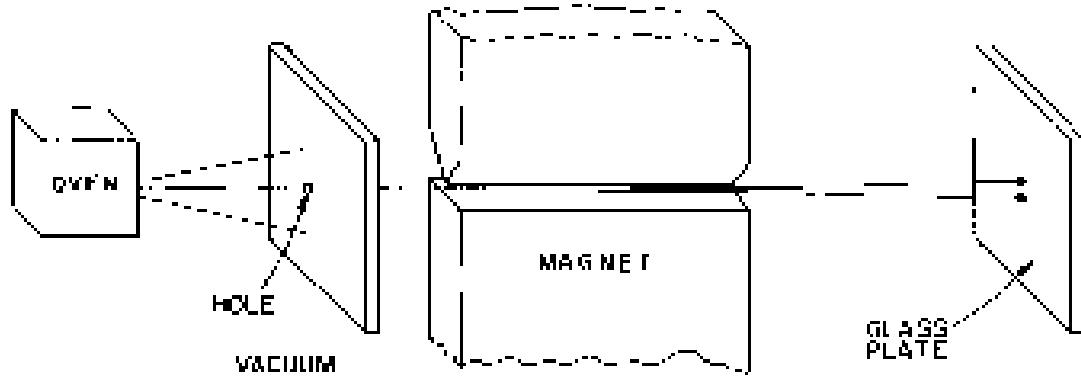

Fig. 35-2. The experiment of Stern and Gerlach.

35-2 The Stern-Gerlach experiment

The fact that the angular momentum is quantized is such a surprising thing that we will talk a little bit about it historically. It was a shock from the moment it was discovered (although it was expected theoretically). It was first observed in an experiment done in 1922 by Stern and Gerlach. If you wish, you can re-enact the experiment of Stern-Gerlach as a direct verification for a below in the supplementary exercises at the end of the chapter. Stern and Gerlach devised an experiment for measuring the magnetic moment of individual silver atoms. They prepared a beam of silver atoms by evaporating silver in a furnace and letting some of them escape out through a series of small holes. This beam was directed between the pole tips of a special magnet, as shown in Fig. 35-2. Their idea was the following. If this beam has a magnetic moment μ , then in a magnetic field B it has an energy $-\mu B$, where θ is the direction of the magnetic field. In the classical theory, θ would be equal to the magnetic moment times the cosine of the angle between the magnet and the magnetic field, so the extra energy in the field would be

$$\Delta E = -\mu B \cos \theta. \quad (35.3)$$

If θ gets out of the plane, then the magnetic moments would point in every possible direction, so there would be all values of θ . Now, if the magnetic field was so very rapidly varied, if there is a strong field going out from the magnet, θ would also vary with position, and there would be a force on the magnetic moments whose direction will depend on whether θ is positive or negative. The atoms will be pulled up or down by a force proportional to the derivative of the magnetic energy, from the $\mu B \cos \theta$ potential work,

$$F_x = -\frac{\partial E}{\partial z} = \mu \sin \theta \frac{\partial B}{\partial z}. \quad (35.4)$$

Stern and Gerlach made their magnet with a very sharp edge on one of the pole tips in order to produce a very rapid variation of the magnetic field. The beam of silver atoms was directed right along this sharp edge, so that the atoms would feel a vertical force in the inhomogeneous field. A silver atom with its magnetic moment directed horizontally would have no force on it and would go straight past the magnet. An atom whose magnetic moment was exactly vertical would have a force pulling it up toward the sharp edge of the magnet. An atom whose magnetic moment was pointed downward would feel a downward push. Thus,

as they left the magnet, the atoms would be spread out according to their vertical components of magnetic moment... In the classical theory all angles are possible so that when the silver atoms were reflected by deposition on a glass plate one should expect a series of silver atoms in a curved line. The height of the line would be proportional to the magnitude of the magnetic moment. The observation of classical theory was completely revealed when Stern and Gerlach saw what actually happened. They found on the glass plate two distinct spots. The silver atoms had formed two beams.

They asked me if you are going to appear in my lecture on molecular beam methods. How does the magnetic moment know there is only allowed to have a certain amount in the direction of the magnetic field? Well, that was only the beginning of the discovery of the quantization of angular momentum, for instead of trying to give you a theoretical explanation, we can just say that you are stuck with the result of this experiment just as the physicists of that day had to accept the result when the experiment was done. It is an experimental fact that the energy of an atom in a magnetic field takes on a series of individual values. For each of these values the energy is proportional to the field strength. So in a region where the field varies, the number of levels will tell us that the possible magnetic fields on the atom will have a series of definite values, the force is different for each state, so the beam of atoms is split into a small number of separate beams. From a measurement of the reflection of the beams, one can find the strength of the magnetic moment.

35-3 The Rabi molecular-beam method

We would now like to describe an improved apparatus for the measurement of magnetic moments which was developed by J. S. Rabi and his collaborators. In the Stern-Gerlach experiment the deflection of atoms is very small and the measurement of the magnetic moment is not very precise. Rabi's technique permits a large-scale improvement in the measurement of the magnetic moment. The method is based on the fact that the typical energy of the atoms in a magnetic field is proportional to the number of cycles per second. And the energy of an atom in a magnetic field can have only certain exactly definite values, it is really no more surprising than it is fact that atoms in general occupy only a few discrete energy levels; something we mentioned often in Volume I. Why should the same thing not hold for atoms in a magnetic field? It does. But it is the attempt to correlate this with the ideas of the second quantum theory that brings out some of the strange implications of quantum mechanics.

When an atom has two levels which differ in energy by the amount ΔE , it can make a transition from the upper level to the lower level by emitting a light quantum of frequency ω , where

$$\hbar\omega = \Delta E \quad (35.7)$$

The same thing can happen with atoms in a magnetic field. Only here, the energy difference is so small that the frequency does not correspond to light, but to microwave or radio frequencies. The atom has to make a lower-energy transition to an upper-energy level of an atom can also take place with such an external light or, in the case of atoms in a magnetic field, by the absorption of microwave energy. Thus if we have an atom in a magnetic field, we can cause transitions if we are able tocouple by applying an additional electromagnetic field of the proper frequency. In other words, if we have an atom in a strong magnetic field and we have the atom with a weak varying electromagnetic field, there will be a certain probability of "switching" it to another level if the frequency is near to the one in Eq. (35.7). For an atom in a magnetic field, this frequency ω_{res} at which we have calculated ω , will be given in terms of the magnetic field by Eq. (35.4). If the atom is coupled with the exciting frequency, the chance of causing a transition is very small. This leads to a sharp resonance at ω_{res} ; the probability of causing a transition. By measuring the frequency of this resonance in a known magnetic field B , we can measure the quantity μ_0/μ_B —and hence the ρ -factor—with great precision.

It is interesting that one comes to the same conclusion from a classical point of view. According to the classical picture, when we place a small gyroscope with a magnetic moment μ and an angular momentum J in an external magnetic field B , the gyroscope will precess about an axis parallel to the magnetic field. (See Fig. 35-2.) Suppose we ask: How can we change the angle of the classical gyroscope with respect to the field—namely, with respect to the z -axis? The magnetic field produces a torque around a horizontal axis. Such a torque you would think is going to line up the magnet with the field, but it only causes the precession. If we want to change the angle of the gyroscope with respect to the z -axis, we must exert a torque east along the x -axis. If we apply a torque which goes in the same direction as the precession, the angle of the z -vector will continue to give a smaller component, $\alpha_p \cdot J$ in the z -direction. In Fig. 35-3, the angle between J and the z -axis would increase. If we try to reduce the precession, J moves toward the z -axis.

For an s -processing atom in a uniform magnetic field, how can we apply the kind of force we want? The answer is: with a weak magnetic field from the side. You might at first think that the direction of this magnetic field would have to coincide with the precession of the magnetic moment, so that it was always at right angles to the moment, as indicated by the field B' in Fig. 35-4(a). Such a field works very well, but an alternating horizontal field is almost as good. If we have a constant horizontal field B' , which is always in the x -direction (this is a tuning fork, which oscillates with the frequency ω_0), then on each one-half cycle the torque on the magnetic moment reverses, so that it has a cumulative effect which is almost as effective as a rotating magnetic field. Classically, then, we would expect the component of the magnetic moment along the x -direction to change if we have a very weak oscillating magnetic field at a frequency which is exactly ω_0 . Classically, of course, μ_x would change continuously, but in quantum mechanics the component of the magnetic moment cannot adjust continuously. It must jump suddenly from one value to another. We have made the comparison between the consequences of classical mechanics and quantum mechanics to give you some idea as to what might happen classically and how it is related to what actually happens in quantum mechanics. You will notice, incidentally, that the required resonance frequency is the same in both cases.

One additional remark: From what we have said about quantum mechanics, there is no apparent reason why there couldn't also be transitions at the frequency $2\omega_0$. It happens that there isn't, any analog of this in the classical case, and also it doesn't happen in the quantum theory either—so far as we know. The particle method of inducing the transitions that we have described. With a nonrotating horizontal magnetic field, the probability that a frequency $2\omega_0$ would cause a jump of two steps at once is zero. It is only at the frequency ω_0 that there are other allowed or allowed, and these in pairs.

Now we are ready to describe Rabi's method for measuring magnetic moments. We will consider here only the apparatus for atoms with a spin of $1/2$. A diagram of the apparatus is shown in Fig. 35-5. This is an oven which gives out a stream of s -process atoms which pass through a hole of three rings. Magnet 1

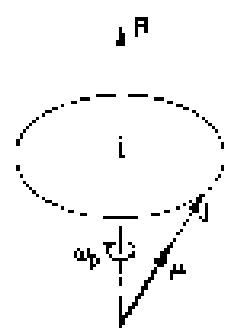

Fig. 35-3. The classical precession of an atom with the magnetic moment μ and the angular momentum J .

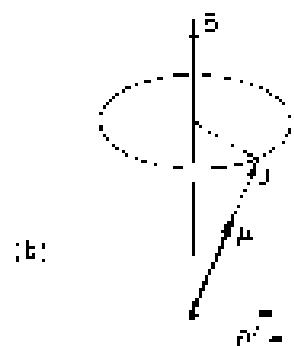

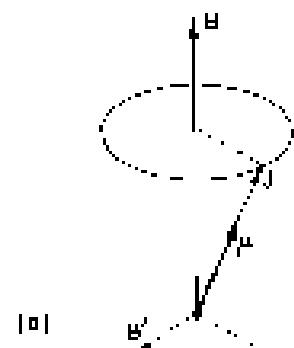

Fig. 35-4. The angular precession of atomic magnets can be changed by a horizontal magnetic field a wave of one angle (a), or by an oscillating (c), as in (b).

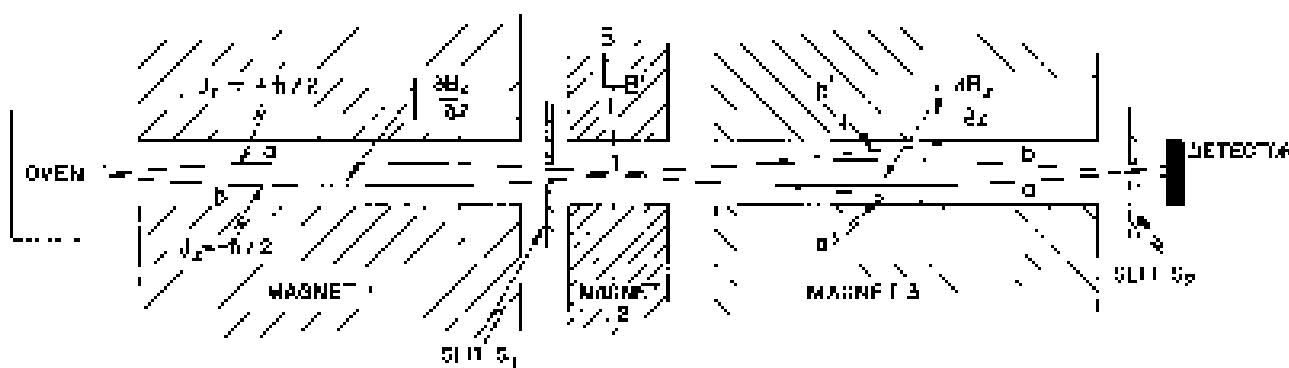

Fig. 35-5. The Rabi molecular-beam apparatus.

is ω , like the one in Fig. 35-2, and the field with a strong field gradient, say, with $\partial B/\partial z$ positive. If the atoms have a magnetic moment, they will be deflected downward if $J_z = -\hbar/2$, or upward if $J_z = \hbar/2$ (since for electrons μ is directly opposite to J). If we consider only those atoms which can get through the slit S_1 , there are two possible trajectories, as shown. Atoms with $J_z = +\hbar/2$ must go along curve a to get through the slit, and those with $J_z = -\hbar/2$ must go along curve b . Atoms which start out from the oven along other paths will not get through the slit.

Magnet 2 has a constant field. There are no forces on the atoms in this region, so they go straight through and enter magnet 3. Magnet 3 is just like magnet 1 but with the field inverted, so that $\partial B/\partial z$ has the opposite sign. The atoms with $J_z = +\hbar/2$ (we say "with spin up"), that felt a downward push in magnet 1, get an upward push in magnet 3; they continue on the path a and go through slit S_2 to a detector. The ones with $J_z = -\hbar/2$ ("with spin down") also have opposite forces in magnet 3 and go along the path b , which also takes them through slit S_2 to the detector.

The reflected ray may be made in various ways, depending on the beam being measured. One way is to let the beam pass through sodium-like sodium, and a detector can be arranged behind the oven to count particles in a stationary current meter. When sodium atoms land on the wire, they undergo ionization at the Na-L shell, leaving an electron behind. There is a current ratio of about 1000 to 1 for the number of sodium atoms arriving per second.

In the gap of magnet 2 there is a set of coils that produces a small oscillating magnetic field B' . The coils are driven with a square wave oscillation at a frequency ω . So between the poles of magnet 2 there is a strong, low $\partial B/\partial z$, vertical field B and a weak, oscillating, horizontal field B' .

Suppose now that the frequency ω of the oscillating field is set at ω_0 , the "precession" frequency of the atoms in the field B . The alternating field ω_0 causes some of the atoms passing by to make transitions from one J_z to the other. An atom whose spin was initially "up" ($J_z = +\hbar/2$) may be flipped "down" ($J_z = -\hbar/2$). Now this atom has the direction of its magnetic moment reversed, so it will feel a downward force in magnet 1 and will move along the path b , shown in Fig. 35-3. It will no longer get through the slit S_2 to the detector. Similarly, some of the atoms whose spins were initially down ($J_z = -\hbar/2$) will have their spins flipped up ($J_z = +\hbar/2$) as they pass through magnet 2. They will then pass through slit S_2 and will not get to the detector.

If the field B' has a frequency appreciably different from ω_0 , it will not cause any spin flips, and all atoms will follow their undisurbed paths to the detector. So you can see that the "precession" frequency ω_0 of the atoms in the field B can be found by varying the frequency ω of the field B' until a decrease in ω increases the current of atoms hitting at the detector. A decrease in ω is called "resonance" when ω_0 is "in resonance" with ω . A plot of the detector current as a function of ω might look like the one shown in Fig. 35-6. Knowing ω_0 , we can obtain the ω_0 value of the atom.

Such microwave-heterodyne, or they are usually called "molecular" beam resonance experiments are a beautiful and delicate way of measuring the magnetic properties of atomic objects. The resonance frequency ω_0 can be determined with great precision—in fact, with a greater precision than we can measure the magnetic field B_0 , which we must know to find ω_0 .

35-4 The paramagnetism of bulk materials

We would like now to describe the phenomenon of the paramagnetism of bulk materials. Suppose we have a substance whose atoms have permanent magnetic moments, for example a crystal like copper sulfide. In the crystal there are copper ions whose inner electron shells are a net angular momentum and a net magnetic moment. So the copper ion is an object who has a permanent magnetic moment. Let's say just a word about which atoms have magnetic moments and which ones don't. Any atom, like sodium for instance, which has an odd number

of electrons will leave a magnetic moment. Sodium has one electron in its un-filled shell. This electron gives the atom a spin and a magnetic moment. Ordinarily, however, when compounds are formed the extra electrons in the valence shell are paired together with other electrons whose spin directions are exactly opposite, so that all the angular momenta and magnetic moments of the valence electrons cancel each other. That's why, in general, molecules do not have a magnetic moment. Of course if you have a gas of separate atoms, there is no such cancellation.⁵ Also, if you have what is called in chemistry a "free radical," an object with an odd number of valence electrons—then the bonds are not completely broken, and there is a net angular momentum.

In most bulk materials there is a net magnetic moment only if there are atoms present whose outer electron shell is not filled. Then there can be a net angular momentum and a magnetic moment. Such atoms are found in the "transition elements" part of the periodic table—Fe, manganese, chromium, cobalt, iron, nickel, cobalt, palladium, and platinum are elements of this kind. Also, all of the rare earth elements have unfilled outer shells and permanent magnetic moments. There are a couple of other strange things that also happen to have magnetic moments, such as liquid oxygen, but we will leave it to the chemistry department to explain the reason.

Now suppose that we have a box full of atoms or molecules with permanent moments, say a gas, or a liquid, or a crystal. We would like to know what happens if we apply an external magnetic field. With no applied field, the moments are kicked around by the thermal motion, and the moments wind up pointing in all directions. But when there is a magnetic field, it tries to line up the little magnets; then there are more moments lying toward the field than away from it. The material is "magnetized."

We define the magnetization M of a material as the net magnetic moment per unit volume, by which we mean the vector sum of all the atomic magnetic moments in a unit volume. If there are N atoms per unit volume and their average moment is $\langle \mathbf{p} \rangle_0$, then M can be written as N times the average atomic moment:

$$M = N\langle \mathbf{p} \rangle_0. \quad (35.8)$$

The definition of M corresponds to the definition of the electric polarization P of Chapter 19.

The classical theory of paramagnetism is just like the theory of the dielectric constant we derived you in Chapter 11. One assumes that each of the atoms has a magnetic moment μ , which always has the same magnitude but which can point in any direction. In a field B , the magnetic torque is $-\mu \cdot B = -\mu B \cos \alpha$, where α is the angle between the moment and the field. From statistical mechanics, the relative probability of having any angle is $e^{-\beta \mu B \cos \alpha}$, so angles near zero are more likely than angles near π . Proceeding exactly as we did in Section 11.3, we find that for small magnetic fields M is directly proportional to B and has the magnitude

$$M = \frac{\chi \mu^2 B}{3kT}. \quad (35.9)$$

[See Eq. (11.30).] This approximate formula is correct only for $\mu B/kT$ much less than one.

We find that the induced magnetization—the magnetic moment per unit volume—is proportional to the magnetic field. This is the phenomenon of paramagnetism. You will see that the effect is stronger at low temperatures and weaker at higher temperatures. When we put a field on a substance, it develops, for small fields, a magnetic moment proportional to the field. The ratio of M to B (for small fields) is called the magnetic susceptibility.

Now we want to look at paramagnetism from the point of view of quantum mechanics. We take first the case of an atom with a spin of $1/2$. In the absence of

⁵ Obviously Na vapor is mostly monatomic, although there are also some molecules of Na_2 .

In a magnetic field the atoms have a certain energy. But in a magnetic field there are two possible energies, one for each value of J_z . For $J_z = +1/2$, the energy is changed by the magnetic field by the amount

$$\Delta E_+ = -g \left(\frac{qA}{2m} \right) \cdot \frac{1}{2} \cdot B \quad (35.10)$$

(The energy shift is positive for an atom because the electron charge is negative.) For $J_z = -1/2$, the energy is changed by the amount

$$\Delta E_- = -g \left(\frac{qA}{2m} \right) \cdot \frac{1}{2} \cdot B \quad (35.11)$$

To save writing, let's set

$$\mu_B = g \left(\frac{qA}{2m} \right) \cdot \frac{1}{2} \cdot B \quad (35.12)$$

Then

$$\Delta E = \pm \mu_B B. \quad (35.13)$$

The meaning of μ_B is clear: μ_B is the component of the magnetic moment in the upper state, and $-\mu_B$ is the component of the magnetic moment in the down-spin case.

New statistical mechanics tells us that the probability that an atom is in one state or another is proportional to

$$e^{-\Delta E / kT} \propto e^{-\Delta E / kT},$$

With no magnetic field the two states have the same energy; so when there is no field, the probabilities are proportional to

$$e^{-\Delta E / kT}. \quad (35.14)$$

The number of atoms per unit volume with spin up is

$$N_{up} = n e^{-\mu_B B / kT}, \quad (35.15)$$

and the number with spin down is

$$N_{down} = n e^{\mu_B B / kT}. \quad (35.16)$$

The constant n is to be determined so that

$$N_{up} + N_{down} = N. \quad (35.17)$$

The total number of atoms per unit volume. So we get that

$$n = \frac{N}{e^{-\mu_B B / kT} + e^{\mu_B B / kT}}. \quad (35.18)$$

What we are interested in is the average magnetic moment along the axis. The atoms with spin up will contribute a moment of $+\mu_B$, and those with spin down will have a moment of $-\mu_B$, so the average moment is

$$\text{moment} = \frac{N_{up}(+\mu_B) + N_{down}(-\mu_B)}{N} \quad (35.19)$$

The magnetic moment per unit volume M is then $M(\mu_B) ...$ Using Eqs. (35.15), (35.16), and (35.17), we get that

$$M = N \mu_B \frac{e^{1.38 \times 10^{-23} T}}{e^{-\mu_B B / kT} + e^{\mu_B B / kT}}. \quad (35.20)$$

This is the quantum-mechanical formula for M for atoms with $m_J = 1/2$. Incidentally, this formula is valid for most elements more complex in terms of the

$$M = N \mu_B \tanh \frac{\omega_0 B}{kT}. \quad (35.21)$$

A plot of M as a function of B is given in Fig. 35-7. When B goes very large, the hyperbolic tangent approaches 1, and M approaches the limiting value $N\mu_B$; $S_z = \pm \frac{1}{2}$ has the magnetization averages. We can see why that is: at high enough fields the moments are all lined up in the same direction. In other words, they are all in the spin-down state, and each atom contributes the moment μ .

In most normal cases—say, for typical materials, room temperatures, and 1 eV fields one can accurately get (like 10,000 esus)—the ratio $\omega_0 B / kT$ is about 0.02. One must go to very low temperatures to see the saturation. For normal temperatures we can usually replace $tanh x$ by x , and write

$$M = \frac{N\mu_B^2 B}{kT}. \quad (35.22)$$

Just as we saw in the classical theory, M is proportional to B . In fact, the formula is almost exactly the same, except that there seems to be a factor of 1/2 missing. But we still need to relate $\omega_0 B$ to our quantum formula to the ω that appears in the classical result, Eq. (35.9).

In the classical formula, what appears is $\omega^2 = \mu \cdot \mu$, the square of the vector magnetic moment... or

$$\mu \cdot \mu = \left(\epsilon \frac{g_e}{2m} \right)^2 J \cdot J. \quad (35.23)$$

We pointed out in the last chapter that you can very likely get the right answer from a classical calculation by replacing $J \cdot J$ by $j(j+1)$. In our particular example, we have $j = 1/2$, so

$$(j(j+1))^2 = \frac{1}{4}.$$

Substituting this for $J \cdot J$ in Eq. (35.23), we get

$$\mu \cdot \mu = \left(\epsilon \frac{g_e}{2m} \right)^2 \frac{1}{4},$$

or in terms of μ_0 , defined in Eq. (35.12), we get

$$\mu \cdot \mu = \frac{3}{4} \mu_0^2.$$

Substituting this for ω^2 in the classical formula, Eq. (35.9), does indeed reproduce the correct quantum formula, Eq. (35.22).

The quantum theory of paramagnetism is easily extended to atoms of spin $\frac{1}{2}$. The 'new-field' magnetization is

$$M = N g_e \mu_0 B + \frac{1}{2} \mu_B B, \quad (35.24)$$

where

$$\mu_B = \frac{e \hbar}{2m} \quad (35.25)$$

is a combination of constants with the dimensions of a magnetic moment. Most atoms have moments of roughly this size. It is called the Bohr magneton. The spin magnetic moment of the electron is almost exactly one Bohr magneton.

35-5 Cooling by adiabatic demagnetization

There is a very interesting second application of paramagnetism. At very low temperatures it is possible to line up the atomic magnets in a strong field. It is then possible to get down to extremely low temperatures by a process called adiabatic demagnetization. We can take a para magnetic salt (for example, one

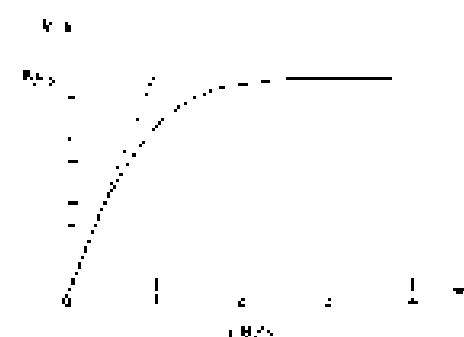

Fig. 35-7. The variation of the paramagnetic magnetization with the magnetic field strength B .

containing a number of rare-earth atoms (like praseodymium or gadolinium), and start by cooling it down with liquid helium to just 4.2 degrees Kelvin in a strong magnetic field. Then the factor $\mu B/kT$ is larger than 1—say more like 10/3. Most of the spins are lined up, and the magnetization is nearly saturated. Let's say, to make it easy, that the field is very powerful and the temperature is very low, so that nearly all the atoms are lined up. Then you rotate the salt. You only pay, by removing the liquid helium and leaving a good vacuum, and turn off the magnetic field. The temperature of the salt goes way down.

Now if you were to turn off the field suddenly, the jiggling and shaking of the atoms in the crystal would gradually knock all the spins out of alignment. Some of them would be up and some down. But if there is no field (and disregarding the interactions between the atomic magnets, which will make only a slight error), it takes no energy to turn over the atomic magnets. They could randomize their spins without any energy change and, therefore, without any temperature change.

Suppose, however, that while the atomic magnets are being flipped over by the thermal motion there is still some magnetic field present. Then it requires some work to flip them over opposite to the field—over *costs* work against the field. This takes energy from the thermal motions and lowers the temperature. So if the strong magnetic field is not removed too rapidly, the temperature of the salt will decrease—it is cooled by the demagnetization. From the quantum-mechanical view, when the field is strong all the atoms are in the lower state, because the odds against any being in the upper state are impossibly big. But as the field is lowered, it gets more and more likely that thermal fluctuations will knock an atom into the upper state. When that happens, the atom absorbs the energy $\Delta E = \mu B\delta$. So if the field is turned off slowly, the magnetic transitions can take energy out of the thermal vibrations of the crystal, cooling it off. It is possible in this way to go from a temperature of a few degrees absolute down to a temperature of a few thousandths of a degree.

Would you like to make something even colder? Let that be James and I. We have already mentioned that there are also paramagnetic moments for the atomic nuclei. One reason for paramagnetism weak, just as well for nuclei, except that the moments of nuclei are correspondingly *tiny* smaller. [They are of the order of magnitudes of μ_B/m_N , where m_N is the proton mass, so they are smaller by the ratio of the masses of the electron and proton.] With such magnetic moments, even at a temperature of 2°K, the factor $\mu B/kT$ is only a few parts in a thousand. But if we use the paramagnetic demagnetization process to get down to a temperature of a few thousandths of a degree, $\mu B/kT$ becomes a number near 1—or these low temperatures we can begin to saturate the nuclear moments. That is good luck, because we can then use the adiabatic demagnetization of the nuclear magnetism to reach still lower temperatures. Thus it is possible to do two stages of magnetic cooling. First we use adiabatic demagnetization of paramagnetic ions to reach a few thousandths of a degree. Then we use the cold paramagnetic salt to cool some material which has a strong nuclear magnetism. Finally, when we remove the magnetic field from this material, its temperature will go down to within a millionth of a degree of absolute zero—if we have done everything very carefully.

35-6 Nuclear magnetic resonance

We have said that atomic paramagnetism is very small and that nuclear magnetism is even a thousand times smaller. Yet it is relatively easy to observe the nuclear magnetism by the phenomenon of "nuclear magnetic resonance." Suppose we take a substance like water, in which all of the electron spins are exactly balanced so that their net magnetic moment is zero. The molecules will still have a very, very tiny magnetic moment due to the nuclear magnetism, of the hydrogen nuclei. Suppose we put a single sample of water in a magnetic field B . Since the protons (of the hydrogen) have a spin of 1/2, they will have two possible energy states. If the water is in thermal equilibrium, there will be slightly more

protons in the lower energy states, with their moments directed parallel to the field. There is a small net magnetic moment per unit volume. Since the proton moment is only about one-thousandth of an atomic moment, the magnetization which goes as μ^2 —using Eq. (25.22)—is only about one-millionth as strong as liquid atomic paramagnetism. (That's why we have to pick a material with the same magnetism.) If you work it out, the difference between the number of protons with spin up and with spin down is only one part in 20%, so the effect is indeed very small! It can still be observed, however, in the following way.

Suppose we surround the water sample with a small coil that produces a small, horizontal oscillating magnetic field. If this field oscillates at the frequency ω_0 , i.e., will induce transitions between the two energy states just as we described for the Rabi experiment in Section 35-3. When a proton flips from an upper energy state to a lower one, it will give up the energy $\mu_0 B$ which, as we have seen, is equal to E_{sp} . That flip from the lower energy state to the upper one, it will absorb the energy $\mu_0 B$, leave the coil. Since there are slightly more protons in the lower state than in the upper one, there will be a net absorption of energy from the coil. Although the effect is very small, the signal energy absorbed can be even well measured by the right kind of filter.

Just as in the Rabi molecular-beam experiment, the energy absorption will be zero only when the oscillating field is in resonance, that is, when

$$\omega = \omega_0 = 2 \left(\frac{\gamma}{g \mu_0} \right) B$$

It is often more convenient to search for the resonance by varying B while keeping ω_0 fixed. The energy absorption will evidently appear when

$$B = \frac{g \mu_0 \omega}{0.6}$$

A typical nuclear magnetic resonance apparatus is shown in Fig. 35-8. A high-frequency oscillator drives a small coil placed just above the mass of a large electromagnet. Two small iron bars (yokes) around the pole tips are driven with a 60-cycle current so that the magnet has a "resonator" winding which carries about as a very short loop circuit. As a result, say that the main current of the magnet is set to give a field of 5000 gauss, and the auxiliary coils make a current of +1 gauss about this value. If the oscillator is set at 21.2 megacycles per second, it will tune to the proton resonance each time the field sweeps through 5000 gauss [using Eq. (34.13) with $g = 2.0$ for the proton].

The circuit of the oscillator is arranged to give an additional output signal proportional to any change in the power being absorbed from the oscillator. This signal is fed to the vertical deflection amplifier of an oscilloscope. The horizontal sweep of the oscilloscope is triggered once during each cycle of the field sweeping frequency. (More usually, the horizontal deflection is made to follow in proportion to the sweeping field.)

Before the water sample is placed inside the high-frequency coil, the power drawn from the oscillator is some value. (It doesn't change with the magnetic field.) When a small bottle of water is placed in the coil, however, a signal appears on the oscilloscope, as shown in the figure. We see a picture of the power being absorbed by the flipping over of the protons.

In practice, it is difficult to know how to set the main magnet to exactly 5000 gauss. What one does is to adjust the main magnet current until the resonance signal appears on the oscilloscope. It turns out that this is now the most convenient way to make an accurate measurement of the strength of a magnetic field. Of course, at some time someone had to measure accurately the magnetic field and therefore to determine the g -value of the proton. But now that this has been done, a coil-in-resonance apparatus has that of the figure can be used as a "precision magnetometer."

We should say a word about the shape of the signal. If we were to sweep the magnetic field very slowly, we would expect to see a normal resonance curve. The energy absorption would reach a maximum when ω_0 arrived exactly at the

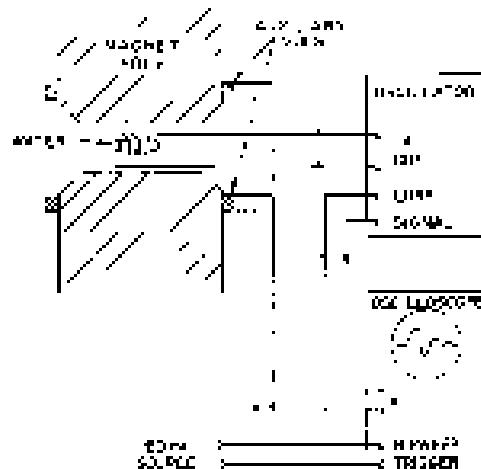

Fig. 35-8. A nuclear magnetic resonance apparatus.

oscillator frequency. There would be some absorption at nearby frequencies because all the protons are not in exactly the same field—and different fields mean slightly different resonant frequencies.

One might wonder, incidentally, whether at the resonance frequency we should see any signal at all. Shouldn't we expect the high-frequency field to equilibrate the populations of the two states—so that there should be no signal except, when the water is first put in?² No, exactly, because although we are trying to equilibrate the two populations, the thermal motions of their part are trying to keep the proton ratios the same temperature T . If we sit at the resonance, the power being absorbed by the nuclei is just what is being lost to the thermal motions. This is, however, relatively little “torsional motion” between the motion magnetic moments and proton positions. The protons are relatively localized down in the center of the electron distributions. So, in pure water, the resonance signal is, in fact, usually too small to be seen. To increase the absorption, it is necessary to increase the “precessing magnet.” This is usually done by adding salt to the water. The ions provide like small magnets; as they precess around in their local fields, they make tiny precessing magnetic fields of their own. These varying fields “couple” the proton magnets to the salt so strongly and long that equilibrium does not establish itself. It is through this “coupling,” that protons in the higher energy states can lose their charge so that they are again capable of absorbing energy from the oscillator.

To practice the共振 signal of a nuclear resonance apparatus does not look like a normal resonance curve. It is usually a more complicated signal with oscillations like the one drawn in the figure. Such signal shapes appear because of the changing fields. The explanation should be given in terms of quantum mechanics, but it can be shown that in such experiments the classical ideas of precessing momenta always give the correct answer. Classically, we would say that when we arrive at resonance we start driving a lot of the precessing nuclear magnets synchronously. In so doing, we make them precess together. These nuclear magnets, all rotating together, will set up an induced emf in the oscillator coil at the frequency ω_0 . But because the magnetic field is increasing with time, the precession frequency is increasing also, and the induced voltage is soon at a frequency a little higher than the oscillator frequency. As the induced emf goes alternately in phase and out of phase with the oscillator, the “absorbed” power goes alternately positive and negative. So on the oscilloscope we see the beat note between the precess frequency and the oscillator frequency. Because the proton frequencies are not all identical (different protons are in slightly different fields) and also possibly because of the disturbance of ions that come into the water, the steady precession increases from jet out of phase, and the beat signal disappears.

These phenomena of nuclear resonance have been put to use in many ways as does the living cell does. Little about matter—especially in electricity and nuclear physics. It goes without saying that the numerical values of the magnetic moments of nuclei tell us something about their structure. In particular, much has been learned from the studies of the shifts of the resonances. Because of the static fields produced by nearby nuclei, the exact position of a nuclear resonance is shifted somewhat, depending on the environment in which any particular nucleus finds itself. Measuring these shifts helps determine which atoms are near which other ones and helps to elucidate the details of the structure of molecules. Equally important is the electron spin resonance of free radicals. Although not present to any very large extent in equilibrium, such radicals are often intermediate states of chemical reactions. A measurement of an electron spin resonance is a delicate test for the presence of free radicals and is often the key to understanding the mechanism of certain chemical reactions.

Paramagnetism

36-1 Magnetization currents

In this chapter we will discuss some materials in which the net magnetization, \mathbf{M} , is much greater than in the case of paramagnetism or diamagnetism. The phenomenon is called *ferromagnetism*. In paramagnetic and diamagnetic materials the induced magnetic moments are usually so weak that we don't have to worry about the additional fields produced by the magnetic moments. For ferromagnetic materials, however, the magnetic moments induced by applied magnetic fields are quite enormous and have a great effect on the fields themselves. In fact, the induced moments are so strong that they are often the dominant effect on producing the observed fields. So one of the things we will have to worry about is the mathematical theory of large induced magnetic moments. That is, of course, just a technical question. The real problem is, why are the magnetic moments so strong—how does it all work? We will come to that question in a little while.

Induce the magnetic fields of ferromagnetic materials is something like the problem of finding the electrostatic field in the presence of dipoles. You will remember that we first described the internal properties of a dielectric in terms of a vector field, \mathbf{P} , the dipole moment per unit volume. Then we figured out that the effects of this polarization are equivalent to a charge density ρ_{pol} given by the expression of P :

$$\rho_{pol} = -\nabla \cdot \mathbf{P}. \quad (36.1)$$

The total charge in any situation can be written as the sum of this polarization charge plus all other charges, whose density we write⁴ ρ_{total} . Then the Maxwell equation which relates the divergence of E to the charge density becomes

$$\nabla \cdot E = \frac{\rho}{\epsilon_0} = \frac{\rho_{total} + \rho_{pol}}{\epsilon_0},$$

or

$$\nabla \cdot E = -\frac{\nabla \cdot P}{\epsilon_0} + \frac{\rho_{total}}{\epsilon_0}.$$

We can then pull out the polarization part of the charge and put it on the other side of the equation, to get the new law

$$\nabla \cdot (\epsilon_0 E + \mathbf{P}) = \rho_{total}. \quad (36.2)$$

The new law says the divergence of the quantity $(\epsilon_0 E + \mathbf{P})$ is equal to the density of the other charges.

Moving E and P together as in Eq. (36.2), of course, is useful only if we know some relation between them. We have seen that the theory which relates the induced electric dipole moment to the field was a relatively complicated business and can easily only be applied to certain simple situations, and even then as an approximation. We would like to use in your of one of the approximations we used. To find the induced dipole moment of an atom inside a dielectric, it is necessary to know the electric field that acts on an individual atom. We made the approximation—which is true for bar in many cases—that the field on the atom

surfaces

⁴ If all of the "other" charges were on conductors, ρ_{total} would be the same as our ρ of Chapter 10.

so the source of a would be at the center of the small hole which would be left if we took out the atom (keeping the dipole moments of all the neighboring atoms the same). You will also remember that the electric field in a hole in a polarized crystal depends on the shape of the hole. We summarize our earlier results in Fig. 36.1. For a thin, disc-shaped hole perpendicular to the polarization, the electric field in the hole is given by

$$E_{\text{hole}} = E_{\text{exterior}} + \frac{P}{\epsilon_0},$$

which we showed by using Gauss' law. On the other hand, in a needle-shaped slot parallel to the polarization, we showed—by using the fact that the end of \mathbf{A} is zero—that the electric fields inside and outside of the slot are the same. Finally, we found that for a spherical hole the electric field was one-third of the way between the field of the slot and the field of the cavity.

$$E_{\text{hole}} = E_{\text{exterior}} + \frac{1}{3} \frac{P}{\epsilon_0} \text{ (spherical hole)} \quad (36.3)$$

This was the field we used in thinking about what happens in an atom inside a polarized dielectric.

Now we have to discuss the analog of all this for the case of magnetism. The simplest, easiest way of doing this is to say the M , the magnetic moment per unit volume, is just like P , the electric dipole moment per unit volume, and that, therefore, the negative of the divergence of \mathbf{M} is equivalent to a "magnetic charge density" ρ_m , whatever that may mean. The trouble is, of course, that there is no such thing as a "magnetic charge" in the physical world. As we know, the divergence of \mathbf{B} is always zero. Far that does not stop us from making an artificial entity and writing

$$\nabla \cdot \mathbf{M} = -\rho_m \quad (36.4)$$

where it is to be understood that ρ_m is purely mathematical. Then we could make a complete analogy with the electrostatic case and use all our old equations from electrodynamics. People have often done something like that. In fact, historically, people once believed that the analogy was right. They believed that the quantity ρ_m represented the density of "magnetic poles." These days, however, we know that the magnetization of materials comes from circulating currents in the atoms—either from the spinning electrons or from the motion of the electrons in the atom. J is therefore not even a physical point of view to describe things realistically in terms of the atomic currents rather than in terms of a density of some artificial "magnetic poles." Historically, these currents are sometimes called "Amperian" currents, because Ampere first suggested that the magnetism of matter came from circulating atomic currents.

The actual microscopic current density in an insulating material is, of course, very complicated. Its value depends on where you look in the atom—it's large at some places and small in others; it goes one way in one part of the atom and the opposite way in another part (just as the microscopic electric field varies enormously inside a dielectric). In many practical problems, however, we are interested only in the fields outside of the material or in the average magnetic field inside of the material. When we measure energy taken over time, many atoms. It is only for such macroscopic problems that it is convenient to drop the magnetic state of the matter in terms of M , the average dipole moment per unit volume. What we want to show now is that the atomic currents of magnetized matter can give rise to certain large-scale currents which are related to M .

What we are going to do, then, is to separate the current density j —which is the net source of the magnetic field—into various parts: one part to describe the individual currents of the atomic magnets, and the other parts to describe what other currents there may be. It is extremely convenient to separate the currents into three parts. In Chapter 32 we made a distinction between two concepts which few freely on conductors and the ones which lead one to the back side for the others

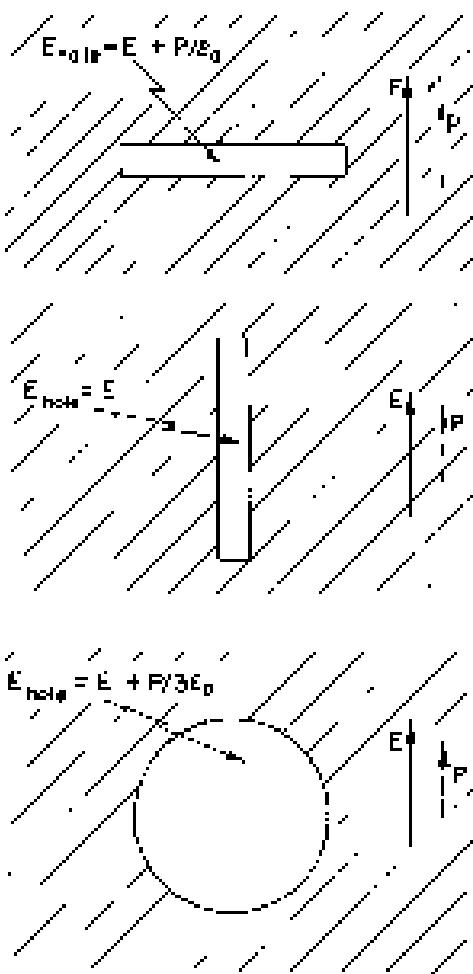

Fig. 36.1. The electric field in a cavity in a dielectric depends on the shape of the cavity.

of the bound charges in dielectrics. In Section 32-2 we wrote

$$\mathbf{j} = \mathbf{j}_{\text{ext}} - \mathbf{j}_{\text{bound}}$$

where \mathbf{j}_{ext} represented the currents from the motion of the bound charges in the electric field and $\mathbf{j}_{\text{bound}}$ took care of all other currents. Now we want to go further. We want to separate $\mathbf{j}_{\text{bound}}$ into one part, \mathbf{j}_{mag} , which describes the average currents inside of magnetized materials, and an additional term which we can call \mathbf{j}_{rest} for whatever is left over. The last term will generally refer to currents in conductors, but it may also include other currents. For example, the currents from charges moving freely through empty space. So we will write for the total current density:

$$\mathbf{j} = \mathbf{j}_{\text{ext}} - \mathbf{j}_{\text{mag}} - \mathbf{j}_{\text{rest}}. \quad (36.5)$$

Of course it is this total current which belongs in the Maxwell equation for the curl of \mathbf{B} :

$$\nabla^2 \mathbf{A} \times \mathbf{B} = \frac{\mathbf{j}}{\sigma} + \frac{\partial \mathbf{E}}{\partial t}. \quad (36.6)$$

Now we have to relate the current \mathbf{j}_{mag} to the magnetization vector \mathbf{M} . So that you can see where we are going, we will tell you that the result is going to be that

$$\mathbf{j}_{\text{mag}} = \nabla \times \mathbf{M}. \quad (36.7)$$

If we are given the magnetization vector \mathbf{M} everywhere in a magnetic material, the circulation current density is given by the curl of \mathbf{M} . Let's see if we can understand why this is so.

First, let's take the case of a cylindrical rod which has a uniform magnetization parallel to its axis. Physically, we know that such a uniform magnetization really means a uniform density of atomic circulating currents everywhere inside the material. Suppose we try to imagine what the actual currents would look like in a cross section of the material. We would expect to see currents something like those shown in Fig. 36-2. Each atomic current goes around and around in a little circle, with all the circulating currents going around in the same direction. Now what is the effective current of such a thing? Well, in most of the bar there is no effect at all, because right next to each current there is another current going in the opposite direction. If we imagine a small surface—but one still quite a bit larger than a single atom—such as is indicated in Fig. 36-2 by the line \overline{AB} , the net current through such a surface is zero. There is no net current anywhere inside the material. Now, however, just at the surface of the ends of the bar there are atomic currents which are not canceled by neighboring currents going the other way. At the surfaces there is a net current always going in the same direction around the rod. Now you see why we say earlier that a uniformly magnetized rod requires a net current along its entire length.

How does this view fit with Eq. (36.7)? First, recall the material the magnetization \mathbf{M} is constant, so all derivatives are zero. It is represented in the geometric picture. At the surfaces, however, \mathbf{M} is not really constant—it is constant up to the edge and then suddenly collapses to zero. So, right at the surface there are terrific gradients which, according to (36.7), will give a big current density. Suppose we look at some barbers near the point C in Fig. 36-2. Taking the x - and y -directions as in the figure, the magnetization \mathbf{M} is in the z -direction. Writing out the components of Eq. (36.7), we have

$$\begin{aligned} \frac{\partial M_x}{\partial y} &= (j_{\text{mag}})_x \\ -\frac{\partial M_z}{\partial y} &= (j_{\text{mag}})_y. \end{aligned} \quad (36.8)$$

At the point C, the derivative $\partial M_x / \partial y$ is zero, but $\partial M_z / \partial y$ is large and positive. Equation (36.8) says that there is a large current density in the x -direction. This agrees with our picture of a surface current going around the bar.

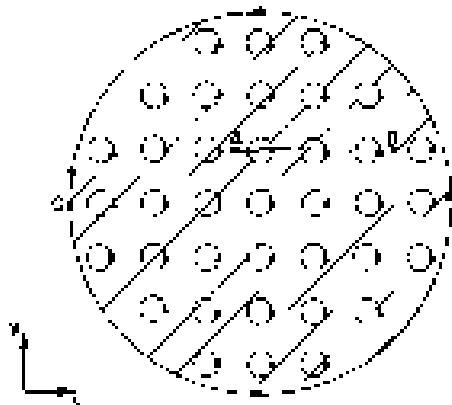

Fig. 36-2. Schematic diagram of the circulating atomic currents as seen in a cross section of an iron rod magnetized in the z -direction.

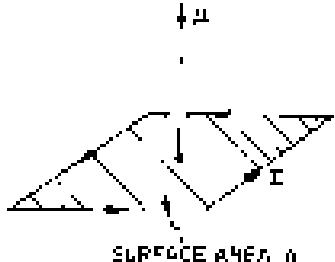

Fig. 36-3. The dipole moment μ of a current loop is IA .

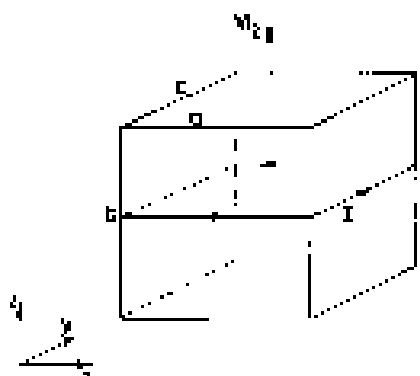

Fig. 36-4. A small magnetized block is equivalent to a circulating surface current.

Fig. 36-5. If the magnetization of two neighbouring blocks is not the same, there is a net surface current between them.

Now we want to find the current density for a more complicated case in which the magnetization varies from point to point in a material. It is easy to see qualitatively that if the magnetization is different in two neighbouring regions, there will not be a perfect cancellation of the circulating currents so that there will be a net current in the volume of the material. It is this effect that we want to work out quantitatively.

First, we need to recall the results of Section 14-5 that a circulating current I has a magnetic moment given by

$$\mu = IA, \quad (36-9)$$

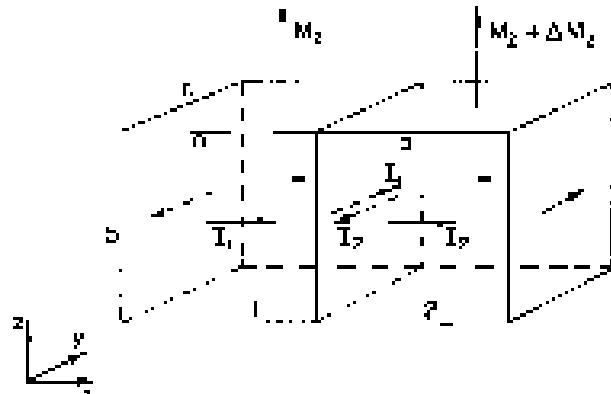

where A is the area of the current loop (see Eq. 36-5). Now let's consider a small rectangular block made of the magnetized material as sketched in Fig. 36-4. We take the block as small that we can consider that the magnetization is uniform inside it. If this block has a magnetization M_2 , in the z-direction, the net effect will be the same as a uniform vertical going around the vertical faces, as shown. We can find the net current off these surfaces from Eq. (36-9). The total magnetic moment of the block is equal to the magnetization times the volume:

$$\mu = M_2 b d b,$$

from which we get (remembering that the area of the loop is bd)

$$I = M_2 b.$$

In other words, the current per unit length (vertically) on each of the vertical surfaces is equal to M_2 .

Now suppose that we insert two such little slabs of size $a \times b \times d$, as shown in Fig. 36-5. Because block 2 is slightly displaced from block 1, i.e., will have a slightly different vertical component of magnetization, which we call $\Delta M_2 = \partial M_2 / \partial x$. Now on the surface between the two blocks there will be two contributions to the total current. Block 1 will produce a current I_1 flowing in the positive y -direction, and block 2 will produce a current I_2 flowing in the negative y -direction. The total surface current on the positive y -direction is the sum:

$$I = I_1 - I_2 = M_1 b - (M_2 + \Delta M_2)b \\ = -\Delta M_2 b.$$

We can write ΔM_2 as the derivative of M_2 in the x -direction to get the displacement from block 1 to block 2, which is, say, σ ,

$$\Delta M_2 = \frac{\partial M_2}{\partial x} \sigma.$$

The current flowing between the two blocks is then

$$I = -\frac{\partial M_2}{\partial x} b \sigma.$$

To relate the current J to our average volume current density \bar{J} , we must realize that the current J is really spread over a certain cross-sectional area. If we imagine the whole volume of the material to be filled with such little blocks, one such side face (perpendicular to the x -axis) can be associated with each block.⁷ Then we see that the area to be associated with the current J is just the area a_2 of one of the front faces. We get the result:

$$\bar{J}_x = \frac{J}{a_2} = -\frac{\partial M_x}{\partial x}.$$

We have at least the beginning of the curl of M .

There should be another term in \bar{J}_y from the variation of the x -component of the magnetization M_x . This contribution to \bar{J}_y will come from the surface between two little blocks stacked one on top of the other, as shown in Fig. 36-6. Using the same arguments we have just made, you can show that this surface will contribute to \bar{J}_y the amount $\partial M_y/\partial x$. These are the only surfaces which contribute to the y -component of the current so we have that the total current density in the y -direction is

$$\bar{J}_y = \frac{\partial M_x}{\partial z} = \frac{\partial M_z}{\partial x}.$$

Working out the currents on the remaining faces of a cube, or using the fact that our z -direction is completely arbitrary, we can conclude that the vector current density is indeed given by the equation

$$\bar{j} = \nabla \times M.$$

So if we choose to describe the magnetic situation in matter in terms of the average magnetic moment per unit volume M , we find that the circulating electric currents are equivalent to an average current density in matter given by Eq. (36.10). If the material is also a dielectric, there may be, in addition, a polarization current $j_{pol} = \partial P/\partial t$. And if the material is also a conductor, we may have a conductive current j_{cond} as well. We can write the total current as

$$\bar{j} = j_{pol} + \nabla \times M + \frac{\partial P}{\partial t}. \quad (36.10)$$

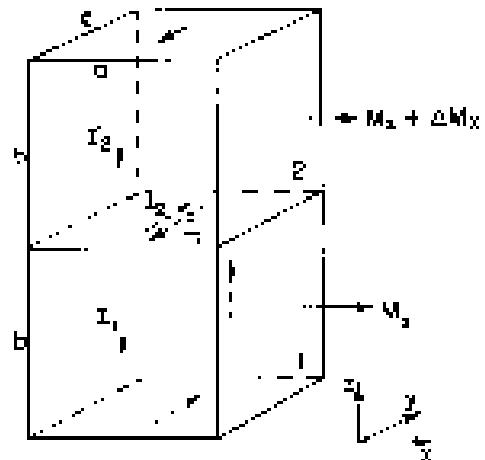

Fig. 36-6. Two blocks, one above the other, may also contribute to \bar{j}_y .

36-2 The field H

Next, we want to insert the current as written in Eq. (36.10) into Maxwell's equations. We get

$$c^2 \nabla \times B = \frac{i}{\epsilon_0} + \frac{\partial E}{\partial t} - \frac{1}{\epsilon_0} \left(j_{pol} + \nabla \times M + \frac{\partial P}{\partial t} \right) - \frac{\partial E}{\partial z}.$$

We can move the term in ΔM to the left-hand side:

$$c^2 \nabla \times \left(B - \frac{M}{\epsilon_0 c^2} \right) = j_{pol} - \frac{i}{\epsilon_0} - \frac{1}{\epsilon_0} \left(E + \frac{P}{c^2} \right). \quad (36.11)$$

As we remarked in Chapter 33, many people like to write $(E - P/c^2)$ as a new vector field B/c^2 . Similarly, it is often convenient to write $(B - M/\epsilon_0 c^2)$ as a single vector field. We choose to define a new vector field H by

$$H = B - \frac{M}{\epsilon_0 c^2}. \quad (36.12)$$

Then Eq. (36.11) becomes

$$c^2 \nabla \times H = j_{pol} - \frac{i}{\epsilon_0}. \quad (36.13)$$

It looks simpler, but all the complexity is just hidden in the letters B and H .

⁷ Or, if you prefer, the current J in each face should be split 50-50 with the blocks on the two sides.

Now we have to give you a warning. Most people who use the mks units have chosen to use a different definition of H . Calling their field H' (Oe , mT , etc.), they still call it H without the prime. It is defined by

$$H' = \mu_0 H = M. \quad (36.14)$$

(Also, they usually write μ_0^{-1} as a pure number 1/4π; then they have one more constant to keep track of!) With this definition, Eq. (36.13) looks even simpler:

$$\nabla \times H' = J_{\text{ext}} + \frac{\partial M}{\partial t}. \quad (36.15)$$

But the difficulties with this definition of H' are, first, that it doesn't agree with the convention of people who don't use the mks system, and second, that it makes H' and B have different units. We think it is more appropriate if H and B have the same units as \mathbf{B} —namely, the units of M , as H' does. But I guess it's going to be an ingrained idea for a week or two. (A dozen? transistors, resistors, and such, yes?) We have to watch out. You will find many books which use the H definition of Eq. (36.1)—rather than our definition of Eq. (36.13), and many other books—especially handbooks of magnetic materials—that use B and H the way we have done. You'll have to be careful to figure out which convention they are using.

One way to tell is by the unit of \mathbf{B} . Remember that in the mks system, B has the same dimensions as the unit of flux: one weber per square meter, equal to 10^8 gauss. In the oersted system, a magnetic moment (a current times an area) is called the "ampere-meter". The unit magnetization M , then, has the units coulombs per meter. But H' (in oersts) has the same units as \mathbf{B} . You can see that this also agrees with Eq. (36.13), since $\nabla \times \mathbf{B}$ (which is of one over length) has the same units as H' (in oersts). People who use the H with B definition often complain about the "unit of H " (with the H definition) being "webers/meter per meter"—thinking of the unit of flux density as a weber/meter. But a "web" is really a dimensionless number, so that doesn't mean much to you. Since our H is equal to H' , erg/cm^2 , if you are using the oersted system, H (in webers/meter²) is equivalent to $4\pi \times 10^{-4}$ times H' (in ampères per meter). It is perhaps more convenient to remember that H (in gauss) = 10^4 times H' (in oersts).

There is one more horrible thing. Many people who use our definition of H have decided to call the ratio of H and B by different names! Even though they have the same dimensions, they call the ratio of H to B "gauss" and the ratio of H to B "oersted" (after Gauss and Oersted, of course). So, in many books you will find graphs with H plotted in gauss and B in oersts. They are really the same unit— 10^{-4} of the mks unit! We have summarized the conversions about magnetic units in Table 36-1.

36-1 The magnetization curve

Now we will look at some simple situations in which the magnetic field is constant, or in which the light charge slowly enough that we can neglect $\partial B/\partial t$ in comparison with j_{ext} . Then the fields obey the equations

$$\nabla \cdot \mathbf{B} = 0, \quad (36.16)$$

$$\nabla \times \mathbf{H} = J_{\text{ext}}/\mu_0 \epsilon_0, \quad (36.17)$$

$$\mathbf{H} \cdot \mathbf{B} = M/\mu_0 \epsilon_0. \quad (36.18)$$

Suppose we have a torus (a donut) of iron wrapped with a coil of copper wire, as shown in Fig. 36-7(a). A current I flows in the wire. What is the magnetic field? The magnetic field will be mainly inside the iron; there, the law of \mathbf{B} will be valid, as shown in Fig. 36-7(b). Since the law of \mathbf{B} is continuous, its divergence is zero, and Eq. (36.16) is satisfied. Next, we write Eq. (36.17) in another form by 16-8

integrating around the closed loop Γ drawn in Fig. 36-7(b). From Stokes's theorem, we have thus

$$\oint \mathbf{B} \cdot d\mathbf{s} = \frac{1}{\epsilon_0 c^2} \int_S J_{\text{wind}} \cdot \mathbf{n} d\mathbf{a}, \quad (36-29)$$

where the integral of J is to be carried out over any surface S bounded by Γ . This surface is cut once by each turn of the winding. Each turn contributes the current I to the integral, and, if there are N turns in all, the integral is NI . From the symmetry of our problem, B is the same all around the curve Γ ; if we assumed that the magnetization were uniform, the field B is also constant along Γ . Eq. (36-19) becomes

$$NI = \frac{NI}{\mu_0 c^2} \cdot$$

where l is the length of the curve Γ . So,

$$B = \frac{NI}{\epsilon_0 c^2 l}. \quad (36-30)$$

This is because B is directly proportional to the magnetizing current, at least like this one that B is sometimes called the *magnetizing field*.

Now all we need is an equation which relates NI to B . But there isn't any such equation! There is, of course, Eq. (36-18), but it is no help because there is no direct relation between M and B for a ferromagnetic material like iron. The magnetization M depends on the whole past history of the iron, and not only on what B is at the moment.

All is not lost, though. We can get solutions in certain simple cases. If we start you with unity-gauge iron—let's say well iron that has been annealed at high temperature. Then in the simple geometry of the torus, all the iron will have the same magnetic history. Then we can say something about M , and therefore about the relation between B and H , from experiments measurements. The field B in the torus is, from Eq. (36-29), given as a constant times the current I in the winding. The field B can be measured by integrating over time the emf in the coil (or in an extra coil wound over the magnetizing coil shown in the figure). This emf is equal to the rate of change of the flux of B , so the integral of the emf with time is equal to B times the cross-sectional area of the torus.

Figure 36-8 shows the relation between B and H , observer with a torus of soft iron. When the current is first turned on, B increases with increasing H along the curve a . Note the different scales on B and H : initially, it takes only a relatively small H to make a large B . Why is B so much larger with the iron than it would be with air? Because there is a large magnetization M which is equivalent to a large surface current on the iron—the field B comes from the sum of this current and the conduction current in the winding. Why M should be so large, we will discuss later.

At higher values of H , the magnetization curve levels off. We say that the iron saturates. With the scales of our figure, the curve appears to become horizontal. Actually, it continues to rise slightly. For large fields, B becomes proportional to H , and with a unit slope. There is no further increase of M . Incidentally, we should point out that if the torus were made of some diamagnetic material, M would be zero and B would equal H for all fields.

The first thing we notice is that curve a on Fig. 36-8—which is the so-called *magnetization curve*—is highly nonlinear. But it's worse than that. When reaching saturation, we decrease the current in the coil to bring H back to zero, the magnetic field B falls along curve b . When H is zero, there is still some B left. Even with no magnetizing current there is a magnetic field in the iron. It has become permanently magnetized. If we now turn on a negative current in the coil, the B - H curve continues along b until the coil is saturated in the negative direction. If we then bring the current back to zero again, B goes along curve c . If we alternate the current between large positive and negative values, the B - H curve goes back and forth along very nearly the curves b and c . If we vary H in some arbitrary

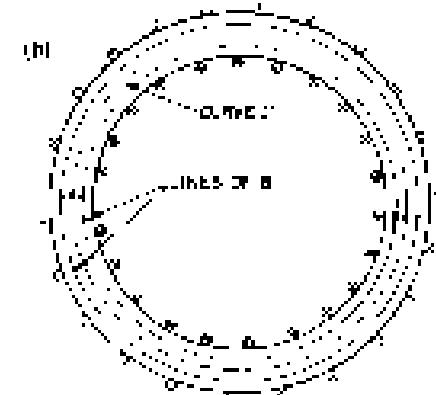

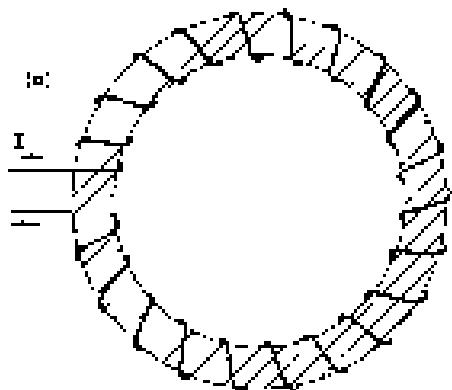

Fig. 36-7. (a) A torus of iron wound with a coil of insulated wire. (b) Cross section of torus showing field lines.

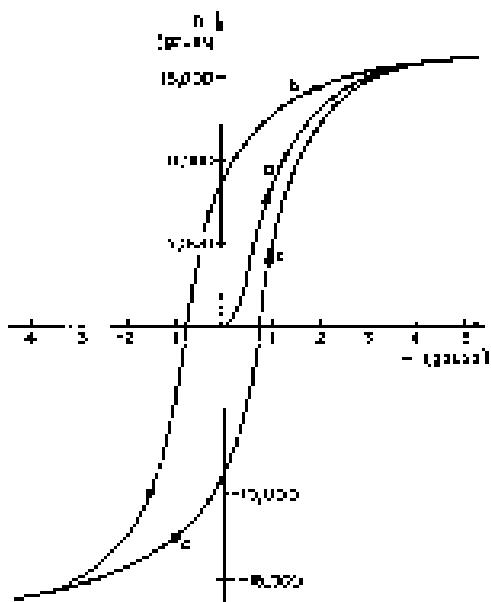

Fig. 36-8. Typical magnetization and hysteresis curve for soft iron.

way. However, we can get more complicated curves which will, in general, lie somewhere between the curves b and c . The loop made by repeated oscillation of the field B is called a hysteresis loop or hysteresis.

We see from this that we cannot write a functional relationship like $B = f(H)$, because the value of B at any instant depends not only on what H is at that time, but on its whole past history. Naturally, the magnetization and hysteresis curves are different for different substances. The shape of the curves depends critically on the elemental composition of the material, and also on the details of its preparation and subsequent physical treatments. We will discuss some of the physical implications of these complications in the next chapter.

36-4 Iron-core inductances

One of the most important applications of magnetic materials is in electrical circuits—for example, in transformers, electric motors, and so on. The reason is that with iron we can control where the magnetic fields go, and also get much larger fields for a given electric current. For example, the typical “toroidal” inductance is made very much like the object shown in Fig. 36-7—but a given inductance, it can be much smaller in volume and use much less copper if it has an equivalent “air-core” inductance. But a point of interest: we get a much greater resistance in the winding, so the inductor is usually very “leaky”—particularly for low frequencies. It is very easy to understand qualitatively how such an inductance works. If I is the current in the winding, then the field B which is produced in the iron is proportional to I , as given by Eq. (36.20). The voltage V across the terminals is related to the magnetic field B . Neglecting the resistance of the winding, the voltage V is proportional to dV/dB . The inductance L , which is the ratio of V to dI/dt (see Section 17-2), thus involves the relation between B and I in the iron. Since the B is so much bigger than the I , we get a large factor in the inductance. Physically, what happens is that a small current in the coil, which would normally produce a small magnetic field, causes the little “Weiss” magnets in the iron to line up and produce a tremendously greater “magnetic” current than the external current in the winding. It is as if we had a lot more current going through the coil than we really have. When we reverse the current, all the little magnets flip over—all those internal currents reverse—and we get a much bigger induced emf than we would get without the iron. If we want to calculate the inductance, we can do so through the energy—as described in Section 17-8. The rate s , which energy is delivered from the current source is I^2L . The voltage V is the cross-sectional area A of the core times N times dV/dB . From Eq. (36.20), $L = \mu_0 A^2/NH$. So we have

$$\frac{dU}{dt} = V^2 = (\mu_0 A^2/N) H \frac{dH}{dt}.$$

Integrating over time, we have

$$U = (\mu_0 A^2/N) \int B dH. \quad (36.21)$$

Notice that $\int B dH$ is the volume of the iron; we will soon show that the energy density $\omega = U/VN$ in a magnetic material is given by

$$\omega = \mu_0 A^2 \int B dH. \quad (36.22)$$

An interesting feature is noticed here. When we use alternating currents, the iron is driven around a hysteresis loop. Since B is not a single-valued function of H , the integral of $\int B dH$ around one complete cycle is not equal to zero. It is the same audience inside the hysteresis curve. Thus, the driving source delivers a certain net energy each cycle—an energy proportional to the area inside the hysteresis loop. And that energy is “lost.” It is lost from the electromagnetic energy or, put this up to Law of Conservation, it is called the hysteresis loss. To keep such energy losses small, we would like the hysteresis loop to be as narrow as

possible. One way to decrease the area of the loop is to reduce the maximum field that is reached during each cycle. For smaller maximum fields, we get a hysteresis curve like the one shown in Fig. 36-9. Also, special materials are designed to have a very narrow loop. The so-called "transformer iron"—which are iron alloys with a small amount of silicon—have been developed to have this property.

When an inductor is run over a small hysteresis loop, the relationships between B and H can be approximated by a linear equation. People usually write

$$B = \mu_0 H \quad (36.23)$$

The constant μ is *not* the magnetic moment we have used before. It is called the *permeability* of the iron. (It is also sometimes called the "relative permeability.") The permeability of ordinary iron is typically several thousand. Transformer iron always has a "superconducting" which has permeabilities as high as a million.

If we use the approximation that $B = \mu_0 H$ in Eq. (36.21), we can write the energy in A toroidal inductors as

$$U = \left(\epsilon_0 c^2 M\right) \mu \int B dH = (\epsilon_0 c^2 / 4) \frac{\mu H^2}{2}. \quad (36.24)$$

So the energy density is approximately

$$\epsilon = \frac{\epsilon_0 c^2}{2} \mu H^2.$$

We can now set the energy of Eq. (36.24) equal to the energy $I^2/2$ of an inductance, and solve for I . We get

$$I = \left(\epsilon_0 c^2 / 4\right) \mu \left(\frac{H}{J}\right)^2$$

Using H/J from Eq. (36.20), we have

$$I = \frac{\mu M^2 A}{\epsilon_0 c^2 J}. \quad (36.25)$$

The inductance is proportional to μ . If you want inductances for such things as audio amplifiers, you will try to operate them on a hysteresis loop where the B - H relationship is as linear as possible. (You will remember that we spoke in Chapter 30, Vol. I, about the generation of harmonics in nonlinear systems.) For such purposes, Eq. (36.24) is a useful approximation. On the other hand, if you want to generate harmonics, you may use an inductance which is intentionally operated in a highly nonlinear way. Then you will have to use the complete B - H curves, and analyze wave shapes by graphical or numerical methods.

A "transformer" is often made by putting two coils on the same core—or core—of a magnetic material. (For the larger "transformers, the core is made with laminations for convenience.) Then a varying current in the "primary" winding causes the magnetic field in the core to change, which induces an emf in the "secondary" winding. Since the flux through each turn of both windings is the same, the emfs in the two windings are in the same ratio as the number of turns on each. A voltage applied to the primary is transformed to a different voltage at the secondary. Since a certain net current around the core is needed to produce the required change in the magnetic field, the algebraic sum of the currents in the two windings will be fixed and equal to the required "magnetizing" current. If the current drawn from the secondary increases, the primary current must increase in proportion—there is a "transformation" of currents as well as voltage.

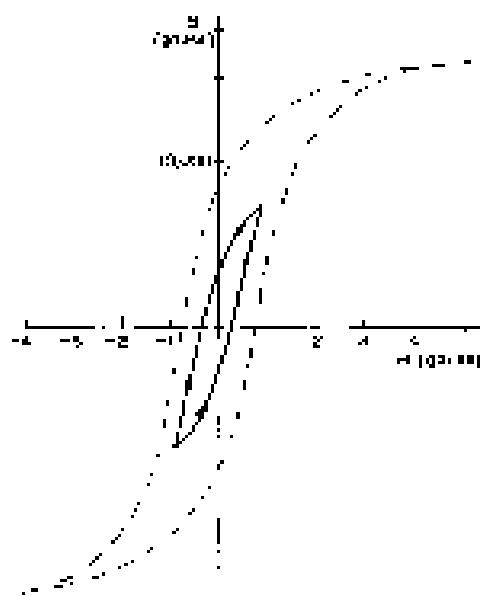

Fig. 36-9. A hysteresis loop that doesn't reach saturation.

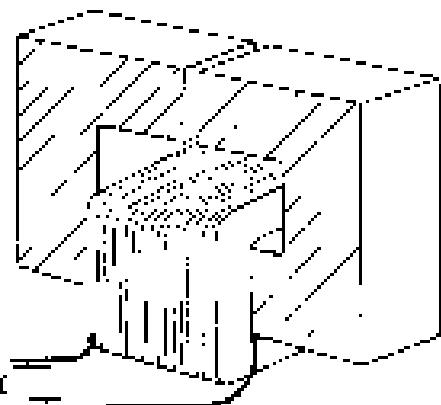

Fig. 36-10. An electromagnet.

36-3 Electromagnets

Now let's discuss a practical situation which is a little more complicated. Suppose we have an electromagnet of the rather standard form shown in Fig. 36-10—there is a "C-shaped" yoke of iron, with a slot or "air gap" in the center. What is the magnetic field B in the gap?

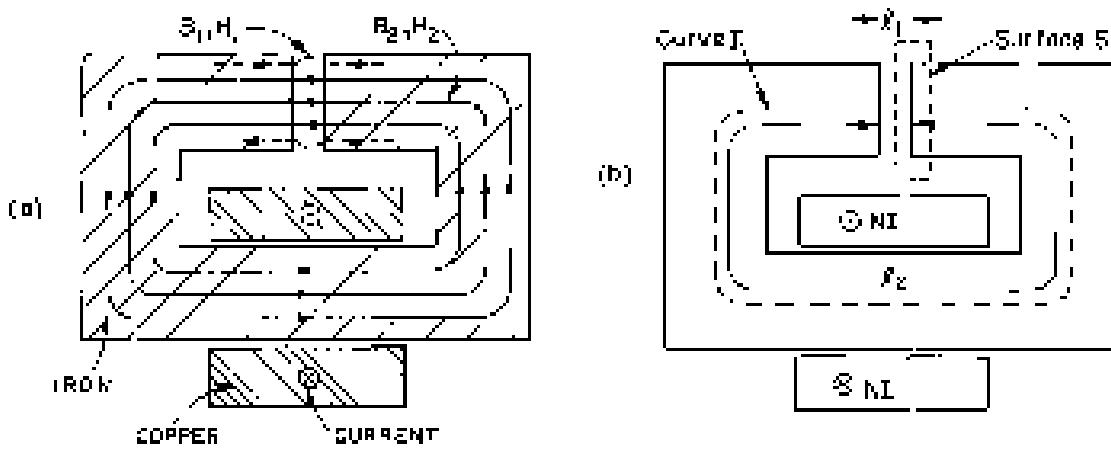

Fig. 36-11. Cross section of an electromagnet.

If the gap thickness is small compared with all the other dimensions, we can, as a first approximation, assume that the lines of \mathbf{B} will go around straight the loop, just as they did in the torus. They will look more or less as shown, in Fig. 36-11(a). They tend to spread out, somewhat in the gap, but if the gap is narrow, this will be a small effect. It is a fair approximation to assume that the flux of \mathbf{B} through any cross section of the yoke is a constant. If the yoke has a uniform cross-sectional area—and if we neglect any edge effects at the yoke ends—the current —we can, say. Let B be uniform across the yoke.

Also, B will have the same value in the gap. This follows from Eq. (36.6), because the closed surface S , shown in Fig. 36-11(b), which lies one face in the gap and the other in the iron. The total flux of \mathbf{B} out of this surface must be zero. Calling B_1 the field in the gap and B_2 the field in the iron, we have that

$$B_1 A_1 - B_2 A_2 = 0.$$

Since $A_1 = A_2$ (in our approximation), it follows that $B_1 = B_2$.

Now let's look at M . We can again use Eq. (36.19), taking the line integral around the curve J , in Fig. 36-11(b). As before, the right-hand side is MI , the number of turns times the current. Now, however, H will be different in the iron and in the air. Call the H_2 the field in the iron and H_1 the path length around the yoke, this part of the curve will contribute the amount $H_2 l_2$ to the integral. Calling H_1 the field in the gap and t the gap thickness, we get the contribution $H_1 l_1$ from the gap. We have that

$$H_1 l_1 + H_2 l_2 = \frac{\mu I}{\epsilon_0 A}. \quad (36.26)$$

Now we know something else: that in the air gap, the magnetization is negligible, so that $B = H$. Since $B_1 = B_2$, Eq. (36.26) becomes

$$B_2 l_2 + H_2 l_2 = \frac{M}{\epsilon_0 A}. \quad (36.27)$$

We still have two unknowns. To find B_2 and H_2 , we need another relationship between the one which relates B to H in the iron.

If we can make the approximation that $B_2 = \mu H_2$, we can solve this equation algebraically. However, let's do the graphical test, in which the magnetization curve of the iron is one like that shown in Fig. 36-3. What we want is the simultaneous solution of this functional relationship together with Eq. (36.27). We can find it by plotting a graph of Eq. (36.27) on the same graph with the magnetization curve, as is done in Fig. 36-12. Where the two curves intersect, we have our solution.

For a given current I , the function (36.27) is the straight line marked $f > 0$ in Fig. 36-12. This line intersects the H -axis ($B_2 = 0$) at $H_2 = M/\mu_0 \epsilon_0 A_2$, and the slope is $-\mu_0/\mu_1$. Different currents just shift the line horizontally. From Fig. 36-10

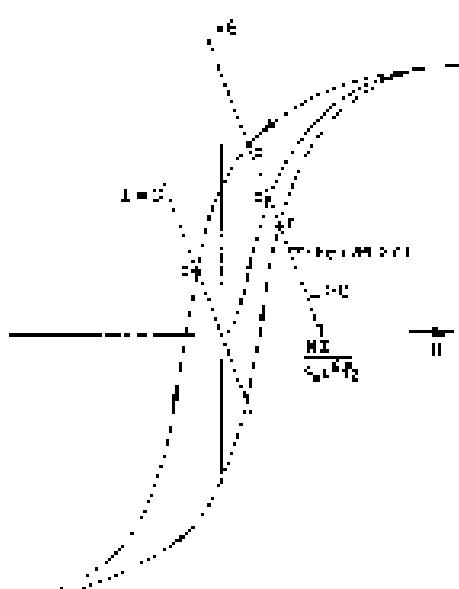

Fig. 36-12. Solving for the field in an electromagnet.

36-12, we see that for a given applied there are several different solutions, depending on how you put it in. If you have just made the magnet and turned the current up to I_1 , the field B_2 (which is also B_1) will have the value given by point *a*. If you increase the current to some very high value and come down to I_1 , the field will be given by point *b*. Or, if you have just had a high negative current in the magnet, and then come up to I_1 , the field is the one at point *c*. The field in the gap will depend on what you have done in the past.

When the current in the magnet is zero, the relation between M_1 and M_2 in Eq. (36.27) is shown by the blue marker ($I = 0$) in the figure. There are still various possible solutions. If you have first saturated the iron, there may be a considerable residual field in the magnet as given by point *d*. You can take the coil off, and you have a permanent magnet. You can see that for a good permanent magnet, you simply want a material with a wide hysteresis loop. Special alloys, such as Alnico V, give very wide loops.

36-6 Spontaneous magnetization

We now turn to the question of why it is that in ferromagnetic materials a small magnetic field produces such a large magnetization. The magnetization of ferromagnetic materials like iron and nickel comes from the magnetic moment of the electrons in the inner shell of the atom. Each electron has a magnetic moment μ equal to $e/2m$ times its v -factor, times its angular momentum J . For a single electron with no net orbital motion, $v = 2$, and the component of J in any direction—say the z -direction—is $-1/2$, so the component of μ along the z -axis is

$$\mu_z = \frac{e\hbar}{2m} = 0.923 \times 10^{-23} \text{ amp}\cdot\text{m}^2. \quad (36.28)$$

In an iron atom, there are actually two electrons that contribute to the ferromagnetism, so to keep the discussion simpler we will talk about nickel, which is ferromagnetic like iron but which has only one electron in the inner shell. It is easy to extend the arguments to iron.

Now the point is that, in the presence of an external field B , the atomic magnets tend to line up with the field, but are knocked about by thermal motions just as we described for paramagnetic materials. In the last chapter we found out that the balance between a magnetic field trying to line up the atomic magnets and the thermal motions tends to dominate their produce the result that the magnetization per unit volume will end up as

$$M = M_0 \tanh \frac{\mu B}{kT}. \quad (36.29)$$

By B_0 we mean the field acting at the atom, and kT is the Boltzmann energy. In the theory of paramagnetism we used for B_0 just B itself, neglecting the part of the field at any given atom contributed by the atoms nearby. In the ferromagnetic case, there is a complication. We shouldn't use the average field in the iron for the B_0 acting on an individual atom. Instead, we must do as we did in the case of dielectrics—we have to find the local field acting on a single atom. For an exact calculation we should add up the fields of the atoms in question contributed by all of the other atoms in the crystal lattice. But as we did for dielectrics, we will make the approximation that the field at a atom is the same as we would find in a small spherical hole in the material—assuming that the moments of the atoms in the neighborhood are not changed by the presence of the hole.

Following the arguments we made in Chapter 11, we might think that we could write

$$B_{\text{atom}} = M + \frac{1}{3} \frac{M}{r_{\text{sat}}}, \quad (\text{wrong}).$$

But that is not right. We can, however, make use of the results of Chapter 11 if we make a careful comparison of the equations of Chapter 11 with the April 30

for ferromagnetism in this chapter. Let's put together the corresponding equations. For regions where there are no conductive currents or charges we have:

Electrostatics Static ferromagnetism

$$\nabla \cdot \left(\mathbf{E} + \frac{\mathbf{P}}{\epsilon_0 c^2} \right) = 0 \quad \nabla \cdot \mathbf{B} = 0 \quad (36.10)$$

$$\nabla \times \mathbf{E} = 0 \quad \nabla \times \left(\mathbf{B} - \frac{\mathbf{M}}{\mu_0 c^2} \right) = 0$$

These two sets of equations can be thought of as analogies if we make the following purely *mathematical* correspondence:

$$\mathbf{E} \rightarrow \mathbf{B} - \frac{\mathbf{M}}{\mu_0 c^2}, \quad \mathbf{E} + \frac{\mathbf{P}}{\epsilon_0 c^2} \rightarrow \mathbf{B}.$$

This is the same as making the analogy

$$\mathbf{E} \rightarrow \mathbf{H}, \quad \mathbf{P} \rightarrow M/c^2. \quad (36.11)$$

In other words, if we write the equations of ferromagnetism as

$$\begin{aligned} \nabla \cdot \left(\mathbf{H} + \frac{\mathbf{M}}{\epsilon_0 c^2} \right) &= 0, \\ \nabla \times \mathbf{H} &= 0, \end{aligned} \quad (36.12)$$

they look like the equations of electrostatics.

This purely algebraic correspondence has led to some confusion in the past. Poynting tended to think that \mathbf{H} was "the magnetic field." But, as we have seen, \mathbf{B} and \mathbf{E} are physically the fundamental fields, and \mathbf{H} is a derived field. Although the equations are analogous, the physics is not analogous. However, that doesn't mean we stop us from using the principle that the same equations have the same solutions.

We can use our earlier results for the electric field inside of holes of various shapes in dielectrics—summarized in Fig. 36-1—to find the field \mathbf{H} inside of corresponding holes. Knowing \mathbf{H} , we can determine \mathbf{B} . For instance (using the results we summarized in Section 1), the field \mathbf{H} in a needle-shaped hole parallel to \mathbf{M} is the same as the \mathbf{E} in the material.

$$H_{\text{hole}} = H_{\text{material}}$$

But since M in the hole is zero, we have

$$H_{\text{hole}} = B_{\text{material}} = \frac{M}{\mu_0 c^2}. \quad (36.13)$$

On the other hand, for a disc-shaped hole, perpendicular to \mathbf{M} , we have

$$E_{\text{hole}} = E_{\text{material}} + \frac{P}{c},$$

which translates into

$$H_{\text{hole}} = B_{\text{material}} = \frac{M}{\mu_0 c^2}.$$

Or, in terms of B ,

$$B_{\text{hole}} = B_{\text{material}}. \quad (36.14)$$

Finally, for a spherical hole, by making our analogy with Eq. (36.3) we would have

$$H_{\text{hole}} = H_{\text{material}} + \frac{M}{\mu_0 c^2}$$

or

$$B_{\text{hole}} = B_{\text{material}} + \frac{2}{3} \frac{M}{\mu_0 c^2}. \quad (36.15)$$

This result is quite different from what we got for E .

It's, of course, possible to get these results in a more physical way, by using the Maxwell equations directly. For example, Eq. (36.34) follows directly from $\nabla \cdot \mathbf{B} = 0$. (You use a gaussian surface that is half in the material and half out.) Similarly, you can get Eq. (36.35) by using a line integral along a curve that goes up inside the hole and returns through the 'material'. Physically, the field in the hole is reduced because of the surface current, which are given by $\nabla \times \mathbf{M}$. We will leave it for you to show that Eq. (36.36) can also be obtained by considering the effects of the surface currents on the boundary of the spherical cavity.

In finding the equilibrium magnetization from Eq. (36.29), it turns out to be most convenient to deal with M , so write

$$B_0 = H + \lambda \frac{M}{kT}, \quad (36.37)$$

In the spherical hole approximation, we would have $\lambda = \beta$, but, as you will see, we will want later to use some other value, so we leave it as an adjustable parameter. Also, we will take all the fields in the same direction so that we won't need to worry about the vector directions. If we were now to substitute Eq. (36.36) into Eq. (36.29), we would have one equation that relates the magnetization M to the magnetizing field H :

$$\alpha x = \tanh \left(\frac{H - \lambda M_{sat}}{kT} \right).$$

It is, however, an equation that cannot be solved explicitly, so we will do it graphically.

Let's put the problem in a generalized form by writing Eq. (36.29) as

$$\frac{M}{M_{sat}} = \tanh x, \quad (36.38)$$

where M_{sat} is a constant value of the magnetization, namely, M_0 , and x represents $(H - \lambda M_{sat})/kT$. The dependence of M/H_{ext} on x is shown by curves in Fig. 36.13. We can also write x as a function of M using Eq. (36.36) for B_0 , as

$$x = \frac{\alpha B_0}{kT} = \frac{\alpha H}{kT} + \left(\frac{\alpha \lambda M_{sat}}{kT^2} \right) \frac{M}{M_{sat}}. \quad (36.39)$$

For any given value of H , this is a straight-line relationship between M/M_{sat} and x . The x -intercept is at $x = \alpha H/kT$, and the slope is $\alpha \lambda^2 T^2 / (\alpha \lambda kT) M_{sat}$. For any particular H , we would have a line like the one marked b in Fig. 36.13. The intersection of curves a and b gives us the solution for M/M_{sat} . We have solved the problem.

Let's look at how the solutions will go for various temperatures. We start with $H = 0$. There are two possible situations, x over or the lines b_1 and b_2 in Fig. 36.14. You will notice from Eq. (36.48) that the slope of the line is proportional to the absolute temperature T . So, at high temperatures we would have x below b_1 . The solution is $M/M_{sat} = 0$. When the magnetizing field H is zero, the magnetization is also zero. But, at low temperatures, we would have x like b_2 , and there are two solutions for M/M_{sat} , one with $M/M_{sat} = 0$ and one with $M/M_{sat} > 0$. It turns out that only the upper solution is stable, as you can see by doing a bit of calculations about these solutions.

According to these ideas, then, a magnetic material should magnetize itself spontaneously at sufficiently low temperatures. In short, when the thermal motions are small enough, the coupling between the atomic magnetic causes them all to line up parallel to each other, we have a permanently magnetized material analogous to the ferroelectrics we discussed in Chapter 11.

If we start at high temperatures and come down, there is a critical temperature, called the Curie temperature T_c , where the ferromagnetic behavior suddenly stops. This temperature corresponds to the line b_3 of Fig. 36.14, which is tangent to the curve a , and has, therefore, a slope of 1. The Curie temperature is given by

$$\frac{e\alpha kT_c}{\mu M_{sat}} = 1. \quad (36.40)$$

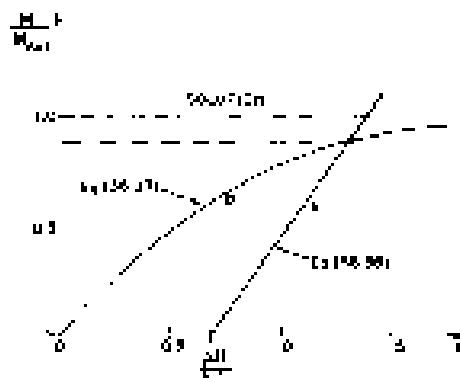

Fig. 36.12. A graphic solution of Eqs. (36.37) and (36.38).

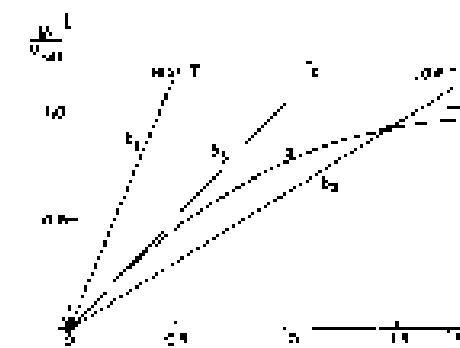

Fig. 36.14. Finding the magnetization when $H = 0$.

We can, if we wish, write Eq. (36.38) more simply in terms of T , as

$$\sigma \approx \frac{\mu H}{kT} + \frac{T_c}{T} \left(\frac{M}{M_{\text{sat}}} \right) \quad (36.40)$$

Now we want to see what happens for small magnetizing fields H . We can see from Fig. 36-4 how things will go if we shift our straight lines a little to the right. For the low-temperature case, the intersection point will move out a little since the low-slope part increases, and M will change relatively little. For the high-temperature case, however, the intersection point runs up the steep part of curve σ , and M will change relatively rapidly. In fact, we can approximate this part of curve σ by a straight line of unit slope, and write:

$$\frac{d\sigma}{dT} = 1 - \frac{\mu H}{kT} - \frac{T_c}{T} \left(\frac{M}{M_{\text{sat}}} \right)$$

Now we can solve for M/M_{sat} :

$$\frac{M}{M_{\text{sat}}} = \frac{kT}{k(T - T_c)} \cdot \frac{\mu H}{1 - \frac{\mu H}{kT}} \quad (36.41)$$

We have a law that is something like the one we had for paramagnetism. For unmagneation, we find

$$\frac{M}{M_{\text{sat}}} = \frac{\mu H}{kT} \quad (36.42)$$

One difference now is that we have the magnetization in terms of H , which includes some of the effects of the saturation of the atomic magnets, but the main difference is that the magnetization is inversely proportional to the difference between T and T_c , instead of to the absolute temperature T , above. Neglecting the interactions between neighboring atoms corresponds to taking $\lambda = 0$, which from Eq. (36.39) means taking $T_c = 0$. Then the results are just what we had in Chapter 35.

We can check our theoretical picture with the experimental data for nickel. It is observed empirically that the Curie-Weiss law above of M vs T disappears when its temperature is raised above 601°K. We can compare this with T_c calculated from Eq. (36.39). Remembering that $A_{\text{sat}} = \mu N$, we have

$$T_c = \frac{3}{N} \frac{A_{\text{sat}}^2}{k\mu_0^2}$$

From the density and atomic weight of nickel, we get

$$N = 9.3 \times 10^{28} \text{ m}^{-3}$$

Taking μ from Eq. (36.28), and setting $\lambda = \frac{1}{3}$, we get

$$T_c = 0.24^\circ\text{K}$$

There is a discrepancy of a factor of about 2600! Our theory of ferromagnetism fails completely.

We can try to "patch up" the theory as Weiss did, by saying that for some unknown reason λ is not one-third, but 2600 times it, or about 2000. It turns out that one gets similar values for other ferromagnetic materials like iron. To see what this means, let's go back to Eq. (36.36). We see that a large λ means that B_s , the local field on the atom, appears to be much, much larger than we would think. In fact, writing $H = B - M/\mu_0 r^2$, we have

$$B_s = B - \frac{(2 - 1)M}{\mu_0 r^2}$$

According to our original idea—with $\lambda = \frac{1}{3}$ —the local magnetization M reduces the effective field B_s by the amount $-4M/\mu_0 r^2$. Even if our model of a spherical hole were not very good, we would still expect some reduction. Instead, to explain

the phenomenon of ferromagnetism, we have to imagine that the magnetization of the field enhances the local field by some large factor—like one thousand or more. There doesn't seem to be any reasonable way to manufacture such enormous fields at an atom—or even likely of the proper sign! Clearly, our “magnetic” theory of ferromagnetism is a dream vision. We must conclude then, that ferromagnetism has to do with some antiferromagnetic interaction between the spinning electrons in neighboring atoms. This interaction must generate a strong tendency for all of the nearby spins to line up in one direction. We will see later that it has to do with quantum mechanics and the Pauli exclusion principle.

Finally, we look at what happens at low temperatures—see $T \ll T_c$. We have seen that there will then be a spontaneous magnetization—even with $H = 0$ —given by the intersection of the curves σ and b_2 of Fig. 36-14. If we solve for M for various temperatures—by varying the slope of the line b_2 —we get the theoretical curve shown in Fig. 36-15. This curve should be the same in all ferromagnetic materials for which the quantum moment consists of a single system. The curves for other materials are only slightly different.

In the limit as T goes to absolute zero, M goes to M_{sat} . As the temperature is increased, the magnetization decreases, falling to zero at the Curie temperature. The points in Fig. 36-16 are the experimental observations for nickel. They fit the theoretical curve quite well. Even though we don't understand the basic mechanism, the general features of the theory seem to be correct.

Finally, there is one more interesting discrepancy in our attempt to understand ferromagnetism. We have found that above some temperature the material should behave like a paramagnetic substance with a magnetization M proportional to H (or B), and that below that temperature it should become spontaneously magnetized. But that's not what we find when we measure the magnetization curves for iron, i.e., only because permanently magnetized after we had “magnetized” it. According to the ideas just discussed, it would demagnetize itself! What is wrong? Well, it turns out that if you look at a small enough piece of iron or nickel, i.e., a piece completely magnetized! But at large pieces of iron, there are many small regions or “domains” that are magnetized in different directions, so that on a large scale the average magnetization appears to be zero. In each small domain, however, the iron has a locked-in magnetization with M equal to M_{sat} . The consequences of this domain structure are that most properties of large pieces of material are quite different from the microscopic properties that we have really been treating. We will take up in the next lecture the story of the practical behavior of bulk magnetic materials.

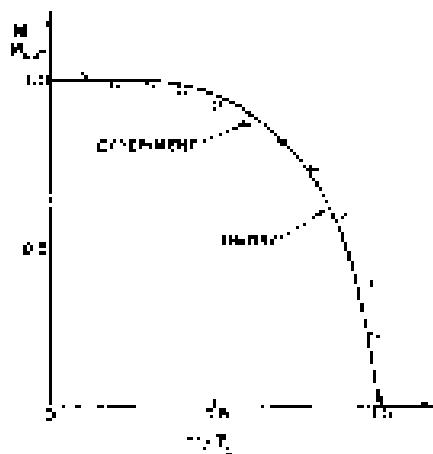

Fig. 36-15. Spontaneous magnetization as a function of temperature for nickel.

Magnetic Materials

37-1 Understanding Ferromagnetism

In this chapter we will discuss the behavior and peculiarities of ferromagnetic materials and of other strong magnetic materials. Before proceeding to study magnetic materials, however, we will review very quickly some of the things about the general theory of magnets that we learned in the last chapter.

First, we imagine the atomic currents inside the material that are responsible for the magnetism, and then describe them in terms of a volume current density $\mathbf{j}_{\text{vol}} = \mathbf{v} \times \mathbf{M}$. We emphasize that this is not supposed to represent the actual currents. When the magnetization is uniform the currents do not really cancel out precisely; that is, the whirling currents of one electron in one atom and the whirling currents of an electron in another atom do not overlap in such a way that the sum is exactly zero. Even within a single atom the distribution of magnetism is not smooth. For instance, in an iron atom the magnetization is distributed in a more or less spherical shell, not too close to the nucleus and not too far away. Thus, magnetism in matter is quite a complicated thing in its details; it is very irregular. However, we are obliged now to ignore this detailed complexity and discuss phenomena from a gross, average point of view. Then it is true that the average current in the interior region over any little area that is big compared with an atom is zero when $\mathbf{M} = 0$. So, what we mean by magnetism is not volume and long range, so on, at the tree, we are now concerning us an average over regions that are large enough just with the spins occupied by a single atom.

In the last chapter, we also discovered that a ferromagnetic material has the following interesting property: above a certain temperature it is not strongly magnetic, whereas below this temperature it becomes magnetic. This fact is easily demonstrated. A piece of nickel wire at room temperature is attracted by a magnet. However, if we heat it above its Curie temperature with a gas flame, it becomes non-magnetic; it is attracted toward the magnet—even when brought quite close to the magnet. If we cool the wire the magnet while it exceeds T_C , the instant its temperature falls below the critical temperature it is suddenly attracted again by the magnet!

The general theory of ferromagnetism [as we will see] supposes that the spin of the electron is responsible for the magnetization. The electron has spin (one-half the charge) and Bohr magneton ($1/2$ a quantum of magnetism) $\mu_B = e\tau = q\hbar/2m_e$. The electron spin can be pointed either "up" or "down." Because the electron has a negative charge, when its spin is "up" it has a negative moment, and when its spin is "down" it has a positive moment. With our usual conventions, the moment \mathbf{m} of the electron is opposite its spin. We have found that the energy of orientation of a magnetodipole in a given applied field \mathbf{B} is $-\mu \cdot \mathbf{B}$, and the energy of the spinning electron depends on the neighboring spin alignments as well. In iron, if the moment of a nearby atom is "up," there is a very strong tendency that the moment of the one next to it will also be "up." That is what makes iron, cobalt, and nickel so strongly magnetic—the moments all want to be parallel. The first question we have to discuss is why.

Soon after the development of quantum mechanics, it was noticed that there is a very strong quantum force—not a magnetic force or any other kind of normal force, but only an apparent force—trying to line the spins of nearby electrons opposite to one another. These forces are closely related to chemical valence forces. There is a principle in quantum mechanics called the exchange principle that

Kittel, C., *An Introduction to Solid State Physics*, John Wiley and Sons, Inc., New York, 2nd ed., 1956.

Two electrons cannot occupy exactly the same state, and they cannot be in exactly the same position as to location and spin orientation.² For example, if they are at the same point, the only alternative is to have their spins opposite. So, if there is a gap of space between atoms where electrons like to congregate (as in a chemical bond) and we want to put another electron on top of one already there, the only way to do it is to have the spin of the second one parallel opposite to the spin of the first one. To have the spins parallel is against the law, unless the electrons stay away from each other. This has the effect that a pair of parallel-spin electrons try to go in different directions away from a pair of oppo. in-spin electrons; the net effect is as though there were a force trying to turn the spin layer. Sometimes this spin-torsion force is called the exchange force, but that only makes it more mysterious, it is not a very good term. It is just, because of the exclusion principle, that electrons have a tendency to have their spins opposite. In fact, that is the explanation of the kind of magnetism in most solid substances! The spins of the free electrons and the moments of the nuclei have tremendous tendency to balance in opposite directions. The problem is to explain why for materials like iron, cobalt, etc., the forces of what we should expect.

We can summarize the proposed magnetic effect by adding a suitable term to the energy equation, by saying that if the electrons happen to be neighboring and have a given magnetization M , then the moment of an electron has a strong tendency to have the same orientation as the average magnetization of the atoms in the neighborhood. Thus, we may write for the two possible spin orientations:

$$\begin{aligned} \text{Spin "up" energy} &= E_0 \left(H + \frac{\lambda M}{\epsilon_0 c^2} \right), \\ \text{Spin "down" energy} &= -E_0 \left(H + \frac{\lambda M}{\epsilon_0 c^2} \right). \end{aligned} \quad (3.11)$$

When it was clear that quantum mechanics could supply a reasonable spin-orbit coupling, even if, apparently, of the wrong sign, it was suggested that ferromagnetism might arise in similar fashion, but due to the complexities of iron and the large number of electrons involved, the size of the coupling energy would come out the other way around. Since the time this was written off in 1937, some quantum mechanics was finally understood, many people have been working very seriously and successfully, trying to get the correct prediction for λ . The best calculations of the energy between the two electrons spins in iron, assuming that the interaction is a direct one between the two electrons in neighboring atoms, will give the wrong sign. The present understanding of this is again to assume that the complexity of the situation is somehow responsible and to hope that the perturbation which takes us into a more complicated situation will give the right answer!

It is believed that the energy of one valence electron in the neighborhood, which is making the magnetism come to pass, is completely electric in character, and the outside have the opposite spin. One might expect this to happen because the conduction electrons come into the same region as the "magnetic" electrons. Since they move around, they can carry their magnetism by being upside down over to the next atom; thus, the "magnetic" electron tries to force the conduction electrons to be opposite, and the conduction electron then makes the next "magnetic" electron opposite to it. The double interaction is a very similar to the interaction which tries to line up the two "magnetic" electrons. In other words, the tendency to make parallel spins is the result of no necessity that needs to cause either to be opposite to both. This mechanism does not require that the conduction electron be completely "upside down." They can do just about a slight angle to be enough, just enough to "tip" the "magnetic" atom the other way. Thus, if the magnetism is big

² See Chapter 13.

³ We write these equations with $H = B - \lambda M/c^2$, so that $\lambda M/c^2$ is added to the work of the last chapter. You might prefer to write $H = -\mu B - \mu(\lambda B + \lambda M/c^2)/c^2$, where $\lambda = 1 - 1/c^2$ for very things.

the people who have calculated such things now believe is responsible for ferromagnetism. But we must emphasize that to this day nobody can calculate the magnitude of α simply by knowing that the material is number 26 in the periodic table. In short, we don't thoroughly understand it.

Now let us continue with the theory, and then come back later to discuss a certain error involved in the way we have set it up. If the magnetic moment of a certain electron is "up," energy comes both from the external field and also from the tendency of the spins to be parallel. Since the energy is lower when the spins are parallel, the effect is sometimes described as due to an "effective internal field." But remember, i.e., is not due to a true magnetic force, it is an interaction that is more complicated. In any case, we use Eqs. (37.1) as the formulas for the energies of the two spin states of a "magnetic" electron. At a temperature T , the relative probability of these two states is proportional to $e^{-E/E}$, which we can write as $e^{-\beta E}$, with $\beta = \mu(H + 2M/k_B T)/k_B^2$. Then, if we continue the model so far all the magnetic moments, we find that in the last chapter that is

$$M = N_\text{A} \mu \tanh \beta. \quad (37.2)$$

Now we would like to calculate the internal energy of the material. We note that the energy of an electron is exactly proportional to the magnetic moment, so that the calculation of the mean moment and the calculation of the mean energy are the same—except that in place of μ in Eq. (37.2) we would write $-M\beta$, which is $-\mu(H + 2M/k_B T)^2/k_B^2$. The mean energy is then

$$\langle U \rangle_{\text{av}} = -N_\text{A} \left(H + \frac{M\beta}{k_B T} \right) \tanh \beta.$$

Now this is very queer! The term $M\beta/k_B T$ represents interactions of all possible pairs of atoms, and we must remember to count each pair only once. (When we calculate the energy of one electron in the field of the rest and then the energy of a second electron in the field of the rest, we have counted part of the Coulomb energy twice.) Thus, we must divide the *internal interaction term* by two, and our formula for the energy then turns out to be

$$\langle U \rangle_{\text{av}} = -N_\text{A} \left(H + \frac{M\beta}{2k_B T} \right) \tanh \beta. \quad (37.3)$$

In the last chapter we discovered an interesting thing—that below a certain temperature the material finds a solution to the equations in which the magnetic moment A is zero, even with no external magnetizing field. When we set $H = 0$ in Eq. (37.3), we found that

$$\frac{M}{M_{\text{sat}}} = \tanh \left(\frac{T_c}{T} \frac{M}{M_{\text{sat}}} \right). \quad (37.4)$$

where $M_{\text{sat}} = N_\text{A} \mu$ and $T_c = (2M_{\text{sat}}/\mu k_B)^{1/2}$. When we solve this equation (graphically or otherwise), we find that the ratio M/M_{sat} , as a function of T/T_c , is a curve like that labeled "quantum theory" in Fig. 37.1. The dashed curves marked "copper, nickel" show the experimental results for crystals of these elements. The theory and experiment are in moderately good agreement. The figure also shows the result of the classical theory in which the calculation is carried out assuming that the atoms happen to have all possible orientations in space. You can see that this assumption gives a prediction that is not even close to the experimental facts.

Even the quantum theory deviates from the observed behavior at both high and low temperatures. The reason for the deviations is that we have made a rather simple approximation in the theory: We have assumed that the energy of a given electron comes from magnetization of its neighboring atoms. In other words, for each one that is "up" in the neighborhood of a given atom, there will be a contribution of energy due to this quantum mechanical alignment effect. But how many *are* there pointed "up"? On the average, that is measured by the

Fig. 37-1. The spontaneous magnetization $M = M_0$ of ferromagnetic crystals as a function of temperature. [Permission from Encyclopaedia Britannica.]

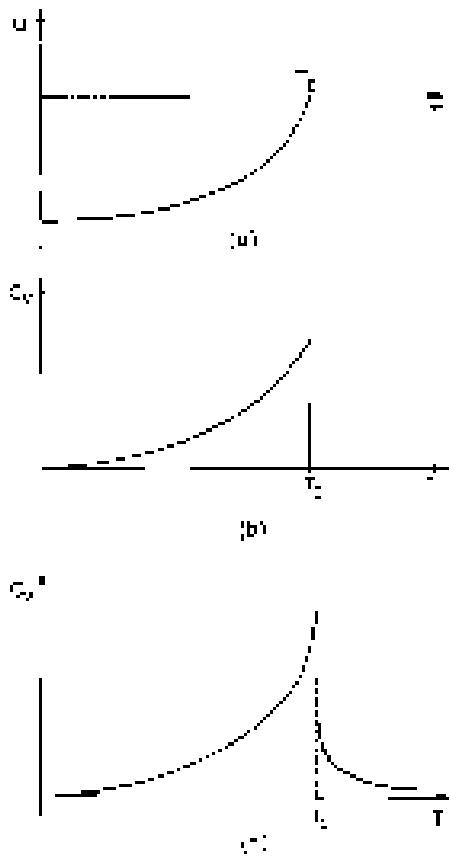

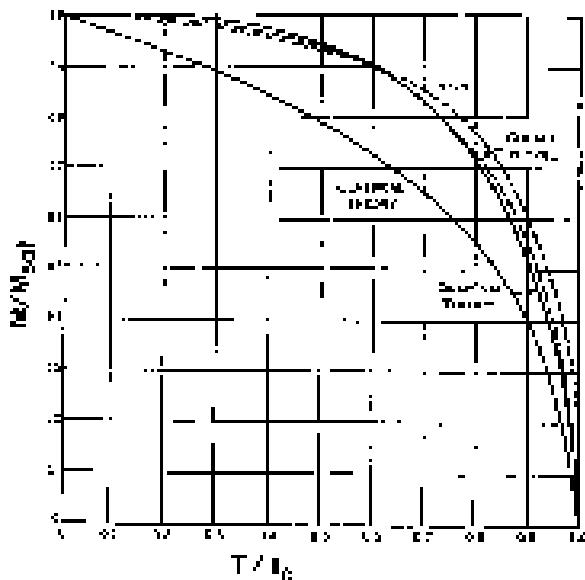

Fig. 37-2. The energy per unit volume and specific heat of a ferromagnetic crystal.

magnetization M —but only on the average. A particular atom somewhere might find all its neighbors "up." Then its energy will be larger than the average. Another one might find some up and some down, perhaps averaging to zero, and it would have no energy from that term, and so on. What we ought to do is to use a somewhat complicated kind of average, because the atoms in different places have different environments, and the numbers up and down are different for different cells. Instead of just taking one atom, supposed to be the average individual, we should take each one in its actual situation, compute its energy, and find the average average. But how do we find out how many are "up" and how many are "down" in the neighborhood? That is, of course, just what we are trying to calculate—the numbers "up" and "down"—so we have a very complicated autocorrelation problem of correlations, a problem which has never been solved. It is an intriguing and tantalizing one which has cast a fog over much of the related research in physics for several years, but even they have not completely solved it.

I think that at low temperatures, + or - almost all the atomic magnets are "up" and only a few are "below," it is easy to solve, and at high temperatures, far above the Curie temperature T_C , when they are almost all random, it is again easy. It is also easy to calculate small temperatures from some simple idealized situation, so I am fairly well understood why there are deviations from the simple theory at low temperature. It is less understood physically that for physical reasons the magnetization might deviate at high temperatures. But the exact behavior near the Curie point has never been thoroughly figured out. This is an interesting problem to work out someday if you want a problem that has never been solved.

37-2 Thermodynamic properties

In the last chapter we laid the groundwork necessary for calculating the thermodynamic properties of ferromagnetic materials. These are, naturally, related to the internal energy of the crystal, which includes interactions of the various spins, given by Eq. (37.1). For the energy of the spontaneous magnetization below the Curie point, we can set $M = 0$ in Eq. (37.1), and noticing that $m = M/M_0$, we find a mean energy proportional to M^2 :

$$(37.5) \quad \langle U \rangle_s = -\frac{8\pi\mu_0 M^2}{350e^2 M_0^2}.$$

If we now plot the energy due to the magnetism as a function of temperature, we get a curve which is the negative of the curve of the curve of Fig. 37-1, as shown in Fig. 37-2(a). If we were to measure the specific heat of such a magnet we would obtain a curve which is the derivative of 37-2(a). It is shown in Fig. 37-4.

37-3g). It rises slowly with increasing temperature, but falls according to zero at $T = 0$. The sharp dip is due to the change in sign of the magnetic energy and is reached right at the Curie point. So without any magnetic measurement at all we could have discovered that something was going on inside of iron or nickel by measuring this thermodynamic property. However, both experiment and improved theory (with fluctuations included) suggest that this simple curve is wrong and that the true situation is really more complicated. The curve goes higher at the peak and falls to zero much more slowly. Even if the temperature is high enough to randomize the spins on the average, there are still local regions where there is a certain amount of polarization, and in these regions the spins will have a little extra energy of interaction which only dies out slowly as things get more and more random with further increases in temperature. So the actual curve looks like Fig. 37-2(c). One of the challenges of theoretical physics today is to find an exact theoretical description of the character of the specific heat near the Curie transition—an intriguing problem which has not yet been solved. Naturally, this problem is very closely related to the shape of the magnetization curve in the same region.

Now we want to describe some experiments, other than thermodynamic ones, which show that there is something right about our interpretation of magnetism. When the material is magnetized to saturation at low enough temperatures, M is very nearly equal to M_s , - nearly all the spins are parallel, as well as their magnetic moments. We can check this by an experiment. Suppose we suspend a bar magnet by a thin fiber and then surround it by a coil so that we can reverse the magnetic field without touching the magnet or putting any torque on it. This is a very difficult experiment, because the magnetic forces are so enormous that any inaccuracy, any deposit of dust, or any lack of perfection in the coil will produce accelerated decays. However, the experiment has been done under careful conditions in which such accelerations are minimized. By means of the magnetic field from a coil that surrounds the bar, we turn all the atomic magnets over at first. When we do this we also change the angular momenta of all the spins from "up" to "down" (see Fig. 37-3). If angular momentum is to be conserved when the spins all turn over, the axis of the bar must have an opposite change in angular momentum. The whole magnet will start to spin. And sure enough, when we do the experiment, we find a slight turning of the magnet. We can measure the total angular momentum given to the whole magnet, and this is simply N times \hbar , the change in the angular momentum of each spin. The ratio of angular momentum to angular momentum is $1/N$. This why you can't be within about 10 percent of what we calculate. Actually, one says that the atoms' magnetic moments are due, mostly to the electrons. But there is, in addition, some orbital motion also in these materials. The orbital motion is not completely free of the lattice and does not contribute much more than a few percent to the magnetism. As a matter of fact, the saturation magnetic field that one gets taking $M_s \approx M_p$ and using the density of iron of 7.9 and the mass m_e of the spinning electron is about 20,000 gauss. This is a typical magnitude of error - 5 or 10 percent - due to neglecting the contributions of the orbital motions that have not been included in solving the analysis. Thus, a slight discrepancy with the gyromagnetic measurements is quite understandable.

37-3 The hysteresis curve

We have concluded from our theoretical analysis that a ferromagnetic material should spontaneously become magnetized below a certain temperature so that all the magnetic would be in the same direction. But we knew that this is not true for an ordinary piece of unannealed iron. Why isn't all iron magnetized? We can explain it with the help of Fig. 37-4. Suppose the iron were all a big single crystal of the shape shown in Fig. 37-4(a) and spontaneously magnetized all in one direction. Then there would be a considerable external magnetic field, which would have a lot of energy. We can reduce that field energy if we arrange that one side is

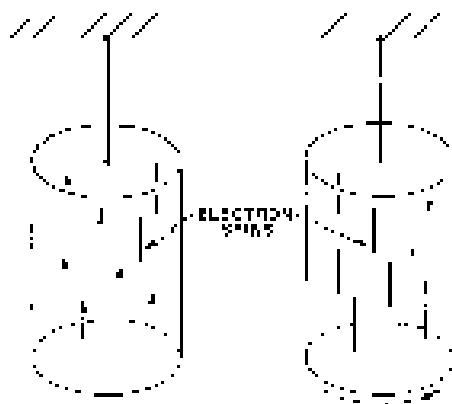

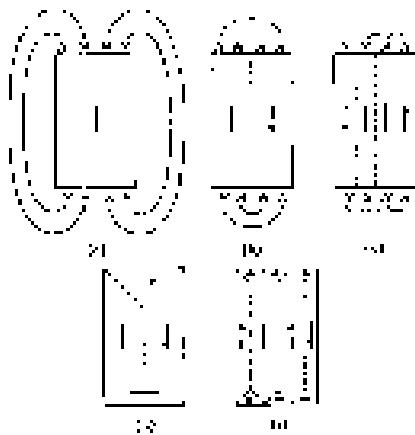

Fig. 37-3. When the magnetization of a bar of iron is reversed, the bar is given some angular velocity.

Let's say it is magnetized "up" and the other side magnetized "down," as in Fig. 37-4(b). Then, since the two take up less volume, so there would be less energy there.

But, but wait! In the layer between the two regions we have up-spinsing electrons adjacent to down-spinsing electrons. But ferromagnetism appears only in those materials for which the energy is reduced if the electrons are parallel rather than opposite. So, we have added some extra energy along the dotted line in Fig. 37-4(b); this energy is sometimes called *wall energy*. A region having only one direction of magnetization is called a domain. At the interface—the "wall"—between two domains, where we have up-spins on opposite sides which are spinning in different directions, there is an energy per unit area of the wall. We have described it as though two adjacent atoms were spinning exactly opposite, but it turns out that nature adjusts things so that the transition is more gradual. But we don't need to worry about such fine details at this point.

Now the question is: When is it better or worse to make a wall? The answer is that it depends on the size of the domains. Suppose that we were to scale up a block so that the whole thing was twice as big. The volume in the space outside filled with a given magnetic field strength would be eight times bigger, and the energy in the magnetic field, which is proportional to the volume, would also be eight times greater. But the surface area between two domains, which will give the wall energy, would be only four times as big. Therefore, if the piece of iron is big enough, it will pay to split it into many domains. This is why very big crystals can have but a single domain. Any large object—say, more than about a μm long² of a millimeter in size—will have at least one domain wall, and the larger the "magnetic" object will be split into many domains, as shown in the figure. Spinning out a domain gives you just the energy needed to get it moving; the wall is as large as the energy difference in the magnetic field outside the crystal.

Actually nature has devised a still another way to lower its energy. It is not necessary to have that and previously described, a little bit of the domain magnetized sideways, as in Fig. 37-4(a). Then with the arrangement of Fig. 37-4(c) we see that there is no external field, but instead only a little more domain wall.

But this introduces a new kind of problem. It turns out that when a single crystal of iron is magnetized, it changes its length in the direction of magnetization, so an "ideal" cube with its magnetization, say, "up," is no longer a perfect cube. The "vertical" dimension will be different from the "horizontal" dimension. This effect is called *magnetostriction*. Because of such geometric changes, the little triangular pieces of Fig. 37-1(d) do not, so to speak, "fit" into the available space anymore—the crystal has got too long one way and too short the other way. Of course, it does fit, really, but only by being squashed in; and this involves some mechanical stresses. So, this arrangement also introduces an extra energy. It is the balance of all these various energies which determines how the domains finally arrange themselves in their complicated fashion in a piece of unmagnetized iron.

Now, what happens when we put on an external magnetic field? To take a simple case, consider a crystal whose domains are as shown in Fig. 37-4(c). If we apply a horizontal magnetic field in the upward direction, in what manner does the crystal become magnetized? First, the middle domain wall can move over sideways (to the right) and reduce the energy. It turns out so that the region—which is "up" becomes bigger than the region which is "down". There are more elementary magnets lined up with the field, and it is given a lower energy. So, for a piece of iron in weak fields—at the very beginning of magnetization—the domain walls begin to move and ear into the regions which are magnetized opposite to the field. As the field continues to increase, a whole crystal shifts gradually into a single

² You may be wondering how come that here the words "up" or "down" can also be "sideways"! That's a good question, but we won't worry about it right now. Well, sort of... In the classical point of view, thinking of the atomic magnets as classical dipoles which can be polarized sideways. Quantum mechanics requires somewhat experience to understand how things can be quantized but "up-down-left-right" and "right-and-left" all at the same time.

large domain which the external field helps to keep lined up. In a strong field, the crystal "lives" to bend one way just because its energy in the applied field is reduced. It is no longer merely the crystal's own external field which matters.

What if the geometry is not so simple? What if the axes of the crystal and its spontaneous magnetization are in one direction, but we apply the magnetic field in some other direction—say at 15° ? We might think that domains would return themselves with their magnetization parallel to the field, and then as before, they could all grow into one domain. But this is not easy for the iron to do, for the energy needed to magnetize a crystal depends on the direction of magnetization relative to the crystal axis. It is relatively easy to magnetize iron in a direction parallel to the crystal axes, but it takes more energy to magnetize it in some other direction—like 15° with respect to one of the axes. Therefore, if we apply a magnetic field in such a direction, what happens first is that the domains which point along one of the preferred directions which is near to the applied field grow until the magnetization is all along one of those directions. Then, with much stronger fields, the magnetization is gradually pulled around, parallel to the field, as sketched in Fig. 37-5.

In Fig. 37-6 are shown some observations of the magnetization curves of single crystals of iron. To understand them, we must first explain something about the notation that is used in describing directions in a crystal. There are many ways in which a crystal can be sliced so as to produce a face which is a plane of atoms. Everyone who has driven past an orchard or surveyed lawns knows this. It is fascinating to watch. If you look carefully, you see lines of trees; if you look another way, you see different lines of trees, and so on. In a similar way, a crystal has definite "planes" of planes that hold many atoms, and the planes have this important characteristic (we consider a cubic crystal to make it easier): If we observe where the planes intersect the three Cartesian axes, we find that the reciprocals of the three coordinates from the origin are in the ratio of simple whole numbers. These three whole numbers are taken as the definition of the planes. For example, in Fig. 37-7(a), a plane parallel to the yz plane is shown. This is called a [100] plane; the reciprocals of its intersection of the x - and z -axes are both zero. The direction perpendicular to such a plane (in a cubic crystal) is given the same set of numbers. It is easy to understand the idea in a cubic crystal, for then the indices [100] mean a vector which has a unit component in the x -direction and none in the y - or z directions. The [1,0,0] direction is in a direction 15° from the x - and y -axes, as in Fig. 37-7(a); and the [111] direction is in the direction of the cube diagonal, as in Fig. 37-7(c).

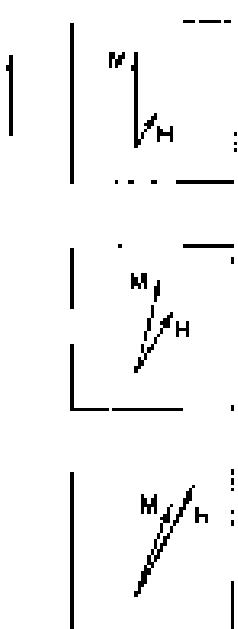

Fig. 37-5. A magnetizing field H at an angle with respect to the crystal axis will gradually change the direction of the magnetization without changing its magnitude.

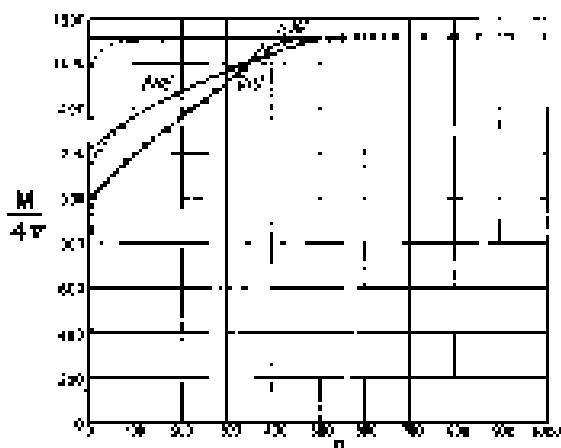

Fig. 37-6. The component of M parallel to H , for different directions of H (with respect to the crystal axes). [From E. Biller, *Introduction to Ferromagnetism*, McGraw-Hill Book Co., Inc., 1937.]

Returning now to Fig. 37-6, we see the magnetization curves of a single crystal of iron for various directions. First, note that for very tiny fields—so weak that it is hard to see them on the scale at all—the magnetization increases extremely rapidly to quite large values. If the field is in the [100] direction—namely along one of those nice, easy directions of magnetization—the curve goes up to a high value, curves around a little, and then is saturated. What happened is that the

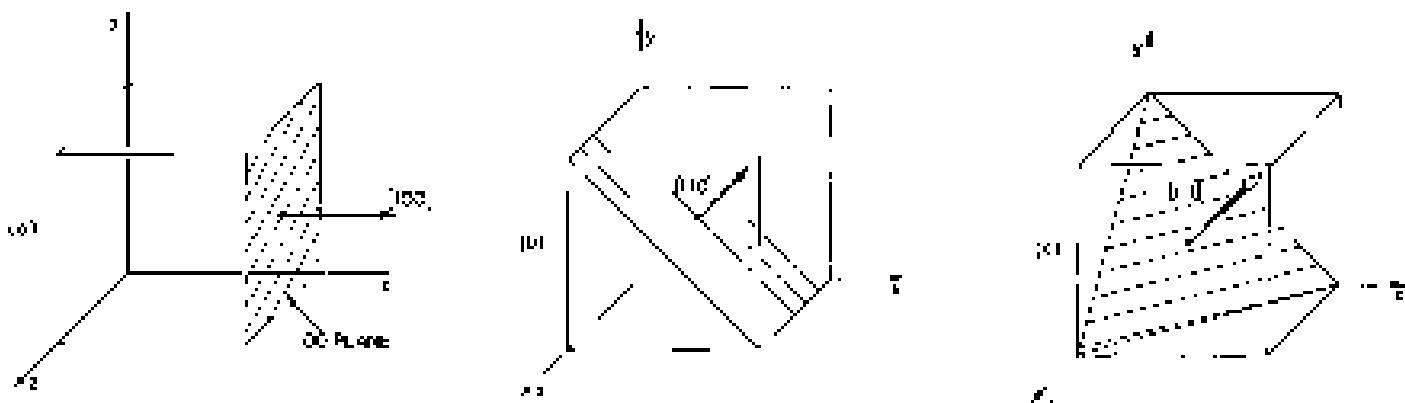

Fig. 37-7. The way the crystal planes are labeled.

domains which were already there are very easily reviewed. Only a small field is required to make the domain walls move and set up all of the "two-way" domains. Single crystals of iron are enormously permeable (magnetic sense), much more so than ordinary polycrystalline iron. A perfect crystal magnetizes extremely easily. Why is it curved at all? Why does it just go right up to saturation? We are not sure. You might study that some day. We do understand why it is flat for high fields. When the whole block is a single domain, the extra magnetic field cannot make any increase in the magnetization—it is already at M_s , with all the electrons lined up.

Now, if we try to do the same thing in the [110] direction—which is at 45° to the crystal axes—what will happen? We turn on a little bit of field and the magnetization loops up as the domains grow. Then as we increase the field some more, we find that it takes quite a lot of field to get up to saturation, because now the magnetization is turning easier from an "easy" direction. If this explanation is correct, the point at which the [110] curve extrapolates back to the vertical axis should be at $1/\sqrt{2}$ of the saturation value. It turns out, in fact, to be very, very close to $1/\sqrt{2}$. Similarly, in the [111] direction—which is along the cube diagonal—we find, as we would expect, that the curve extrapolates back to nearly $1/\sqrt{3}$ of saturation.

Figure 37-8 shows the corresponding curves for two other elements, nickel and cobalt. Nickel is different from iron. In nickel, it turns out that the [111] direction is the easy direction of magnetization. Cobalt has a hexagonal crystal form, and people have figured out the system of magnetization for this case. They want to have three axes on the bottom of the octahedron and one perpendicular to these, so they have used four indices. The [1000] direction is the direction of the easy axis of the hexagon, and [0100] is perpendicular to that axis. We see that crystals of different metals behave in different ways.

Now we must start a polycrystalline material, such as in your many pieces of iron. Inside such materials there are many, many little crystals with their crystalline axes pointing every which way. These are not as easy to analyze. Remember that the domains were all part of a single crystal, but in a piece of iron there are

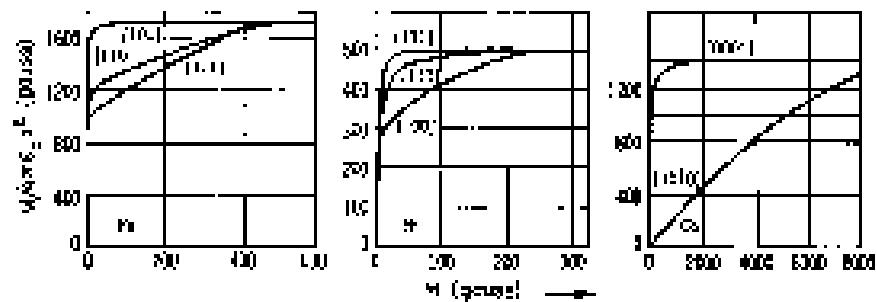

Fig. 37-8. Magnetization curves for single crystals of iron, nickel, and cobalt. (From Charles Kittel, *Introduction to Solid State Physics*, John Wiley and Sons, Inc., New York, 2nd ed., 1956.)

many different crystals with axes at different orientations, as shown in Fig. 37-9. Within each of these crystals, there will also generally be some domains. When we apply a small magnetic field to a piece of polycrystalline material, what happens is that the domain walls begin to move, and the domains which have a favorable direction of easy magnetization grow larger. This process is reversible so long as the field stays very small. If we turn the field off, the magnetization will return to zero. The part of the magnetization curve is marked in Fig. 37-10.

For larger fields—in the region B of the magnetization curve shown—things get more complicated. In every small crystal of the material, there are strains and dislocations; there are impurities, shift, and imperfections. And at all but the smallest fields, the domain wall, in moving, gets stuck or loose. There is an interaction of energy between the domain wall and a dislocation, or a grain boundary, or an impurity. So when the wall tries to run off, it gets stuck. It stays there at a certain field. But then if the field is raised a little more, the wall suddenly snaps past. So the motion of the domain wall is not smooth the way it is in a perfect crystal—it gets hung up every once in a while and moves in jerks. If we were to look at the magnetization on a microscopic scale, we would see something like the insert of Fig. 37-10.

Now the important thing is that these jerks in the magnetization can cause an energy loss. In the first place, when a boundary finally slips past an impediment, it moves very quickly to the next one, since the field is already above what would be required for the unimpeded motion. The rapid motion means that there are rapidly changing magnetic fields which produce eddy currents in the crystal. These currents lose energy in heating the metal. A second effect is that when a domain suddenly changes, part of the crystal changes its dimensions from the magnetostriction. Each sudden shift of a domain wall sets up a little sound wave that carries away energy. Because of such effects, the second part of magnetization curve is irreversible, and there is energy loss here. This is the origin of the hysteresis effect, because to move a boundary wall forward—snap—and then to move it back—snap—produces a different result. It's like "jerky" friction, and it takes energy.

Eventually, for large enough fields, when we have moved all the domain walls and magnetized each crystal in its best direction, there are still some crystallites which happen to have their easy directions of magnetization not in the direction of our external magnetic field. Then it takes a lot of extra field to turn these magnetic moments around. So the magnetization increases slowly, but smoothly, for high fields—namely in the region marked C in the figure. The magnetization does not snap sharply to its saturation value, because not to say, just all the easy directions align are having in the strong field. So we see why the magnetization curve of an ordinary polycrystal is hysteresis, such as the one shown in Fig. 37-10. Notice that the last and reversible part has three steps by, and then curves over steadily. Of course, there is no sharp break-point between the three regions—they blend smoothly one into the other.

It is not hard to show that the magnetization process in the middle part of the magnetization curve is jerky—that the domain walls jerk and snap as they shift. All you need is a coil of wire with many thousands of turns, connected to an amplifier and a loudspeaker, as shown in Fig. 37-11. If you put a few thin iron sheets (of the type used in transformers) at the center of the coil and bring a bar magnet slowly near the steel, the sudden changes in magnetization will produce imulses of electricity in the coil, which are heard as distinct clicks in the loudspeaker. As you move the magnet nearer to the iron you will hear a whole rush of clicks that sound something like the noise of sand grains falling over each other as a can of sand is tilted. The domain walls are jumping, stopping, and jiggling as the field is increased. This phenomenon is called the Barkhausen effect.

As you move the magnet even closer to the iron sheets, the noise grows louder and louder for a while but then there is relatively little noise when the contact gets very close. Why? Because nearly all the domain walls have moved as far as they can go. Any greater field is merely turning the magnetization in each crystal, which is a smooth process.

Fig. 37-9. The microscopic structure of an unmagnetized ferromagnetic material. Each crystal grain has an easy direction of magnetization and is broken up into domains which are spontaneously magnetized usually parallel to this direction.

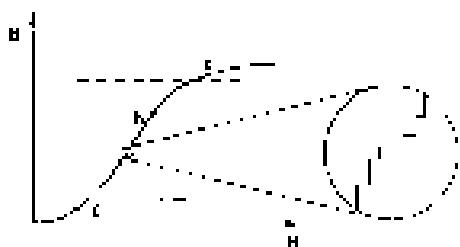

Fig. 37-10. The magnetization curve for polycrystalline iron.

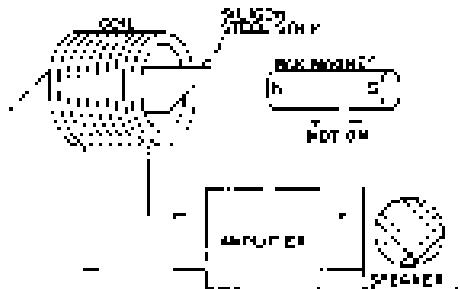

Fig. 37-11. The sudden changes in the magnetization of the steel strip are heard as clicks in the loudspeaker.

If you play with your magnet, as we have done, you can see the downward branch of a hysteresis loop. You might try to get back to zero energy again, and you find a series of "backward-going peaks." You can appreciate that if you bring the magnet too far down, it becomes unstable, because then, the magnetic force is very little indeed. It is unique, like iron, to have a "soft" metal, one the plumb softest piece, in all measurements of the magnetic field of the magnet, because the same current in the magnetic field can't produce the next tiny hysteresis loop, say in the "up" part.

37-4 Ferromagnetic materials

Now we would like to talk about the various kinds of magnetic materials that there are in the technical world and to consider some of the problems involved in designing magnetic materials for different purposes. First, the term "the magnetic properties of iron," which one often hears, is a misnomer. There is no such thing. "Iron" is not a well-defined material—the properties of iron depend critically on the amount of impurities and also on how the iron is formed. You can appreciate that the magnetic properties will depend on how easily the domain walls move and that this is a gross property, not a property of the individual atoms. So practical ferromagnetism is not really a property of an iron atom—it is a property of what you do to a certain atom. For example, iron can take on two different crystalline forms. The common form has a body-centered cubic lattice, but it can also have a face-centered cubic lattice, which is, however, stable only at temperatures above 1200°C. Of course, at that temperature the body-centered cubic structure is already past the Curie point. However, by alloying chromium and nickel with the iron, two possible amounts of 18 percent chromium and 5 percent nickel, we can get what is called stainless steel, which, although it is mainly iron, retains the body-centered cubic even at low temperatures. Because its crystal structure is different, it has completely different magnetic properties. Most kinds of stainless steel are not magnetic to any appreciable degree, although there are some kinds which are somewhat magnetic—it depends on the composition of the alloy. Even when such an alloy is magnetized, it is *not* ferromagnetic like ordinary iron—even though it is mostly just iron.

We want to look now to close to a few of the special materials which have been developed for their particular magnetic properties. First, if we want to make a permanent magnet, we want the material with an extremely wide hysteresis loop so that, when we turn the current off and come down to zero magnetizing field, the magnetization will remain large. For such materials the domain boundaries should be "frozen" in place as much as possible. One such material is the remarkable alloy "Alnico V" (50% Fe, 20% Al, 12% Ni, 8% Cu, 2% Ti, 2% Cr). The rather complex composition of this alloy is because of the fact that it contains a bit that has gone into making good magnets. What happens is to take the two things together and heat them until you find the most ideal situation. When aluminum solidifies, there is a "second phase" which precipitates out, making many tiny cycles and very high internal strains. In this material, the domain boundaries have a hard time moving at all. In addition to having a precise composition, Alnico is microscopically "worked" in a way that causes the crystals appear in the form of long grains along the direction in which the magnetization is going to be. Then the magnetization will have a natural tendency to be lined up in these directions and will be fixed there from the annealing effects. Furthermore, the material is even cooled in an external magnetic field when it is manufactured, so that the grains will grow with the right crystal orientation. The hysteresis loop of Alnico V is shown in Fig. 37-12. You see that it's about 300 times wider than the hysteresis curve for iron, and that we showed in the last chapter in Fig. 36-8.

Let's turn now to a different kind of material. For inducting transformers and motors, we want a material which is magnetically "soft"—one in which the magnetism is easily changed so that an enormous amount of magnetization results from a very small applied field. For example, this we need pure, well-crucible materials which will have very low dislocations and impurities so that the domain

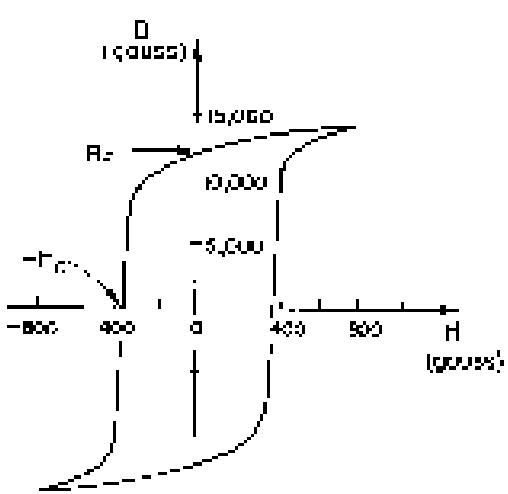

Fig. 37-12. The hysteresis curve of Alnico V.

walk can move easily. It would also be nice if we could make the anisotropy small. Then, even if a grain of the material sits at the wrong angle with respect to the field, it will still magnetize easily. Now we have said that iron prefers to magnetize along the [001] direction, whereas nickel prefers the [111] direction; so, if we mix iron and nickel in various proportions, we might hope to find that with just the right proportions the alloy wouldn't prefer any direction. The [100] and [111] directions would be equivalent. It turns out that this happens with a mixture of 70 percent nickel and 30 percent iron. In addition—possibly by luck or maybe because of some physical relationship between the anisotropy and the magnetostatic effects—it turns out that the magnetostatic of iron and nickel has the opposite sign. And in an alloy of the two metals, this property goes through zero at about 30 percent nickel. So somewhere between 30 and 50 percent nickel we get very "soft" magnetic materials—alloys that are very easy to magnetize. They are called the *permalloys*. Permalloys are useful for high-quality transformers (a few signal levels), but they would be no good at all for induction, magnets. Permalloys are very easily made and handled. The magnetic properties of a piece of permalloy are essentially unchanged if stressed beyond the elastic limit—*i.e.*, until it's bent. This shape stability is reduced because of the dislocations, slip bands, and so on, which are produced by the mechanical deformations. The domain boundaries are no longer very precise. The high permeability can, however, be destroyed by passing it at high temperatures.

It is often useful to have some numbers to characterize the various magnetic materials. One useful one is the intercept of the hysteresis loop with the B - and H -axes, as indicated in Fig. 37-12. These intercepts are called *coercive forces* (*field* B_c and *current* H_c). In Table 37-1 we list these numbers for a few magnetic materials.

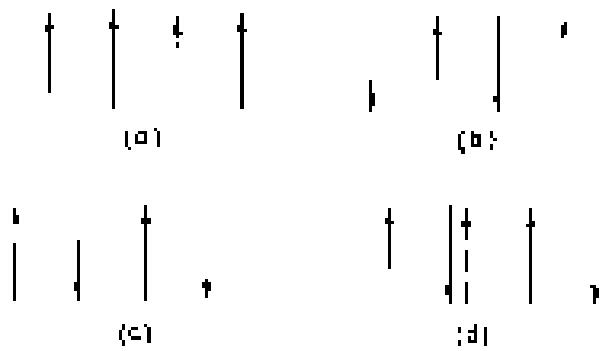

Fig. 37-12. Relative orientation of electron spins in various materials. (a) ferromagnetic, (b) anti-ferromagnetic, (c) ferrimagnetic, (d) chromium-alloy. (Remember always show direction of total angular momentum, including orbital motion.)

37-6. Extraordinary magnetic materials

We would now like to discuss some of the more exotic magnetic materials. There are many elements in the periodic table which have negative mass-electron shells and hence have negative magnetic moments. For instance, right next to Sc (Scandium) you have Cr, Mn, Co, Ni, Cu, and Fe. You will find chromium and manganese. Why aren't they ferromagnetic? The answer is that the term in Eq. (37.1) has the opposite sign for these elements. In the chromium lattice, for example, the spins of the chromium atoms alternate above and below, as shown in Fig. 37-13(d). So chromium is magnetized from the point of view, but it is not technically interesting because there are no *anomalous magnetic effects*. Chromium, then, is an example of a material in which quantum mechanical effects make it a spin insulator. Such a material is called *antiferromagnetic*. The "anomalous" in a ferromagnetic material is also temperature dependent. Below a critical temperature, all the spins are lined up in the alternating array, but when the material is heated above a certain temperature—which is again called the Curie temperature—the spins suddenly become random. There is, interestingly, a surface transition. This behavior can be seen in the specific heat curve. Also, it shows up in some spin-orbit effects. For instance, the existence of the alternating spins can be seen, for instance, in the neutron Bragg scattering of chromium. Because a neutron "isn't" has a spin,

Table 37-1

Properties of some ferromagnetic materials

Material	B_c Gauss (approx.)	H_c Oerst. (approx.)
Supermagnet	> 9000	0.03
Stainless steel (permeability)	12000	1.0
Alnico V	2400	0.6
Alnico V	12000	0.03

(of a magnetic moment), it has different amplitude to be generated, depending on whether its spin is parallel or opposite to the spin of the neighbor. Thus, we get a different influence per unit μ on the spins in a crystal according to how we are when they have σ or τ along a given direction.

There is another kind of interaction which quantum mechanical effects make the electron spins interact, but which is not ferromagnetic—that is, the crystal has a permanent net magnetization. The idea behind such materials is shown in Fig. 37-1. The figure shows the crystal structure of spinel, a magnesium-aluminum oxide which—as it is shown—is nonmagnetic. The oxide has two kinds of metal atoms: magnesium and aluminum. Now if we replace the nonmagnetic ones by two magnetic elements like iron and zinc, or by zinc and manganese—in other words, two paramagnetic atoms instead of the nonmagnetic ones—an interesting thing happens. Let's call one kind of metal atom a and the other kind of metal atom b ; then the following combination of forces is in the crystal. There is an a - a interaction which tries to make the a 's align, and the a 's have opposite spins because quantum mechanics always gives the opposite sign (except for the mysterious crystals of iron, nickel, and cobalt). Then there is a direct a - b interaction which tries to make the a 's opposite, and also a b - b interaction which tries to make the b 's opposite. Now, of course we cannot have everything opposite; everything else— a opposite b , a opposite a , and b opposite b . Presumably because of the distances between the a 's and the presence of the oxygen (which we really don't know well), it turns out that the a - a interaction is stronger than the a - b or the b - b . So the solution that nature uses in this case is to make all the a 's parallel to each other, and all the b 's parallel to each other, but the two systems opposite. That gives the lowest energy by use of the stronger a - a interaction. The result is all the a 's are spinning in one all-use θ^+ and spinning over—at very small, of course. But in the nonmagnetic case of the regular spinel and the v -type spinel are no θ^+ , we can get the situation shown in Fig. 37-1(a), and there will be a net magnetization in the material. The materials will then be ferromagnetic—although somewhat weak. Such materials are called ferrites. They do not have as high a saturation magnetization as iron, for example, because \rightarrow they are only useful for smaller fields. But they have a very important feature—they are insulators, the b 's are not ferromagnetic conductors. In large magnetic fields, they will have very small eddy currents and so can be used, for example, in microwave systems. The microwave fields will be able to get into such insulating material, whereas they would be kept out by the eddy currents in a conductor like iron.

There is another class of magnetic materials which has only recently been discovered—members of the family of the orthosilicates of yttrium. They are again crystals in which the lattice contains two kinds of metallic atoms, and we have again a situation in which two kinds of atoms can be substituted almost at will. Among the many compounds of interest there is one which is completely ferromagnetic. It has yttrium and iron in the garnet structure, and the reason it is ferromagnetic is very curious—it's again quantum mechanics: making the neighboring spins opposite so that there is a locked-in system of spins with the electron spins of the iron one way and the electron spins of the yttrium the opposite way. But the yttrium atom is complicated. It's a rare earth element and gets a large contribution to its magnetic moment from orbital motion of the electrons. For yttrium, the orbital motion contribution is opposite that of the spin and also is bigger. Thus, although quantum mechanics, working through the exclusion principle, makes the spins of the yttrium opposite those of the iron, it makes the total magnetic moment of the yttrium atom *parallel* to the iron because of the orbital effect—as sketched in Fig. 37-2(d). The compounds therefore a regular ferrimagnet.

Another interesting example of ferrimagnetism occurs in some of the rare-earth elements. It has to do with a still more peculiar arrangement of the spins. The material is not ferromagnetic in the sense that the spins are all parallel, nor is it antiferromagnetic in the sense that every site is opposite. In these crystals all of the spins of one layer are parallel and lie in a plane of the layer. In the next

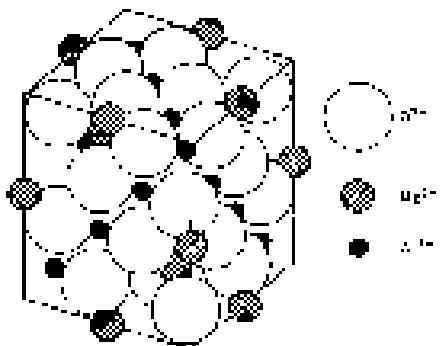

Fig. 37-1. Crystal structure of the mineral spinel ($MgAl_2O_4$), the Mg^{2+} ions occupy tetrahedral sites, and are surrounded by four oxygen ions; the Al^{3+} ions occupy octahedral sites, each surrounded by six oxygen ions. (From Charles Kittel, Introduction to Solid State Physics, John Wiley and Sons, Inc., New York, 2nd ed., 1956.)

layer all spins are again parallel to each other, but point in a somewhat different direction. In the following layer they are in still another direction, and so on. The result is that the local magnetization vector varies in the form of a spiral—the magnetic moments of the successive layers rotate as we proceed along a line perpendicular to the layers. It is interesting to try to analyze what happens when a field is applied to such a spiral—all the twisting and turning that must go on in all these various magnets. (Some people like to amuse themselves with the theory of these things.) Not only are there cases of "flat" spirals, but there are also cases in which the directions the magnetic moments of successive layers map out a cone, so that it has a spiral component and also a uniform ferromagnetic component at every location!

The magnetic properties of materials worked out on a more advanced level than we have been able to do here, have fascinated physicists of all kinds. In the first place, there are those practical people who love to work out ways of making things in a better way—they love to design better and more interesting magnetic materials. The discovery of things like ferrites, or their application, immediately delights people who like to see clever new ways of doing things. Besides this, there are those who find a fascination in the terrible complexity that nature can produce using a few basic laws. Starting with one and the same general idea, nature goes from the ferromagnetism of iron and its alloys, to the antiferromagnetic state of chromium, to the magnetism of ferrites and garnets, to the spiral structure of the rare earth elements, and on, and on. It is fascinating to discover experimentally a lot of strange things that go on in these special substances. Then, to the theoretical physicists, this complex situation presents a number of very interesting, unusual, and beautiful challenges. One challenge is to understand why it exists at all. Another is to predict the statistics of the interacting spins in a solid lattice. Even neglecting any possible exchanges or spin-orbits, the problem has, as far, defied full understanding. The reason that it is so interesting is that it is such an easily solved problem: Given a lot of electron spins in a regular lattice, interacting with such-and-such a law, what do they do? It is so simple stated, but it has defied complete analysis for years. Although it has been analyzed rather carefully for temperatures not too close to the Curie point, the theory of the sudden transition to the Curie point still needs to be completed.

Finally, the whole subject of the system of spinning atomic magnets—in ferromagnetic, or in paramagnetic materials and in nuclear magnetic, has also been a fascinating thing to advanced students in physics. The system of spins can be pushed on and pulled on with external magnetic fields, so one can do things like with resonances, with rotation effects, with spin-orbits, and with other effects. It serves as a prototype of many complicated thermodynamic systems. But in paramagnetic materials the situation is often fairly simple, and people have been delighted both in the experiments and in explaining the phenomena theoretically.

We now close our study of electricity and magnetism. In the first chapter, we spoke of the great strides that have been made since the early Greek observation of the strange behaviors of amber and of lodestone. Yet in all our long and involved discussion we have never explained why it is that when we rub a piece of amber we get a charge on it nor have we explained why a lodestone is magnetic at all. You may say, "Oh, we just didn't get the right sign." No, it is worse than that. Even if we did get the right sign, we would still have the question: Why is the piece of lodestone in the ground magnetized? There is the earth's magnetic field, of course, but where does the earth's field come from? Nobody really knows—there have only been some good guesses. So you see, the physics of ours is a lot of liberty—we start out with the phenomena of lodestone and amber, and we end up not understanding either of them very well. But we have learned a tremendous amount of very exciting and very practical information in the process!

Kinematics

38-1 Hooke's law

The subject of elasticity deals with the behavior of those substances which have the property of recovering their size and shape when the forces producing deformations are removed. We find the elastic properties to some extent in all solid bodies. If we had the time to deal with them at length, we would want to look into many things: the behavior of materials, the general laws of elasticity, the general theory of elasticity, the atomic mechanisms that determine the elastic properties, and finally the limitations of elastic laws when the forces become so great that plastic flow and fracture occur. It would take more time than we have to cover all these subjects in detail, so we will have to leave out some things. For example, we will not discuss plasticity or the limitations of the elastic laws. (We touched on these subjects briefly when we were talking about dislocations in metals.) Also, we will not be able to discuss the internal mechanisms of elasticity—so our treatment will not have the completeness we have tried to achieve in the earlier chapters. Our aim is mainly to give you an acquaintance with some of the ways of dealing with such practical problems as the bending of beams.

When you pull on a piece of material, if "never," the material is unextended. If the force is small enough, the slight expansion rate of the various points in the material are proportional to the force—we say the behavior is *elastic*. We will discuss only the elastic behavior. First, we will write down the mathematical law of elasticity, and then we will apply it to a number of different situations.

Suppose we have a rectangular block of material of length l , width w , and height h , as shown in Fig. 38-1. If we pull on the ends with a force F , i.e., the length increases by an amount Δl , we will suppose in all cases that the change in length is a small fraction of the original length. As a matter of fact, for materials like wood and steel, the material will break if the change in length is more than a few percent of the original length. For a large number of materials, especially as shown in Fig. 38-1, for sufficiently small extensions the force is proportional to the extension:

$$F \propto \Delta l \quad (38.1)$$

This is often known as Hooke's law.

The length change Δl of the bar will also depend on its length. We can figure out how by the following argument. If we hang two identical blocks together end to end, the stress increases in each block, and will stretch by Δl . Thus, the stretch of a block of length $2l$ will be twice as big as a block of the same cross section, $w \times h$, of length l . In order to get a more complete comprehension of the problem, unless of course you do the steps, we can associate with the Δl of (38.1) the length to the original length. This ratio is proportional to the force but independent of it:

$$\frac{\Delta l}{l} \propto F. \quad (38.2)$$

The force F will also depend on the area of the block. Suppose that we put two blocks side by side. Then for a given stretch Δl we would have the force F on each block, or twice as much on the combination of the two blocks. The force, for a given amount of stretch, must be proportional to the cross-sectional area A of the block. To obtain a law in which the coefficient of proportionality is independent of the dimensions of the body, we write Hooke's law for a rectangular

the Hooke's law.

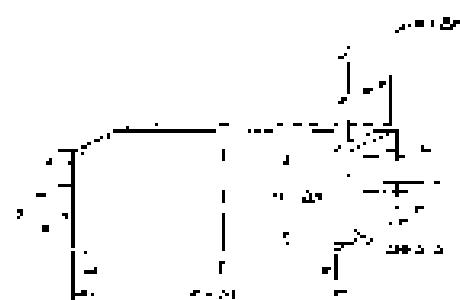

Fig. 38-1. The stretching of a horizontal deformation.

block in the form

$$\sigma = E \frac{\delta l}{l} \quad (38.3)$$

The constant E is a property only of the nature of the material; it is known as Young's modulus. (Usually you will see Young's modulus called E . But we've used E for electric fields, energy, and emf's, so we prefer to use a different letter.)

The force per unit area is called the stress, and the stretch per unit length—i.e., fractional stretch—is called the strain. Equation (38.3) can therefore be rewritten in the following way:

$$\frac{F}{A} = \sigma \times \frac{\delta l}{l} \quad (38.4)$$

$$\text{Stress} = (\text{Young's modulus}) \times (\text{Strain})$$

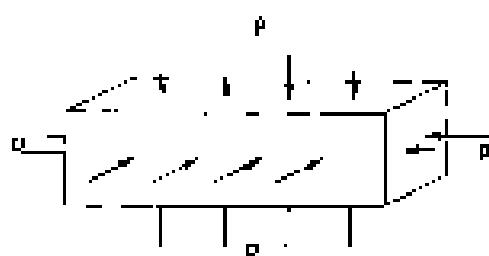

Fig. 38-2 A block under $w/4$ atm hydrostatic pressure.

There is another part to Hooke's law: When you stretch a block of material in one direction it contracts at right angles to the stretch. The contraction in width is proportional to the width w and also to $\delta l/l$. The sideways contraction is in the same proportion for both width and height, and is usually written

$$\frac{\Delta w}{w} = \frac{\Delta h}{h} = -\alpha \frac{\delta l}{l} \quad (38.5)$$

where the constant α is another property of the material called Poisson's ratio. It is always positive in sign and is a number less than 1/2. (It is "reasonable" that α should be generally positive, but it is not quite clear what is meant by that.)

The two constants E and α specify completely the elastic properties of a homogeneous isotropic (that is, noncrystalline) material. In crystal-like materials the stretches and contractions can be different in different directions, so there can be many more elastic constants. We'll return our discussion temporarily to homogeneous/anisotropic materials whose properties can be described by E and α . As usual there are different ways of describing things; some people like to describe the elastic properties of materials by different constants. It always takes two, and they can be related to E and α .

The last general law we need is the principle of superposition. Since the two laws (38.1) and (38.3) are linear in the forces and in the displacements, superposition will work. If you have one set of forces and get some displacements, and then you add a new set of forces and get some additional displacements, the resulting displacements will be the sum of the ones you would get with the two sets of forces acting independently.

Now we have all the general principles—the superposition principle and Eqs. (38.1) and (38.3)—and that's all there is to elasticity. But that is like saying that once you have Newton's laws that's all there is to mechanics. Or, given Maxwell's equations, that's all there is to electricity. It is, of course, true that with these principles you have a great deal, because with your present mathematical ability you could go a long way. We will, however, work out a few special applications.

38-2 Uniform strains

As our first example let's find out what happens to a rectangular block under uniform hydrostatic pressure. Let's put a block under water in a pressure tank. Then there will be a force acting inward on every face of the block proportional to the area (see Fig. 38-2). Since the hydrostatic pressure is uniform, the stress (force per unit area) on each face of the block is the same. We will work out first the change in the length. The change in length of the block can be imagined as the sum of changes in length that would occur in the three independent problems which are sketched in Fig. 38-4.

Fig. 38-3 Hydrostatic pressure is the superposition of three independent compressions.

Problem 1. If we push on the ends of the block with a pressure p , the compressional strain is $\frac{\Delta l}{l} = -\frac{p}{Y}$ and it is negative,

$$\frac{\Delta l}{l} = -\frac{p}{Y}.$$

Problem 2. If we push on the two sides of the block with pressure p , the compressional strain is again $\frac{\Delta l}{l} = -\frac{p}{Y}$, but now we want the lengthwise strain. We can get that from the sideways strain multiplied by $-w$. The sideways strain is

$$\frac{\Delta w}{w} = -\frac{p}{E};$$

so

$$\frac{\Delta l}{l} = -w \frac{p}{E}.$$

Problem 3. If we push out the top of the block, the compressional strain is once more $\frac{\Delta l}{l} = -\frac{p}{Y}$, and the corresponding strain in the sideways direction is again $\frac{\Delta w}{w} = -\frac{p}{E}$. We get

$$\frac{\Delta l}{l} = -w \frac{p}{E}$$

Combining the results of the three problems—that is, taking $\Delta l = \Delta l_1 + \Delta l_2 + \Delta l_3$ —we get

$$\frac{\Delta l}{l} = \frac{p}{Y}(1 - 2w). \quad (36.6)$$

The problem is, of course, symmetric in all three directions; it follows that

$$\frac{\Delta v}{w} = \frac{\Delta h}{h} = -\frac{p}{Y}(1 - 2w). \quad (36.7)$$

The change in the volume under hydrostatic pressure is also of some interest. Since $V = lwh$, we can write, for small displacements,

$$\frac{\Delta V}{V} = \frac{\Delta l}{l} + \frac{\Delta w}{w} + \frac{\Delta h}{h}.$$

Using (36.6) and (36.7), we have

$$\frac{\Delta V}{V} = -2 \frac{p}{Y}(1 - 2w). \quad (36.8)$$

People like to call $\Delta V/V$ the volume strain and write

$$\nu = -K \frac{\Delta V}{V}.$$

The volume strain ν is proportional to the volume strain—Hooke's law once more. The effective K is called the bulk modulus; it is related to the other constants by

$$K = \frac{Y}{(1 + 2w)}. \quad (36.9)$$

Since K is of some practical interest, many textbooks give Y and K instead of Y and ν . If you want ν you can always get it from Eq. (36.9). We can also see from Eq. (36.9) that Poisson's ratio, w , must be less than one-half. If w were not, the bulk modulus K would be negative, and the material would expand under increasing pressure. That would allow us to get mechanical energy out of any old block—it would mean that the block was in unstable equilibrium. If it started to expand it would continue by itself until it release of energy.

Now we want to consider what happens when you put a "shear" stress on something. By shear strain we mean the kind of distortion shown in Fig. 36-4. As is preliminary to this, let's look at the strains in a cube of material subjected to the forces shown in Fig. 36-5. Again we can break it up into two problems: the vertical

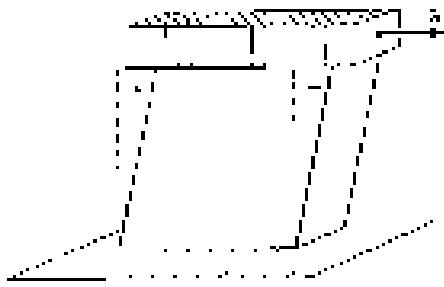

Fig. 36-4. A cube in uniform shear.

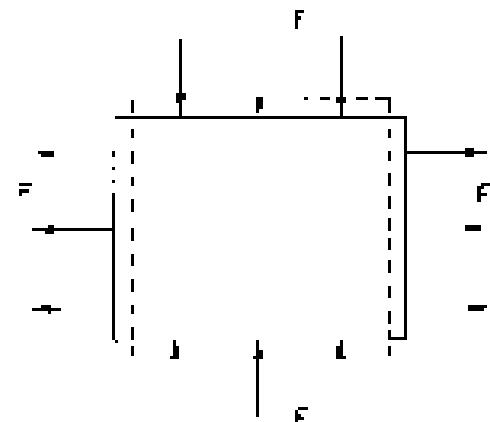

Fig. 36-5. A cube with compressing forces on top and bottom and equating-stressing forces on two sides.

pulses, and the horizontal pull. Calling A the area of the cube face, we have for the change in horizontal length

$$\frac{\Delta l}{l} = \frac{1}{Y} F - \sigma \frac{1}{Y} F = \frac{1 + \sigma}{Y} \frac{F}{A}. \quad (38.10)$$

The change in the vertical height is just the negative of this.

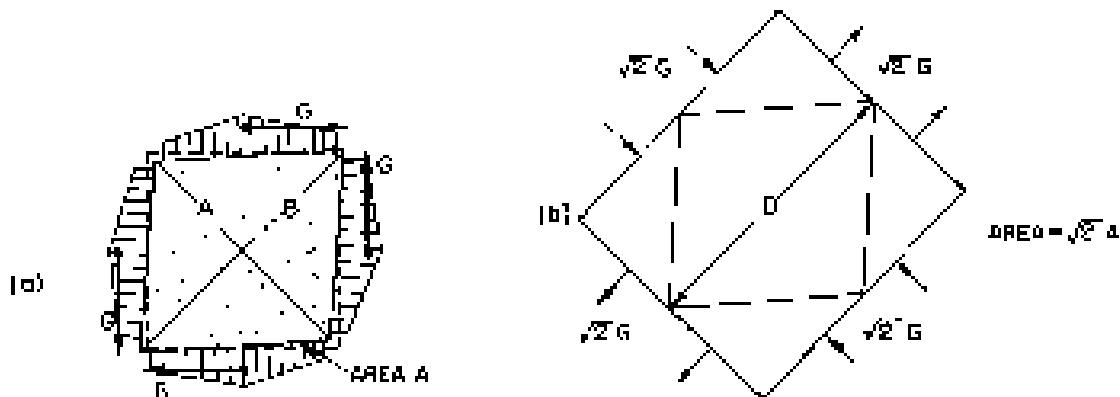

Fig. 38-5. The two pairs of shear forces in (a) produce the same stress as the compressing and stretching forces of (b).

Now suppose we take the same cube and subject it to the shearing forces shown in Fig. 38-6(a). Note that all the forces have to be equal if there are to be no net torques and the cube is to be in equilibrium. (Similar forces must also exist in Fig. 38-4, since the block is in equilibrium.) They are passed through the "glue" that holds the block to the table. (The cube is then said to be in a state of pure shear.) But note that if we cut the cube by a plane at 45°, say along the diagonal d in the figure, the total force acting across the plane is normal to plane d , and is equal to $\sqrt{2}G$. The area over which this force acts is $\sqrt{2}/4$, therefore, the tensile stress normal to this plane is simply $G/\sqrt{2}$. Similarly, if we examine a plane at an angle of 45° the other way—the diagonal d' in the figure—we see that there is a compressional stress normal to this plane of $-G/\sqrt{2}$. From this, we see that the stress in a "pure shear" is equivalent to a combination of tension and compression stresses of equal strength and at right angles to each other, and at 45° to the original faces of the cube. The internal stresses and strains are the same as we would find in the larger block of material with the forces shown in Fig. 38-6(b). (This is the problem we have already solved. The change in length of the diagonal is given by Eq. (38.10).)

$$\frac{\Delta l}{l} = \frac{1 + \sigma}{Y} \frac{F}{A}. \quad (38.11)$$

(One diagonal is elongated, the other is elongated.)

It is often convenient to express a shear strain in terms of the angle by which the cube is twisted—the angle θ in Fig. 38-7. From the geometry of the figure you can see that the longitudinal shift, δ , of the top edge is equal to $\sqrt{1 + \theta^2} - 1$. So

$$\theta = \frac{\delta}{l} = \frac{\sqrt{1 + \theta^2} - 1}{l} = \frac{\sqrt{2}\Delta D}{l} = \frac{2\Delta D}{l}. \quad (38.12)$$

The shear stress σ is defined as the tangential force on one face divided by the area, $\sigma = F/A$. Using Eq. (38.10) in (38.12), we get

$$\theta = k + \frac{\sigma}{Y} l. \quad (38.13)$$

Fig. 38-7. The shear strain θ is $\frac{2\Delta D}{l}$.

(It is useful to remember "shear = constant times strain.")

$$\sigma = \mu k. \quad (38.13)$$

The proportionality coefficient ν is called the shear modulus (or, sometimes, the coefficient of rigidity). It is given in terms of E and σ by

$$\nu = \frac{E}{2(1+\nu)}. \quad (38.14)$$

Obviously, the shear modulus must be positive—otherwise you could get work out of a self-stressing block. From Eq. (38.14), ν must be greater than -1 . We know, then, that ν must be between -1 and $-\frac{1}{2}$; in practice, however, it is always greater than zero.

As a first example of the type of situation where the stresses are uniform through the material, let's consider the problem of a block which is stretched, while it is at the same time constrained so that no lateral contraction can take place. (Technically, it's a little easier to reciprocate it while keeping the sides from bulging out—but it's the same problem.) What happens? Well, there must be sideways forces which keep it from changing its thickness—forces we don't know off-hand but we have to calculate. It's the same kind of problem we have already done, only with a little different algebra. We compute forces on all three sides, as shown in Fig. 38-8; we calculate the changes in dimensions, and we choose the necessary forces to make the width and height equal again. Following the usual arguments, we get for the three strains:

$$\frac{\Delta L_x}{L} = \frac{1}{Y} \frac{F_x}{A_x} - \frac{\sigma}{Y} \frac{F_y}{A_y} - \frac{\sigma}{Y} \frac{F_z}{A_z} = \frac{1}{Y} \left[\frac{F_x}{A_x} - \sigma \left(\frac{F_y}{A_y} + \frac{F_z}{A_z} \right) \right], \quad (38.15)$$

$$\frac{\Delta L_y}{L} = \frac{1}{Y} \left[\frac{F_y}{A_y} - \sigma \left(\frac{F_x}{A_x} + \frac{F_z}{A_z} \right) \right]. \quad (38.16)$$

$$\frac{\Delta L_z}{L} = \frac{1}{Y} \left[\frac{F_z}{A_z} - \sigma \left(\frac{F_x}{A_x} + \frac{F_y}{A_y} \right) \right]. \quad (38.17)$$

Now since ΔL_x and ΔL_z are supposed to be zero, Eqs. (38.16) and (38.17) give two equations relating F_y and F_z to F_x . Solving them together, we get that

$$\frac{F_y}{A_y} = \frac{F_z}{A_z} = \frac{\sigma}{1-\sigma} \frac{F_x}{A_x}. \quad (38.18)$$

Substituting in (38.15), we have

$$\frac{\Delta L_x}{L} = \frac{1}{Y} \left(1 - \frac{\sigma^2}{1-\sigma} \right) \frac{F_x}{A_x} = \frac{1}{Y} \left(\frac{1-\sigma}{1-\sigma^2} \right) \frac{F_x}{A_x}. \quad (38.19)$$

(Once you will see this turned around, and with the quantities in a factored out, it is then written

$$\frac{F_x}{A_x} = \frac{1-\sigma}{(1-\sigma)^2 - 2\sigma} Y \frac{\Delta L}{L}. \quad (38.20)$$

When we constrain the sides, Young's modulus gets multiplied by a complicated function of σ . As you can now easily see from Eq. (38.19), the factor in front of Y is always greater than 1. It is harder to stretch the block when the sides are held, which also means that a block is stronger when the sides are held than when they are not.

38-3 The torsion bar; shear waves

Let's now turn our attention to an example which is more complicated because different parts of the material are stressed by different amounts. We consider a twisted spring, as you would find in a drive shaft of some machinery, or in a spiral telephone suspension used in a telephone instrument. As you probably know from experiments with the torsion pendulum, the rotation of a twisted rod is proportional to the torque. The constant of proportionality obviously depends upon the length L , the radius r , the radius of the rod, and on the properties of the material. The question is "In what way?" We are now in a position to answer this question: it's just a matter of working out some geometry.

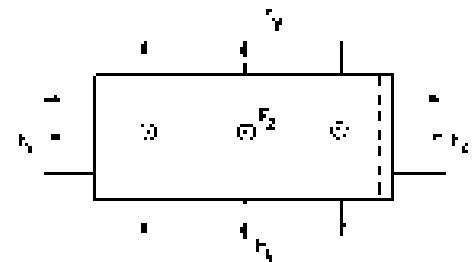

Fig. 38-8. Stretching without lateral contraction.

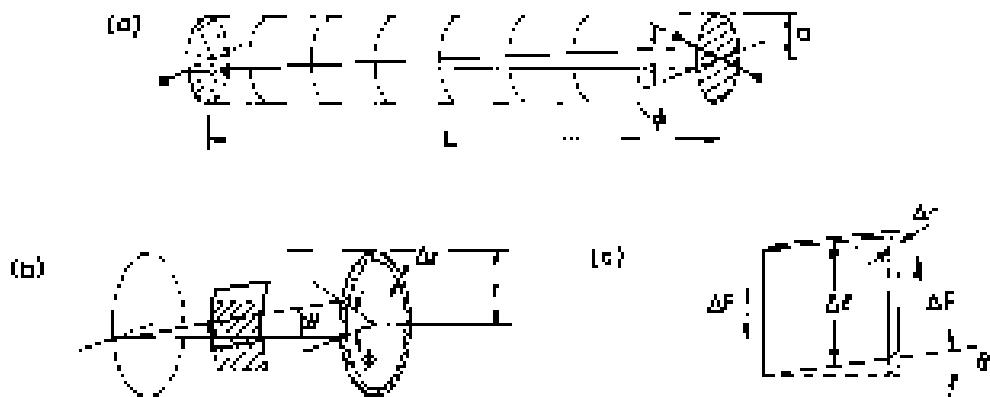

Fig. 19-9. (a) A cylindrical bar in torsion. (b) A cylindrical shell in torsion.
(c) Each small piece of the shell is *r* sheared.

Fig. 19-9(c) shows a cylindrical segment of length $\Delta\ell$ and radius r , with one end twisted by the angle $\Delta\theta$ with respect to the other. If we want to relate the stresses to what we already know, we can think of the rod as being made up of many cylindrical shells and we know separately what happens to each shell. We start by looking at a thin, short cylinder of radius r less than $\Delta\ell$ around the axis of rotation, as shown in Fig. 19-9(b). Now if we look at a piece of this cylinder that was originally a small square, we see that it has been distorted into a parallelogram. Each such element of the cylinder is a *shear*, and the shear angle is

$$\delta = \frac{\Delta\theta}{\ell}.$$

The shear stress τ in the material is, therefore (from Eq. (38.10)),

$$\tau = \mu\delta = \mu \frac{\Delta\theta}{\ell}. \quad (38.21)$$

The shear stress is the tangential force ΔF on the end of the square divided by the area ΔA of the end [see Fig. 19-9(c)].

$$\tau = \frac{\Delta F}{\Delta A}.$$

The force ΔF on the end of such a square contributes a torque $\Delta\tau$ around the axis of the rod equal to

$$\Delta\tau = r \Delta F = r \tau \Delta A. \quad (38.22)$$

The total torque τ is the sum of such torques around the entire diameter of the cylinder. By putting together enough slices as in the disk adding in Fig. 2.6, we find that the total torque for a hollow tube is

$$(\pi r^2 \tau) \Delta r. \quad (38.23)$$

Or, using (38.21),

$$\tau = 2\pi r \frac{r^2 \Delta\theta}{L}. \quad (38.24)$$

We saw that the rotational surface, r/ϕ , of a hollow tube is proportional to the cube of the radius r and to the thickness Δr , and inversely proportional to the length L .

We can now imagine a solid rod to be made up of a series of concentric tubes, each twisted by the same angle $\Delta\theta$ although the internal stresses are different for each tube. The total torque is the sum of the torques required to rotate each solid; for the solid rod

$$\tau = 2\pi r \frac{r^2}{L} \int r^2 dr.$$

where the integral goes from $r = 0$ to $r = a$, the radius of the rod. Integrating, we have

$$\tau = \rho \frac{\partial \phi}{\partial L} \cdot \phi. \quad (38.25)$$

For a rod in torsion, the torque is proportional to the angle and is proportional to the fourth power of the diameter—a rod twice as thick is sixteen times as stiff for torsion.

Before leaving the subject of torsion, let us apply what we have just learned to an interesting problem: torsional waves. If you take a long rod and suddenly twist one end, a wave of twist works its way along the rod, as sketched in Fig. 38-13(a). That's a little more exciting than a steady twist—let's see what happens.

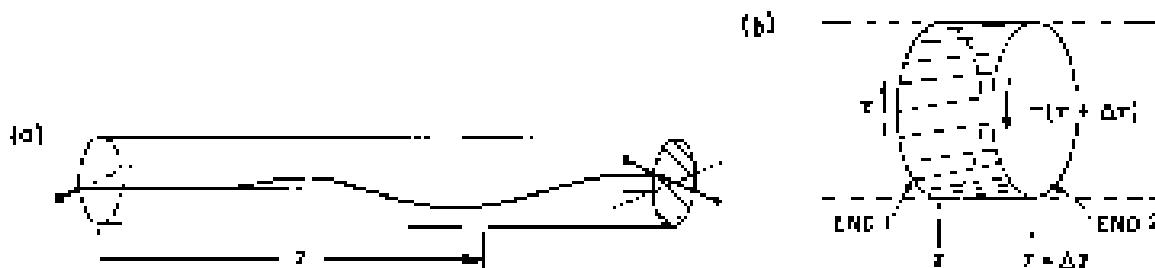

Fig. 38-13. (a) A torsional wave on a rod. (b) A volume element of the rod.

Let z be the distance to some point along the rod. For a static torsion, the torque is the same everywhere along the rod, and is proportional to $\rho \tau / L$, the total torsion angle over the rod length. What matters to the material is the local torsional strain, which is, you will appreciate, $\Delta\phi/L$. When the torsion along the rod is not uniform, we should replace Eq. (38.25) by

$$\tau(z) = \rho \frac{\pi a^4}{2} \frac{\partial \phi}{\partial z}. \quad (38.26)$$

Now let's look at what happens to an element of length Δz shown magnified in Fig. 38-13(b). There is a torque $\tau(z)$ at end 1 of the little hunk of rod, and a different torque $\tau(z + \Delta z)$ at end 2. If Δz is small enough, we can use a Taylor expansion and write

$$\tau(z + \Delta z) = \tau(z) + \left(\frac{\partial \tau}{\partial z} \right)_{z=z} \Delta z. \quad (38.27)$$

The net torque $\Delta\tau$ acting on the little piece of rod between z and $z + \Delta z$ is clearly the difference between $\tau(z)$ and $\tau(z + \Delta z)$, or $\Delta\tau = (\partial\tau/\partial z) \Delta z$. Differentiating Eq. (38.26), we get

$$\Delta\tau = \rho \frac{\pi a^4}{2} \frac{\partial^2 \phi}{\partial z^2} \Delta z. \quad (38.28)$$

The effect of this net torque is to give an angular acceleration to the little slice of the rod. The mass of the slice is

$$\Delta M = (\rho a^2 \Delta z) a,$$

where a is the density of the material. We worked out in Chapter 10, Vol. 1, that the moment of inertia of a circular cylinder is $\pi a^4/4$; calling the moment of inertia of our piece ΔI , we have

$$\Delta I = \frac{\pi}{4} \rho a^4 \Delta z. \quad (38.29)$$

Newton's law says the torque is equal to the moment of inertia times the angular acceleration, or

$$\Delta\tau = \Delta I \frac{\partial^2 \phi}{\partial z^2}. \quad (38.30)$$

Pulling everything together, we get

$$\begin{aligned} \frac{\pi a^2 \rho^2 c^2}{2} \frac{\partial^2 \phi}{\partial r^2} \Delta r &= \frac{\pi}{2} \rho a^4 \Delta r \frac{\partial^2 \phi}{\partial t^2}, \\ \text{or} \quad \frac{\partial^2 \phi}{\partial r^2} - \frac{\rho a^2 \partial^2 \phi}{\mu c^2 \partial t^2} &= 0 \end{aligned} \quad (38.31)$$

You will recognize this as the one-dimensional wave equation. We have found that waves of motion will propagate down the rod with the speed

$$C_{\text{shear}} = \sqrt{\frac{E}{\rho}}. \quad (38.32)$$

The *stiffer* the rod—*for the same stiffness*—the *faster* the waves; and the *stiffer* the rod, the quicker the waves work their way down. The speed does not depend upon the diameter of the rod.

Torsional waves are a special example of shear waves. In general, shear waves are those in which the strains do not change the volume of any part of the material. In torsional waves, we have a permanent distribution of such shear stresses—namely, distributed on a circle. But for any arrangement of shear stresses, waves will propagate with the same speed—the one given in Eq. (38.32). (For example, the seismologists find such shear waves travelling in the interior of the earth.)

We can have another kind of a wave in the elastic world inside a solid material. If you push something, you can start "longitudinal" waves—also called "compressional" waves. They are like the sound waves in air or in water—the displacements are in the same direction as the wave propagation. (At the surfaces of an elastic body there can also be other types of waves, called "Rayleigh waves" or "Love waves." In them, the strains are neither purely longitudinal nor purely transverse. We will not have time to study them.)

While we're on the subject of waves, what is the velocity of the pure compression waves in a dog, in a bird, like the earth? We say "large" because the speed of sound in a thick body is different from what it is, for instance, along a thin rod. By a "thick" body we mean one in which the transverse dimensions are much larger than the wavelength of the sound. Then, when we push on the object, it cannot expand sideways—it can only compress in one dimension. Fortunately, we have already worked out the special case of the compression of a constrained elastic material. We have also worked out in Chapter 17, Vol. I, the speed of sound waves in a gas. Following the same argument, you can see that the speed of sound in a solid is equal to $\sqrt{Y/\rho}$, where Y is the "longitudinal modulus"—or pressure divided by the relative change in length. (For the constrained case, this is just the ratio of E/l to ρ/l ; we got it in Eq. (38.20).) So the speed of the longitudinal waves is given by

$$C_{\text{long}} = \sqrt{\frac{Y}{\rho}} = \sqrt{\frac{1-\sigma}{(1+\sigma)(1+2\sigma)}} \frac{E}{\rho}. \quad (38.33)$$

So long as σ is between zero and $1/2$, the shear modulus ρ is less than Young's modulus Y , and also, Y is greater than ρ , so:

$$2 < Y < 12.$$

This means that longitudinal waves travel faster than shear waves. One of the most precise ways of measuring the elastic constants of a substance is by measuring the density ρ of the material and the speeds of the two kinds of waves. From this information we can get both Y and ρ . It is, incidentally, by measuring the difference in the arrival times of the two kinds of waves from an explosion that a seismologist can estimate—even from the signal at only one station—the distance to the quake.

38-4 The bent beam

We want now to look at another practical situation—the bending of a rod or a beam. What are the forces when we bend a bar of some arbitrary cross section? We will work it out thinking of a bar with a circular cross section, but our answer will be good for any shape. To see this, however, we will cut some corners, so our theory will work out only approximately. Our results will be correct, only when the radius of the bend is much larger than the thickness of the beam.

Suppose you grab the two ends of a straight bar and bend it into some curve like the one shown in Fig. 38-11. What goes on inside the bar? Well, it is curved, that means that the material on the inside of the curve is compressed and the material along the outside is stretched. There is some surface which goes along more or less parallel to the axis of the bar that is neither stretched nor compressed. This is called the *neutral surface*. You would expect this surface to be near the "middle" of the cross section. It can be shown (but we won't do it here) that, for small bending of a simple beam, the neutral surface goes through the "center of gravity" of the cross section. This is true only for "plane" bending—if you are not stretching or compressing the beam at the same time.

For pure bending, then, a thin transverse slice of the bar is distorted as shown in Fig. 38-12(a). The material below the neutral surface has a compressional strain which is proportional to the distance from the neutral surface; and the material above is stretched, as its position is farther from the neutral surface. So the longitudinal stretch is proportional to the height y . The constant of proportionality is just $1/R$, the radius of curvature of the bar (see Fig. 38-12):

$$\frac{dy}{y} = \frac{\beta}{R}$$

So the force per unit area—the stress—in a small strip at y is also proportional to the distance from the neutral surface:

$$\frac{\Delta F}{\Delta A} = \frac{F}{R}, \quad (38.34)$$

Now let's look at the forces that would produce such a strain. The forces acting on the little segment drawn in Fig. 38-12 are shown in the figure. If we think of any transverse cut, the forces acting across it are one way above the neutral surface and the other way below. They come in pairs to make a "bending moment" M —by which we mean the torque about the neutral line. We can compute the total moment by integrating the force times the distance from the neutral surface for one of the strips of the segment of Fig. 38-12:

$$M = \int_{-R/2}^{R/2} y dF. \quad (38.35)$$

From Eq. (38.34), $dF = YI/R dA$, so

$$M = \frac{YI}{R} \int_{-R/2}^{R/2} y^2 dA.$$

The integral of $y^2 dA$ is what we shall call the "moment of inertia" of the geometric cross section about a horizontal axis through its "center of gravity," we will call it I :

$$I = \frac{YI}{R}. \quad (38.36)$$

$$I = \int r^2 dA. \quad (38.37)$$

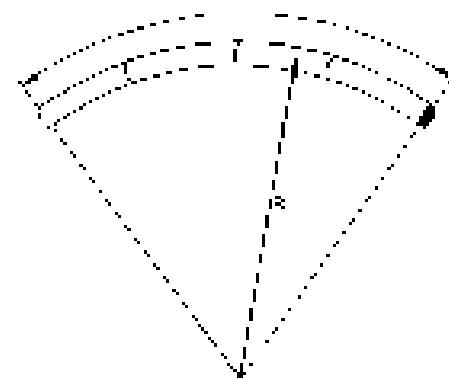

Fig. 38-11. A bent beam.

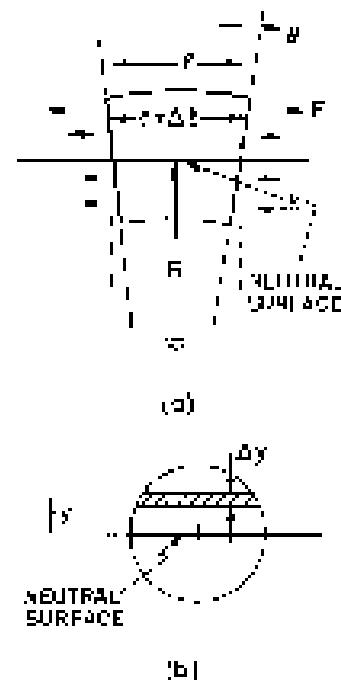

Fig. 38-12. (a) Small segment of a bent beam. (b) Cross section of the beam.

* It is, of course, really the moment of inertia of a beam with width Δx , mass $\rho \Delta x$, and a radius of gyration R .

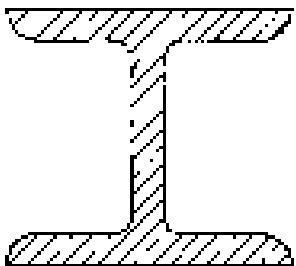

Fig. 38-13. An "I" beam.

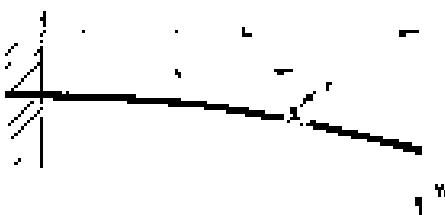

Fig. 38-14. A cantilevered beam with a weight at one end.

Equation (38.36), then, gives us the relation between the bending moment M and the curvature $1/R$ of the beam. The "stiffness" of the beam is proportional to E and to the moment of inertia I . In other words, if you want the stiffer possible beam with a given amount of, say, aluminum, you want to put as much of it as possible as far as you can from the neutral surface, to make a larger moment of inertia. You can't carry this to an extreme, however, because then the thing will not curve as we have supposed—it will buckle or twist and become weaker again. But now you see why structural beams are made in the form of an I or an H, as shown in Fig. 38-13.

As an example of the use of our beam equation (38.36), let's work out the deflection of a concentrated beam with a concentrated force W acting at the free end, as sketched in Fig. 38-14. (By "cantilevered" we simply mean that the beam is supported in such a way that both the position and the slope are fixed at one end—let's call it the center, wall.) What is the shape of the beam? Let's call the deflection at the distance x from the fixed end ζ ; we want to know $\zeta(x)$. We'll work it out only for small deflections. We will also assume that the beam is long in comparison with its cross section. Now, as you know from your mathematics courses, the curvature $1/R$ of any curve $\zeta(x)$ is given by

$$\frac{1}{R} = \frac{\zeta''(x)/dx^2}{1 - (\zeta'(x)/dx)^2} \quad (38.35)$$

Since we are interested only in small slopes (this is usually the case in engineering structures), we neglect $(\zeta'(x)/dx)^2$ in comparison with 1, and take

$$\frac{1}{R} = \frac{\zeta''(x)}{\zeta'(x)} \quad (38.36)$$

We also need to know the bending moment M . It is a function of x because it is equal to the torque about the neutral axis of any cross section. Let's neglect the weight of the beam and take only the downward force W at the end of the beam. (You can put in the beam weight yourself if you want.) Then the bending moment at x is

$$M(x) = W(L - x),$$

because that is the torque about the point x exerted by the weight W —the torque which the beam resists, support of x . We get

$$W(L - x) = \frac{M}{R} = \frac{M}{I} \frac{d^2\zeta}{dx^2}$$

or

$$\frac{d^2\zeta}{dx^2} = \frac{W}{I} (L - x). \quad (38.40)$$

This one we can integrate without any tricks; we get

$$\zeta = \frac{W}{I} \left(\frac{Lx^2}{2} - \frac{x^3}{3} \right), \quad (38.41)$$

using our assumptions that $\zeta(0) = 0$ and that $d\zeta/dx$ is also zero at $x = 0$. That is the shape of the beam. The displacement at the end is

$$\zeta(L) = \frac{W}{I} \frac{L^3}{3}, \quad (38.42)$$

the displacement of the end of a beam increases as the cube of the length.

In deriving our approximate beam theory, we have assumed that the axes section of the beam did not change when the beam was bent. When the thickness of the beam is small compared to the radius of curvature, the cross section changes very little and our result is O.K. In general, however, this effect cannot be neglected, as you can easily demonstrate for yourselves by bending a stiff rubber eraser in your fingers. If the cross section was originally rectangular, you will find that when

it is bent or bended at the bottom (see Fig. 38-15). This happens because when we compress the bar/bam, the material expands sideways – as described by Poisson's ratio. But then it's easy to bend or even to break it, as you only take a liquid in that, it's hard to change the volume – as it's only when you bend the eraser. For an incompressible material, Poisson's ratio would be exactly $1/2$ – for rubber it's nearly that.

38-5 Buckling

We want now to use our beam theory to understand the theory of the "buckling" of beams, or columns, or rods. Consider the situation sketched in Fig. 38-16 in which a rod that would normally be straight is held in its bent shape by two opposite forces that push on the ends of the rod. We would like to calculate the shape of the rod and the magnitude of the force on the ends.

Let the deflection of the rod from the straight line between the ends be $r(x)$, where x is the distance from one end. The bending moment $M(x)$ at the point P in the figure is equal to the force F multiplied by the moment arm, which is the perpendicular distance r ,

$$M(x) = Fr. \quad (38.42)$$

Using the beam equation (38.36), we have

$$\frac{d^2r}{dx^2} = F/EI. \quad (38.43)$$

For small deflections, we see that $1/R = -d^2r/dx^2$ (the minus sign because the curvature is downward). We get

$$\frac{d^2r}{dx^2} = -\frac{F}{EI}/R. \quad (38.44)$$

which is the differential equation of a sine wave. So for small deflections, the curve of such a beam looks is a sine curve. The "wavelength" λ of the sine wave is twice the distance L between the ends. If the bending is small, this is just twice the unbent length of the rod. So the curve is

$$r = R \sin(\pi x/L).$$

Taking the second derivative, we get

$$\frac{d^2r}{dx^2} = -\frac{\pi^2}{L^2}R.$$

Comparing this to Eq. (38.43), we see that the force is

$$F = \pi^2 EI/L^2. \quad (38.45)$$

For small enough the force is *independent of the bending displacement*!

We know that the building is physically – if the force is less than the F , given in Eq. (38.45), there will be no bending at all. But if F is slightly greater than F , the beam will suddenly bend a large amount – that is, it's most often the applied force F that's "YET" (prior to last the "stability") the beam will "buckle". If the bending on the second floor of a building exceeds the Euler angle for the supporting elements, the building will collapse. Another place where the buckling force is used is in space rockets. On one hand, the rocket must be able to withstand own weight on the launching pad and ensure the stresses during steady motion; on the other hand, it is important to keep the weight of the structure to a minimum, so that the pay load and the economy may be made as large as possible.

Actually a beam will just *collapse* completely when the force reaches the Euler force. When the displacements get large, the force is larger than

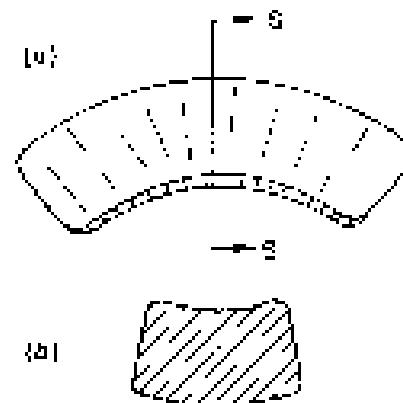

Fig. 38-15. (a) A bent eraser, (b) cross section.

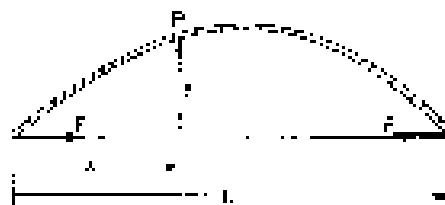

Fig. 38-16. A buckled beam.

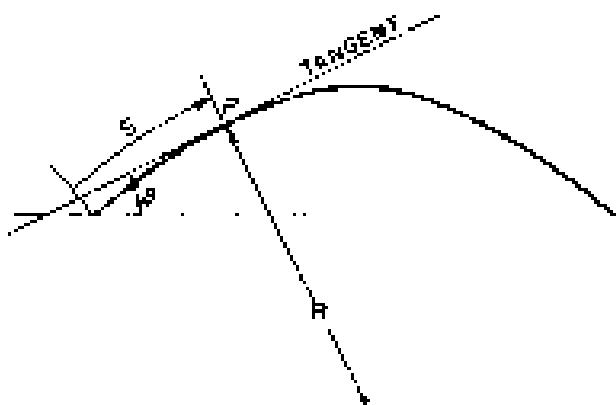

Fig. 38-17. The coordinates S and λ for the curve of a bent beam.

what we have found because of the terms in $1/R$ in Eq. (38.38) that we have neglected. To find the forces for a large bending of the beam, we have to go back to the exact equation, Eq. (38.44), which we had before we used the approximate relation between R and y . Equation (38.44) has a rather simple geometrical property.* It's a little complicated to work out, but rather interesting. Instead of describing the curve in terms of x and y , we can use two new variables: S , the distance along the curve, and λ , the slope of the tangent to the curve. See Fig. 38-17. The curvature is the rate of change of angle with distance:

$$\frac{1}{R} = -\frac{d\lambda}{dy}.$$

We can, therefore, write the exact equation (38.4) as

$$\frac{dy}{dx} = -\frac{F}{pI} \sin \lambda.$$

If we take the derivative of this equation with respect to S and replace dy/dxS by $d\lambda/dS$, we get

$$\frac{d^2\lambda}{dS^2} = -\frac{F}{pI} \sin \lambda. \quad (38.47)$$

[If λ is small, we get back Eq. (38.46). Every line is O.K.]

Now it may or may not delight you to know that Eq. (38.47) is exactly the same one you get for the large-amplitude oscillations of a pendulum with F/I replaced by another constant, of course. We learned how much in Chapter 11. We know how to find the solutions of such an equation by a numerical calculation—but the answers you get are some fascinating curves—known as the curves of the “Elastic.” Figure 38-18 shows three curves for different values of F/I .

* The exact equation appears, interestingly, in the problem of curved structures. In example 10 you saw all the surface of a liquid contained between parallel planes—and the geometric solution can be used.

† The solutions can also be expressed in terms of so-called functions called the “Jacobi elliptic functions,” the so-called Jacobi elliptic functions.

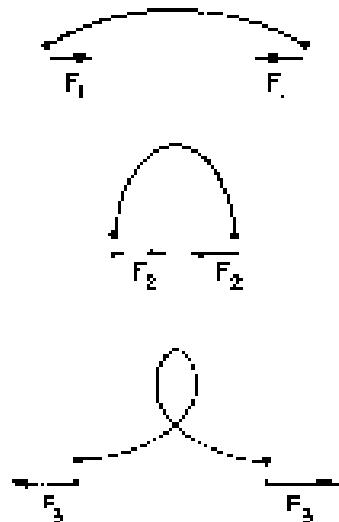

Fig. 38-18. Curves of a bent rod.

Elastic Materials

39-1 The tensor of strain

In the last chapter we talked about the distortions of various elastic objects. In this chapter we want to look at what can happen in general inside an elastic material. We would like to be able to describe the components of stress and strain inside some big blob of stuff which is roughly an sphere or in some complicated way. To do this, we need to be able to extend the idea of strain to every point in an elastic body; we can do this by giving a set of numbers—which are the components of a symmetric tensor—for each point. Earlier, we spoke of the stress tensor (Chapter 31); now we need the tensor of strain.

Imagine that we start with the material initially undeformed and watch the motion of a small speck of "dirt" embedded in the material when the strain is applied. A speck that was at the point P located at $r = (x, y, z)$ moves to a new position P' at $r' = (x', y', z')$ as shown in Fig. 39-1. We will call \mathbf{r} the vector displacement from P to P' . Then

$$\mathbf{r}' = \mathbf{r} + \mathbf{u} \quad (39-1)$$

The displacement \mathbf{u} depends, of course, on which point P we start with, so it is a vector function of r —or, if you prefer, of (x, y, z) .

Let's look first at a simple situation in which the strain is constant over the material—so we have what is called a homogeneous strain. Suppose, for instance, that we have a block of material and we stretch it uniformly. We just change all dimensions uniformly in one direction—say, in the x -direction, as shown in Fig. 39-2. The motion u_x of a speck at x is proportional to x . In fact,

$$\frac{u_x}{x} = \frac{\Delta l}{l}$$

We will write it this way:

$$u_x = \epsilon_{xx} x,$$

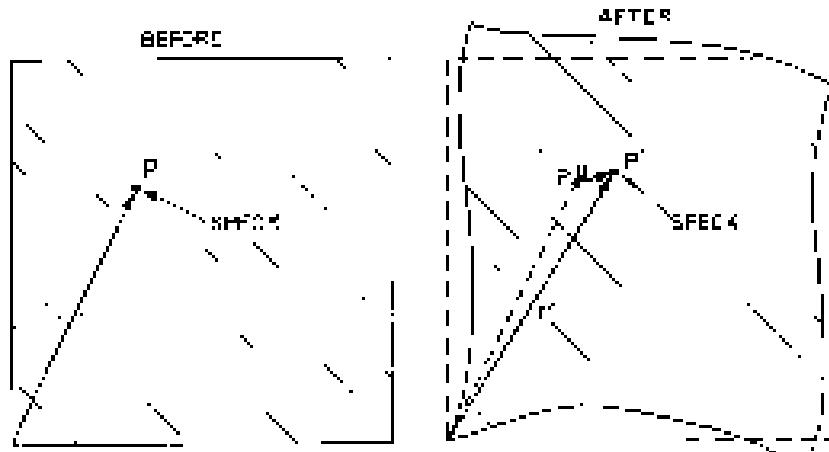

Fig. 39-1. A speck of the material at the point P in an undeformed block moves to P' where the block is strained.

39-4 Nonelastic behavior

39-5 Calculating the elastic constants

Reference: C. Kittel, *Introduction to Solid State Physics*, John Wiley and Sons, Inc., New York, third ed., 1976.

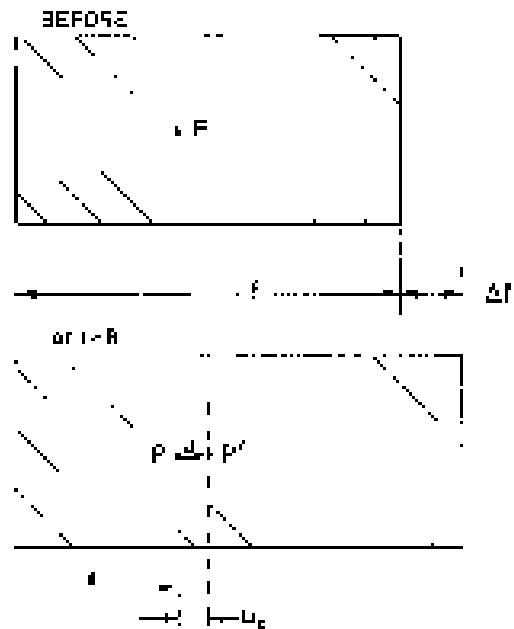

Fig. 39-2. A homogeneous stretch-type strain.

The proportionality constant ϵ_{xx} is, of course, the stretch ratio A/J . (You will see shortly why we use a double subscript.)

If the strain is not uniform, the relation between ϵ_x and ϵ will vary from place to place in the sample. For the general situation, we define the ϵ_{xy} by a kind of local δ/J , namely by

$$\epsilon_{xy} = \frac{\partial u_y}{\partial x}, \quad (39.2)$$

This number—which is now a function of x , y , and z —describes the amount of stretching in the y -direction throughout the block of jello. There may, of course, also be stretching in the x - and z -directions. We describe them by the numbers

$$\epsilon_{xz} = \frac{\partial u_z}{\partial x}, \quad \epsilon_{yz} = \frac{\partial u_z}{\partial y}. \quad (39.3)$$

We now turn to the inhomogeneous shear-type strain. Suppose we imagine a little cube snipped out of the initially unstrained jello. When the jello is passed through a shear, this cube may get elongated in a parallelepipedon, as sketched in Fig. 39.3. Up the back of each side of the cube an equal amount of stretching is proportional to y -displacement.

$$u_x = \frac{\delta}{2} y, \quad (39.4)$$

And there is also a rotation proportional to x ,

$$u_y = \frac{\theta}{2} x, \quad (39.5)$$

So we can describe such a shear-type strain by writing

$$u_x = \epsilon_{xy} y, \quad u_y = \theta x + \epsilon_{yz} x$$

with

$$\epsilon_{xz} = \epsilon_{yz} = \frac{\theta}{2}.$$

Now you might think that when the strains are not homogeneous, we could get rid of the generalized shear strain by defining the quantities ϵ_{xy} and ϵ_{yz} by

$$\epsilon_{xy} = \frac{\partial u_y}{\partial y}, \quad \epsilon_{yz} = \frac{\partial u_z}{\partial y}. \quad (39.6)$$

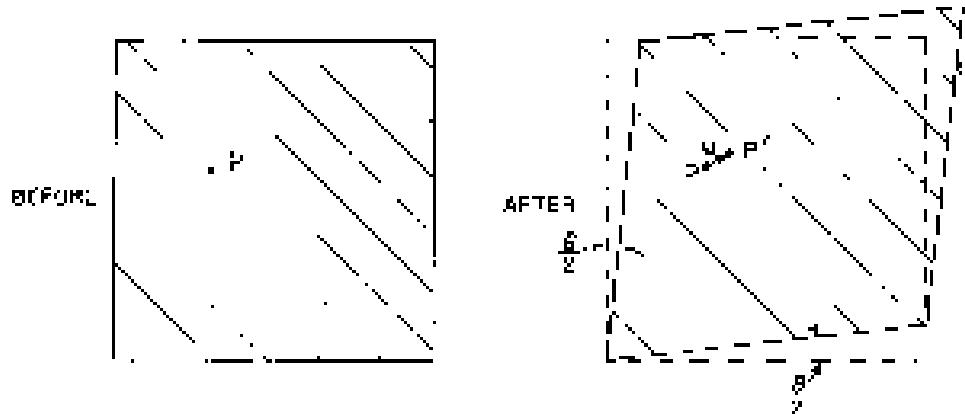

Fig. 39.3. A homogeneous shear strain.

But there is a difficulty. Suppose that the displacements u_x and u_y were given by

$$u_x = \frac{\theta}{2} y, \quad u_y = -\frac{\theta}{2} x,$$

* We propose for the moment to split the total shear angle θ into two equal parts and make the x-axis symmetric with angles $\pi/6$ and $-\pi/6$.

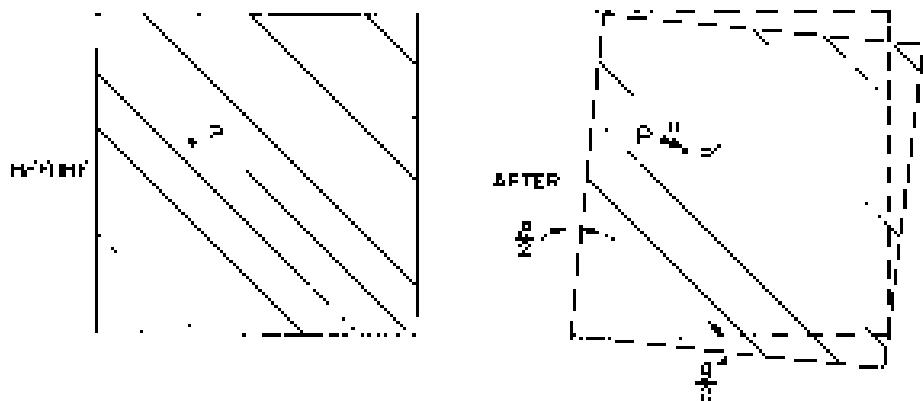

Fig. 39-4. A homogeneous rotation—there is no strain.

They are like Eqs. (39.4) and (39.5) except that the sign of ω_y is reversed. With these displacements a little cube in the jelly simply gets shifted by the angle $\omega_z/2$, as shown in Fig. 39-4. There is no strain at all; just a rotation in space. There is no distortion of the material, the relative positions of all the atoms are unchanged at all. We must somehow make our calculations so that plane rotations are not included in our definitions of a shear strain. The key point is that if ω_x/ω_z and ω_y/ω_z are equal and opposite, that is desirable, so we can lie things up by defining

$$\epsilon_{xy} = \epsilon_{yx} = \frac{1}{2}(\partial u_y / \partial x - \partial u_x / \partial y).$$

For a pure rotation they are both zero, but for a pure shear we get that ϵ_{xy} is equal to ϵ_{yx} , as we would like.

In the most general distortion—which may include stretching or compression as well as shear—we define the state of strain by giving the nine numbers

$$\begin{aligned}\epsilon_{xx} &= \frac{\partial u_x}{\partial x}, \\ \epsilon_{yy} &= \frac{\partial u_y}{\partial y}, \\ \epsilon_{zz} &= \frac{\partial u_z}{\partial z}, \\ \epsilon_{xy} &= \frac{1}{2}(\partial u_y / \partial x - \partial u_x / \partial y), \\ \epsilon_{yz} &= \frac{1}{2}(\partial u_z / \partial y - \partial u_y / \partial z), \\ \epsilon_{xz} &= \frac{1}{2}(\partial u_z / \partial x - \partial u_x / \partial z).\end{aligned}\quad (39.7)$$

These are the terms of a tensor of strain. Because it is a covariant tensor, our definitions make $\epsilon_{xy} = \epsilon_{yx}$ always; there are really only six different numbers. You remember (see Chapter 11) that the general characteristic of a tensor is that the terms transform like the products of the components of two vectors. (If A and B are vectors, $C_{ij} = A_i B_j$ is a tensor.) Each term of ϵ_{ij} is a product (or linear combination of products) of the components of the vector $\omega = (\omega_x, \omega_y, \omega_z)$, and of the vector $\nabla = (\partial/\partial x, \partial/\partial y, \partial/\partial z)$, which we know transforms like a vector. Let's let x_1 , x_2 , and x_3 stand for x , y , and z ; and u_1 , u_2 , and u_3 stand for u_x , u_y , and u_z ; then we can write the general term ϵ_{ij} of the strain tensor as

$$\epsilon_{ij} = \frac{1}{2}(\partial u_j / \partial x_i + \partial u_i / \partial x_j), \quad (39.8)$$

where i and j can be 1, 2, or 3.

When we have a homogeneous strain, which may include both stretching and shear, all of the ϵ_{ij} are constants, and we can write

$$u_i = \epsilon_{ix} x + \epsilon_{iy} y + \epsilon_{iz} z. \quad (39.9)$$

(We choose our origin of x_1 , x_2 , x_3 at the point where ω is zero.) In this case, the strain tensor ϵ_{ij} gives the ratio λ (shear) between two vectors: the coordinate vector $r = (x_1, x_2, x_3)$ and the displacement vector $u = (u_1, u_2, u_3)$.

When the strains are not homogeneous, any piece of the jelly may also get somewhat twisted - there will be a local rotation. If the distortions are all small, we would have

$$\Delta\omega_i = \sum_j (\epsilon_{ij} - \omega_{ij}) \Delta x_{ij}, \quad (39.10)$$

where ω_{ij} is an unperturbed tensor,

$$\omega_{ij} = \frac{1}{2}(\partial u_j / \partial x_i + \partial u_i / \partial x_j), \quad (39.11)$$

which describes the rotation. We will, however, not worry any more about rotations, but only about the strains described by the symmetric tensors.

39-2. The tensor of elasticity

Now that we have described the strains, we want to relate them to the internal forces: the stresses in the material. For the small piece of the material, we assume Hooke's law holds and write just the stresses and proportional to the strains. In Chapter 11 we defined the stress tensor S_{ij} as the P.I. (the product of the force across a unit area) perpendicular to the j -axis. Hooke's law says that each component of S_{ij} is linearly related to each of the components of strain. Since 5 and ϵ each have nine components, there are $9 \times 9 = 81$ possible coefficients which describe the elastic properties of the material. They are constants if the material itself is homogeneous. We write these coefficients as C_{ijkl} and define them by the equation

$$S_{ij} = \sum_k C_{ijkl} \epsilon_{kl}, \quad (39.12)$$

where i, j, k, l all take on the values 1, 2, or 3. Since the coefficients C_{ijkl} relate one tensor to another, they also form a tensor - a tensor of the fourth rank. We can call it the tensor of elasticity.

Suppose that all the C 's are known and that you put a complicated force on an object of some peculiar shape. There will be all kinds of distortion, and the thing will settle down with some twisted shape. What are the displacements? You can see that it is a complicated problem. If you knew the strains, you could find the stresses from Eq. (39.12) - or vice versa. But the stresses and strains you end up with at any point depend on what happens in all the rest of the material.

The easiest way to get at the problem is by thinking of the energy. When there is a force F proportional to a displacement x , say $F = kx$, the work required for any displacement x is $kx^2/2$. In a similar way, the work W that goes into each cubic volume of a distorted material turns out to be

$$W = \frac{1}{2} \sum_{ijkl} C_{ijkl} \epsilon_{kl} \Delta x_{ij}, \quad (39.13)$$

The total work W done in deforming the body is the integral of W over all the

$$W = \int \frac{1}{2} \sum_{ijkl} C_{ijkl} \epsilon_{kl} \Delta x_{ij} d\text{Vol}. \quad (39.14)$$

This is then the potential energy stored in the internal stresses of the material. Now when a body is in equilibrium, this internal energy must be at a minimum. So the problem of finding the strains in a body can be solved by finding the set of displacements throughout the body which will make W a minimum. In Chapter 19 we gave some of the general ideas of the calculus of variations. Let us look at buckling minimization problems like this. We cannot go into the problem in any more detail here.

What we are mainly interested in now is what we can say about the general properties of the tensor of elasticity. First, it is clear that there are not really 81 different terms in C_{ijkl} . Since just S_{ij} and ϵ_{ij} are symmetric tensors, and with only six different terms, there can be at most 36 different terms in C_{ijkl} . There are, however, usually many fewer than this.

Let's look at the special case of a cubic crystal. In it, the energy density is given as follows:

$$\begin{aligned} \epsilon &= \frac{1}{2}(C_{xx}e_{xx}^2 + C_{yy}e_{yy}^2 + C_{zz}e_{zz}^2) \\ &= C_{xy}e_{xy}^2 + C_{yz}e_{yz}^2 + \dots + C_{xz}e_{xz}^2 + \dots \quad (39.15) \end{aligned}$$

with δ_i 's running in all! Now a cubic crystal has certain symmetries, etc. In particular, if the crystal is rotated 90° , it has the same physical properties—it has the same stiffness for stretching in the x -direction as for stretching in the y -direction, etc. Therefore, if we change our definition of the coordinate directions x and y in Eq. (39.15), the energy wouldn't change. It must be true for a cubic crystal

$$C_{xx} = C_{yy} = C_{zz} \quad (39.16)$$

Next we can show that the terms like C_{xy} must be zero. A cubic crystal has the property that it is symmetric under a reflection in any plane perpendicular to one of the axes. If we replace y by $-y$, nothing is different. But changing y to $-y$ changes e_{xy} to $-e_{xy}$, a displacement which was toward y is now toward $-y$. If the energy is not to change, C_{xy} must go into $-C_{xy}$ when we make a reflection. But a reflected crystal is the same as before, so C_{xy} must be the same as C_{-xy} . This can happen only if $C_{xy} = 0$.

You say, "But the same argument will make $C_{xy} = 0$!" No, because there are four y 's. The sign changes once for each y , and four times make a plus. If there are *odd* number's, the term does not have to be zero. It is zero only when there is *even*, etc. Now, for a cubic crystal, any nonzero term of C will have only an even number of identical subscripts. (The arguments we have made for y obviously hold also for x and z .) We might then have terms like C_{xxy} , C_{xyz} , C_{xyz} , and so on. We have already shown, however, that if we change all x 's to y 's and vice versa (or all z 's and x 's, and so on) we must get—for a cubic crystal—the same number. This means that there are only four different nonzero possibilities:

$$\begin{aligned} C_{xxx} &= C_{yyy} = C_{zzz}, \\ C_{xyy} &= C_{yyx} = C_{zyz}, \text{ etc.} \\ C_{xzy} &= C_{zyx} = C_{xyz}, \text{ etc.} \end{aligned} \quad (39.17)$$

For a cubic crystal, then, the energy density will look like this:

$$\begin{aligned} \epsilon &= \frac{1}{2}(C_{xxx}e_{xx}^2 + e_{yy}^2 + e_{zz}^2 \\ &\quad + 2C_{xyy}e_{xy}^2 + e_{yyx}^2 + e_{yyz}^2) \\ &\quad + 4C_{xzy}e_{xz}^2 - e_{yy}^2 - e_{yyz}^2). \end{aligned} \quad (39.18)$$

For an isotropic—that is, monocrystalline—material, the symmetry is still higher. The C 's must be the same for any choice of the coordinate system. Then it turns out that there is another relation among the C 's, namely, that

$$C_{xxx} = C_{yyy} = C_{zzz} \quad (39.19)$$

We can see that this is so by the following general argument. The stress tensor S_{ij} has to be related to e_{ij} in a way that doesn't depend at all on the coordinate directions—it must be related only by *scalar* quantities. "That's easy," you say. "The only way to obtain S_{ij} from e_{ij} is by multiplication by a scalar constant. It's just Hooke's law. It must be that $S_{ij} = (\text{const.})e_{ij}$." But that's not quite right: there could also be the *wave vector* k , multiplied by some scalar, linearly related to e_{ij} . The only invariant you can make that is linear in the e 's is $\sum e_{ii}$. (It transforms like $x^2 + y^2 + z^2$, which is a scalar.) So the most general form for the equation relating S_{ij} to e_{ij} —for isotropic materials—is

$$S_{ij} = 2\mu e_{ii} + \lambda \left(\sum_k e_{kk} \right) \delta_{ij}. \quad (39.20)$$

(The first constant is usually written as two times μ ; then the coefficient λ is equal

to the shear modulus we defined in the last chapter). The constants μ and λ are called the Timoshenko elastic constants. Comparing Eq. (39.20) with Eq. (39.13), you see that

$$\begin{aligned} C_{111111} &= \lambda, \\ C_{222222} &= 2\mu, \\ C_{121212} &= 2\mu + \lambda. \end{aligned} \quad (39.21)$$

So we have proved that Eq. (39.10) is indeed true. You also see that the elastic properties of an isotropic material are completely given by two constants, μ and λ , as in the last chapter.

The C 's can be put in terms of any two of the elastic constants we have used earlier—for instance, in terms of Young's modulus E and Poisson's ratio ν . We will leave it for you to show that

$$\begin{aligned} C_{111111} &= \frac{E}{1 - \nu} \left(1 + \frac{\nu}{2\mu} \right), \\ C_{222222} &= \frac{E}{1 - \nu} \left(\frac{\nu}{2\mu} \right), \\ C_{121212} &= \frac{E}{(1 + \nu)^2}. \end{aligned} \quad (39.22)$$

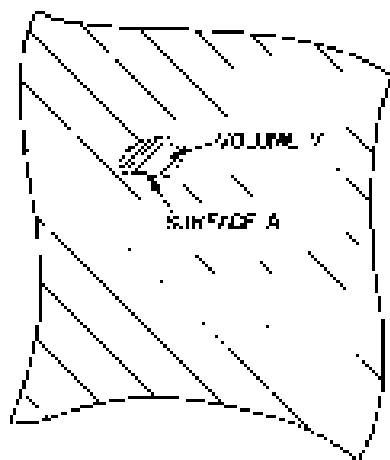

Fig. 39-5. A small volume element V bounded by the surface A .

39-3 The motions in an elastic body

We have pointed out that for an elastic body in equilibrium the internal stresses adjust themselves to make the energy minimum. Now we take a look at what happens when the internal forces are not in equilibrium. Let's say we have a small piece of the material inside some surface A . See Fig. 39-5. If the piece is in equilibrium, the total force F acting on it must be zero. We can think of this force as being made up of two parts. There could be one part due to "external" forces like gravity, which act from a distance on the matter in the piece to produce a force per unit volume f_{ext} . The total external force F_{ext} is the integral of f_{ext} over the volume of the piece:

$$F_{ext} = \int f_{ext} dV. \quad (39.23)$$

In equilibrium, this force would be balanced by the total force F_{int} from the neighboring material which acts across the surface A . When the piece is not in equilibrium—if it is moving—the sum of the internal and external forces is equal to the mass times the acceleration. We would have

$$F_{tot} = F_{int} = \int \rho r dV, \quad (39.24)$$

where ρ is the density of the material, and r is its acceleration. We can now combine Eqs. (39.23) and (39.24) writing

$$F_{int} = \int (f_{ext} - \rho r) dV. \quad (39.25)$$

We will simplify our writing by defining

$$f = -f_{ext} + \rho r. \quad (39.26)$$

Then Eq. (39.25) is written

$$F_{int} = \int f dV. \quad (39.27)$$

What we have called F_{int} relates to the stress in the material. The stress tensor S_{ij} was defined (Chapter 37) so that the i -component of the force of an area dA on a surface element dA , whose unit normal is a_i , is given by

$$dF_i = (S_{xx})_{ij} a_i + (S_{yy})_{ij} a_j + (S_{zz})_{ij} a_k dA. \quad (39.28)$$

The decomposition of F_{ij} on our little piece is then the integral of dF , over the surface. Substituting this into the ϵ_{ijk} -component of Eq. (39.27), we get

$$\int_{\partial V} (S_{ij}\epsilon_{ijk} - S_{kj}\epsilon_{ijk} - S_{ki}\epsilon_{ijk}) d\sigma = \int_V f_j dV. \quad (39.29)$$

We have a surface integral related to a volume integral—and that reminds us of something we learned in electricity. Were I to verify you might see the first component S_{ij} on each of the S 's in the left-hand side of Eq. (39.29); it looks just like the integral of a quantity “ N ” $\cdot \mathbf{n}$, that is, the normal component of a vector over the surface. It would be the flux of “ N ” out of the volume. And this could be written, using Gauss law, as the volume integral of the divergence of “ N ”. It is, in fact, true whether the x -subscript i is there or not; it's just a mathematical theorem you get by integrating by parts. In other words, we can change Eq. (39.29) into

$$\int_V \left(\frac{\partial S_{ij}}{\partial x_i} + \frac{\partial S_{ik}}{\partial x_j} + \frac{\partial S_{jk}}{\partial x_i} \right) dx = \int_V f_j dV. \quad (39.30)$$

Now we can leave off the volume integral and write the differential equation for the general component ϵ_{ijk}^i as

$$f_j = \sum_i \frac{\partial S_{ij}}{\partial x_j}. \quad (39.31)$$

This tells us how the force per unit volume is related to the stress tensor S_{ij} .

The theory of the motions inside a solid works this way. If we start out knowing the initial displacement—given by, say, \mathbf{u} —we can work out the strains ϵ_{ij} . From the strains we can get the stresses from Eq. (39.12). From the stresses we can get the force density f in Eq. (39.31). Knowing f we can go to Eq. (39.16), the acceleration \mathbf{r} of the material, which tells us how the displacements will be changing. Putting everything together, we get the familiar equation of motion for an elastic solid. We will also write down the results that come out for an isotropic material. If you use (39.20) for S_{ij} , and write the ϵ_{ij} as $\partial u_i / \partial x_j = \partial u_j / \partial x_i$, you end up with the vector equation

$$f = (\alpha + \omega) \nabla(\nabla \cdot \mathbf{u}) + \nu \nabla^2 \mathbf{u}. \quad (39.32)$$

You can, in fact, see that the equation relating f and \mathbf{u} must have this form. The force must depend on the second derivatives of the displacement \mathbf{u} . What second derivatives of \mathbf{u} are there that are vectors? One is $\nabla(\nabla \cdot \mathbf{u})$; that's a true vector. The only other one is $\nabla^2 \mathbf{u}$. So the most general form is

$$f = \alpha \nabla(\nabla \cdot \mathbf{u}) + \nu \nabla^2 \mathbf{u},$$

which is just (39.42) with a different relation of the constants. You may be wondering why we can't have a third term using $\nabla \times \nabla \times \omega$, which is also a vector. But remember that $\nabla \times \nabla \times \omega$ is the same thing as $\nabla^2 \omega - \nabla(\nabla \cdot \omega)$, so this linear combination of the relations we have. Adding it would add nothing new. We have proved once more that isotropic material has only two elastic constants.

For the equation of motion of the material, we can set (39.32) equal to $\rho \ddot{\mathbf{u}}^2 / \partial t^2$, neglecting for now any body forces like gravity, and get

$$\rho \frac{\partial^2 \mathbf{u}}{\partial t^2} = (\lambda + \nu) \nabla(\nabla \cdot \mathbf{u}) + \nu \nabla^2 \mathbf{u}. \quad (39.33)$$

It looks something like the wave equation we had in electrostatics, except that there is an additional complicating term. For materials whose elastic properties are everywhere the same we can see what the material looks like in the following way. You will remember that any vector field can be written as the sum of two vectors: one whose divergence is zero, and the other whose curl is zero. In

other words, we can put

$$\mathbf{a} = \mathbf{u}_1 + \mathbf{u}_2, \quad (39.34)$$

where

$$\nabla \cdot \mathbf{u}_1 = 0, \quad \nabla \times \mathbf{u}_1 = 0. \quad (39.35)$$

Substituting $\mathbf{u}_1 + \mathbf{u}_2$ for \mathbf{a} in (39.34), we get

$$\rho \partial^2/\partial t^2[\mathbf{u}_1 + \mathbf{u}_2] = (\lambda + \mu) \nabla(\nabla \cdot \mathbf{u}_2) + \mu \nabla^2(\mathbf{u}_1 + \mathbf{u}_2). \quad (39.36)$$

We can eliminate \mathbf{u}_1 by taking the divergence of this equation,

$$\rho \partial^2/\partial t^2(\nabla \cdot \mathbf{u}_2) = (\lambda + \mu) \nabla^2(\nabla \cdot \mathbf{u}_2) - \mu \nabla \cdot \nabla^2 \mathbf{u}_2.$$

Since the operators (∇^2) and $(\nabla \cdot)$ can be interchanged, we can factor out the divergence to get

$$\nabla \cdot \{\rho \partial^2 \mathbf{u}_2 / \partial t^2 - (\lambda + 2\mu) \nabla^2 \mathbf{u}_2\} = 0. \quad (39.37)$$

Since $\nabla \times \mathbf{u}_2$ is zero by definition, the curl of the bracket $\{\}$ is also zero; so the bracket itself is identically zero, and

$$\rho \partial^2 \mathbf{u}_2 / \partial t^2 = (\lambda + 2\mu) \nabla^2 \mathbf{u}_2. \quad (39.38)$$

This is the vector wave equation for waves which move at the speed $C_0 = \sqrt{\lambda + 2\mu}/\rho$. Since the curl of \mathbf{u}_2 is zero, there is no shearing associated with this wave, it's wave is just the compressional longitudinal wave we discussed in the last chapter, and the velocity is just what we found for C_{long} .

In a similar way—by taking the curl of Eq. (39.36)—we can show that \mathbf{u}_1 satisfies the equation

$$\rho \partial^2 \mathbf{u}_1 / \partial t^2 = \mu \nabla^2 \mathbf{u}_1. \quad (39.39)$$

This is again a vector wave equation for waves with the speed $C_0 = \sqrt{\lambda + 2\mu}/\rho$. Since $\nabla \cdot \mathbf{u}_1$ is zero, \mathbf{u}_1 produces no changes in density; the vector \mathbf{u}_1 corresponds to the transverse, or shear-type, wave we saw in the last chapter, and $C_0 = C_{shear}$.

If we wished to know the static stresses in an isotropic material, we could, in principle, find them by solving Eq. (39.33) with \mathbf{f} equal to zero—or equal to the static body forces from gravity such as \mathbf{g} —under certain conditions which are related to the forces acting on the surfaces of our large block of material. This is somewhat more difficult to do than the corresponding problems in electromagnetism. It is more difficult first, because the equations are a little more difficult to handle, and second, because the shape of the elastic bodies we are likely to be interested in are usually much more complicated. In electromagnetism, we are often interested in solving Maxwell's equations around relatively simple geometric shapes such as cylinders, spheres, and so on, since these are conventional shapes for electrical devices. In elasticity, the objects we would like to analyze may have quite complicated shapes—like a crane hook, or an automobile crankshaft, or the rotor of a gas turbine. Such problems can sometimes be worked out approximately by numerical methods, using the minimum energy principle we mentioned earlier. Another way is to use a model of the object and measure the stresses using experiments, using polarized light.

It works this way. When a transparent isotropic material—like example, a clear plastic like cellophane—is put under stress, it becomes birefringent. If you pass polarized light through it, the plane of polarization will be rotated by an amount related to the stress; by measuring the rotation, you can measure the stress. Figure 39-6 shows how such a setup might look. Figure 39-7 is a photograph of a dielectric model of a complicated shape under stress.

39-4 Nonelastic behavior

In all that has been said so far, we have assumed that stress is proportional to strain; in general, that is not true. Figure 39-8 shows a typical stress-strain curve for a ductile material. For small strains, the stress is proportional to the strain

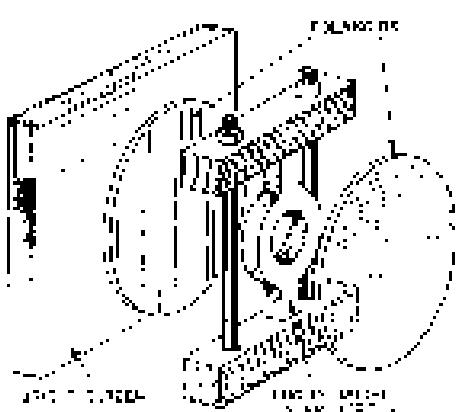

Fig. 39-6. Measuring internal stresses with polarized light.

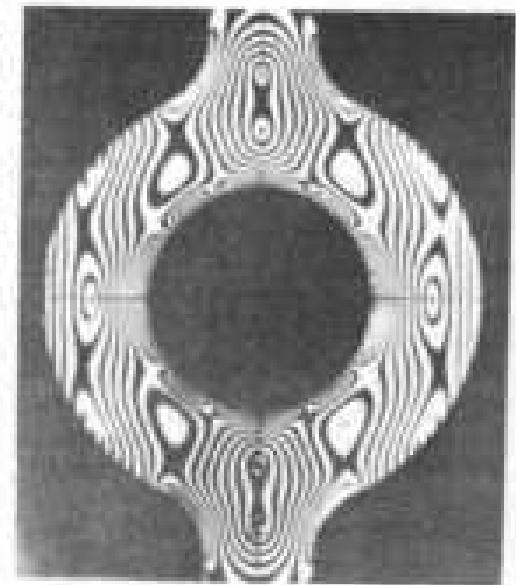

Fig. 39-7. A stressed plastic model, seen between crossed polarizers (From E. W. Sere, Optics, Addison Wesley Publishing Co., Reading, Mass., 1949.)

strain. Eventually, however, after a certain point, the relationship between stress and strain begins to deviate from a straight line. For many materials, the ones we would call "brittle," the object breaks for strains only a little above the point where the curve starts to bend over. In general, there are other complications in the stress-strain relationship. For example, if you strain an object, the stresses may be high at first, but decrease slowly with time. Also, if you go to high stresses, but still just to the "breaking" point, when you lower the strain the stress will return along a different curve. There is a small hysteresis effect (like the one we saw between β and γ in magnetic materials).

The stress at which a material will break varies widely from one material to another. Some materials will break when the maximum tensile stress reaches a certain value. Other materials will fail when the maximum shear stress reaches a certain value. Chalk is an example of a material which is much weaker in tension than in shear. If you pull on the ends of a piece of blackboard chalk, the chalk will break perpendicular to the direction of the applied stress, as shown in Fig. 39-9(a). It breaks perpendicular to the applied force because it is only a bunch of particles packed together which are easily pulled apart. The material is, however, much better in shear, because the particles go in each other's way. Now you will remember that when we had a rod in torsion there was a shear all around it. Also, we showed that shear was equivalent to a combination of a tension and compression at 45° . For these reasons, if you twist a piece of blackboard chalk, it will break along a complicated surface which starts out at 45° to the axis. A photograph of a piece of chalk broken in this way is shown in Fig. 39-9(b). The chalk breaks where the material is in maximum tension.

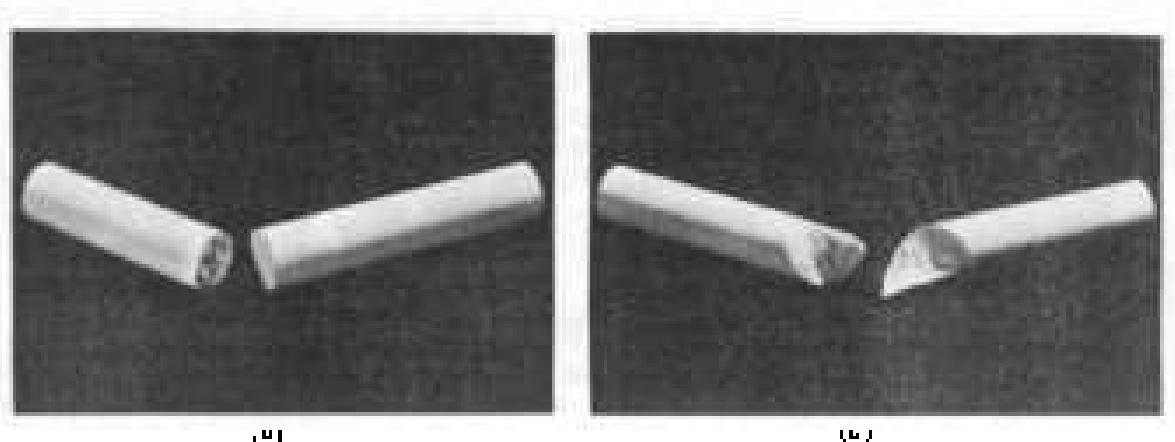

Fig. 39-9. (a) A piece of chalk broken by pulling on the ends; (b) a piece broken by twisting.

Other materials behave in strange and complicated ways. The more complicated the materials are, the more interesting their behavior. If we take a sheet of "Scotch-Wrap" and crumple it up into a ball and throw it on the table, it slowly unfolds itself and returns toward its original flat form. At first sight, we might be tempted to think that it is merely "lazy" and prefers it's returning to its original form. However, a simple calculation shows that the energy is several orders of magnitude too small to account for the effect. There appear to be real important complicating factors: "Something" inside the material "remembers" the shape it had initially and "wants" to get back there, but something else "prefers" the new shape and "resists" the return to the old shape.

We will not attempt to describe the mechanism at play in the Scotch plastic, but you can get an idea of how such an effect might come about from the following model. Suppose you imagine a material made of long, flexible, but strong, fibers mixed together with some hollow cells filled with a viscous liquid. Imagine also that there are narrow pathways from one cell to the next so the liquid can leak slowly from a cell to its neighbor. When we examine a sheet of this stuff, we stretch the long fibers, squeezing the liquid out of the cells in one place and forcing it into other cells which are being stretched. When we let go, the long fibers try to

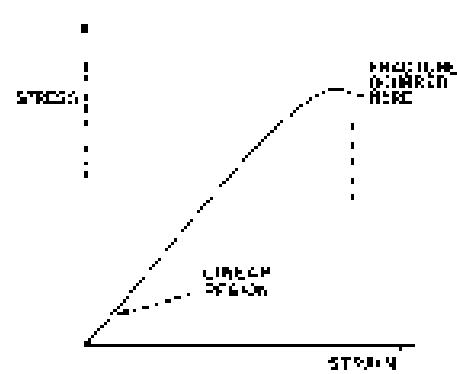

Fig. 39-8. A typical stress-strain relation for large strains.

return to their original shape. But to do that, they have to force the liquid back to its original location, which will happen very slowly because of the viscosity. The forces we apply in stretching a sheet are much larger than the forces exerted by the fibers. We can calculate the sheet quickly, but it will return much slowly. It is fundamentally a consideration of large stiff molecules and smaller, more mobile ones at the *Brown-Wiech* that is responsible for ice behavior. This also fits with the fact that the material returns more quickly to its original shape when it's warmed up than when it's cold—the heat increases the mobility (decreases the viscosity) of the smaller molecules.

Although we have been discussing how Hooke's law breaks down, the remarkable thing is perhaps not that Hooke's law breaks down for large strains but that it should be so *surprisingly* true. We can get some idea of why this might be by looking at the strain energy of a material. To say that the stress is proportional to the strain is the same thing as saying that the strain energy *varies* as a *square* of the strain. Suppose we had a rod and we bent it through a small angle θ . If Hooke's law holds, the strain energy would be proportional to the square of θ . Suppose we were to assume that the energy were some arbitrary function of the angle; we could write it as a Taylor expansion around zero angle:

$$U(\theta) = U(0) + U'(0)\theta - \frac{1}{2}U''(0)\theta^2 + \frac{1}{3}U'''(0)\theta^3 \dots \quad (39.40)$$

The torque τ is the derivative of U with respect to angle; we would have

$$\tau(\theta) = U'(0) + U''(0)\theta - \frac{1}{2}U'''(0)\theta^2 + \dots \quad (39.41)$$

Now if we increase our angles from the equilibrium position, the last term is zero, so the first term, $U'(0)$, is proportional to θ ; and for small enough of θ , this will dominate the term at θ^2 . (Actually, materials are sufficiently symmetric laterally to find $\tau(0) = -\tau(-0)$, the term in θ^3 will be zero, and the dependence from linearity would come only from the θ^2 term.) There is, however, no reason why this should be true for compressions and tensions. [See Fig. 39-10, we have not explained *why* materials usually break soon after the higher-strain terms become significant.]

39-5 Calculating the elastic constants

As our last topic on elasticity we would like to show how one could try to calculate the elastic constants of a material, starting with some knowledge of the properties of the atoms which make up the material. We will take only the simple case of an *ideal* cubic crystal like sodium chloride. When a crystal is strained, its volume or its shape is changed. Such changes result in an increase in the potential energy of the crystal. To calculate the change in strain energy, we have to know where each atom goes. In complicated crystals, the atoms will rearrange themselves in the lattice in very complicated ways to make the total energy as small as possible. This makes the computation of the strain energy rather difficult. In the case of a simple cubic crystal, however, it is easy to see what will happen. The extensions made the crystal will be geometrically similar to the distortions of the cubic host crystal.

We can calculate the elastic constants for a cubic crystal in the following way. First, we can express the law between each pair of atoms in the crystal. Then, we calculate the change in the potential energy of the crystal when it is distorted from its equilibrium shape. This gives us a relation between the energy and the strain which is quadratic in all the strains. Comparing the energy obtained this way with Eq. (39.13), we can identify the coefficient of each term with the elastic constants C_{ijkl} .

For our example we will assume a simple force law: that the force between neighboring atoms is a central force, by which we mean that it acts along the line between the two atoms. We would expect the forces in ionic crystals to be like this, since they are just primarily Coulomb forces. (The forces of covalent bonds are usually more complicated, since they can exert a sideways push on a nearby atom.)

atom; we will leave out this complication.) We are also going to include only the forces between each atom and its nearest and next-nearest neighbors. In other words, we will make no approximations which neglects all forces beyond the next nearest neighbor. The forces we will include are shown for the xy -plane in Fig. 19-10(a). The corresponding forces in the yz - and zx -planes also have to be included.

Since we are only interested in the elastic conditions which apply to small strains, and therefore only want the forces to be linearly related quadratically with the strains, we can imagine that the force between each atom pair varies linearly with the displacements. We can also imagine that each pair of atoms is joined by a linear spring, as drawn in Fig. 39-10(a). All of the springs between a sodium atom and a chlorine atom should have the same spring constant, say k_1 . The springs between two sodiums and between two chlorines would have different constants, but we will make our discussion simpler by taking them equal; we call them k_1 . (We could come back later and make them different after we have seen how the calculations go.)

Now we assume that the crystal is deformed by a homogeneous strain described by the strain tensor ϵ_{ij} . In general, it will have components involving x , y , and z ; but we will consider now only a shear with the three components ϵ_{12} , ϵ_{23} , and ϵ_{13} so that it will be easy to visualize. If we pick one atom at our origin, the displacement of every other atom is given by equations like Eq. (31) by:

$$\begin{aligned} u_2 &= c_{21}x + c_{22}v \\ u_3 &= c_{31}x + c_{32}v \end{aligned} \quad (19.42)$$

Suppose we call the beam or $x = y = 0$ "beam 1" and imagine it's negligible in the xy -plane as shown in Fig. 39-11. Calling the lattice constant a , we get the x and y displacements \bar{u} and \bar{v} , listed in Table 39-1.

Now we can calculate the energy stored in the springs, which is $E^2/3$ times the square of the extension for each spring. For example, the energy in the horizontal spring between atom 1 and atom 2 is

$$\frac{k_1(k_1, \omega)^L}{2}, \quad (39.43)$$

Note that to first order, the y -displacement of atom 2 does not change the length of the spring between atom 1 and atom 2. To get the total energy in a diagonal displacement, such as atom 1 to atom 3, however, we need to calculate the change in length due to both the horizontal and vertical displacements. For small displacements from the

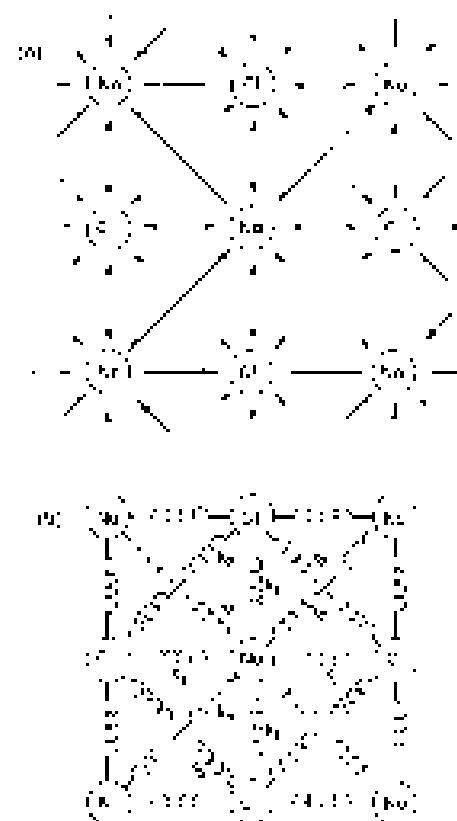

Fig. 99-12. (a) The interatomic forces we are taking into account; (b) a model in which the atoms are connected by springs.

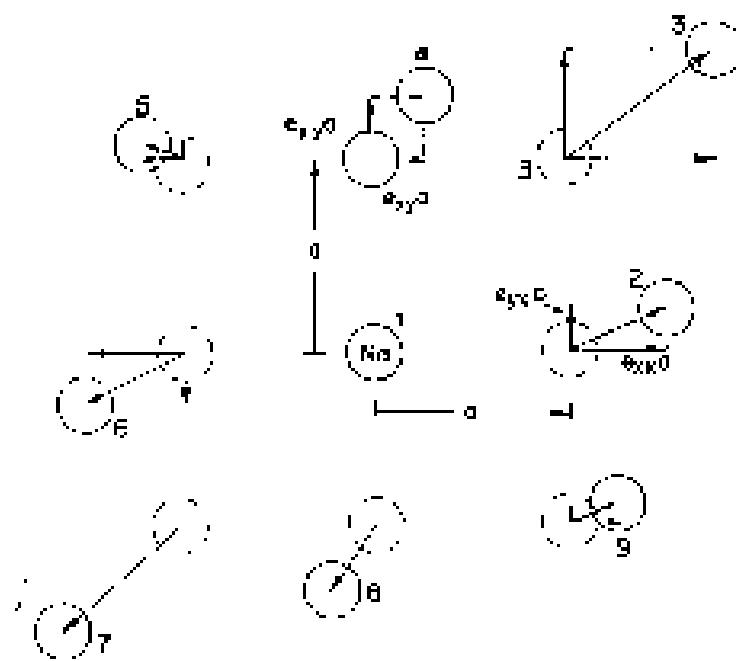

Fig. 39-11. The displacements of the nearest and next-nearest neighbors of whom I (cross-hatched).

Table 39-1

Atom	Location x, y	α_x	α_y	δ
1	0, 0	0	0	—
2	$a, 0$	$c_{xx}v$	$c_{yy}v$	k_1
3	a, a	$(c_{xx} + c_{yy})v$	$(c_{yy} - c_{xx})v$	k_2
4	$0, a$	$c_{yy}v$	$c_{xx}v$	k_1
5	$-a, 0$	$(-c_{xx} - c_{yy})v$	$(-c_{yy} + c_{xx})v$	k_2
6	$-a, a$	$c_{yy}v$	$c_{xx}v$	k_1
7	$-a, -a$	$(c_{xx} - c_{yy})v$	$(c_{yy} + c_{xx})v$	k_1
8	$0, -a$	$-c_{yy}v$	$-c_{xx}v$	k_1
9	$a, -a$	$(c_{yy} - c_{xx})v$	$(c_{xx} + c_{yy})v$	k_2

original cube, we can write the change in the distance to atom 3 as the sum of the components of α_x and α_y in the diagonal direction, namely as

$$\frac{1}{\sqrt{2}}(\alpha_x + \alpha_y).$$

Using the values of α_x and α_y from the table we get the energy

$$\frac{k_2}{2} \left(\frac{\alpha_x + \alpha_y}{\sqrt{2}} \right)^2 = \frac{k_2 v^2}{4} (c_{xx} + c_{yy} + c_{xy} + c_{yz})^2. \quad (39.43)$$

For the total energy for all the springs in the xy -plane, we need the sum of eight terms like (39.43) and (39.44). Calling this energy E_1 , we get

$$\begin{aligned} E_1 = & \frac{a^2}{2} \left[k_1 c_{xx}^2 + \frac{k_2}{2} (c_{xx} + c_{yy} + c_{xy} + c_{yz})^2 \right. \\ & + k_1 c_{yy}^2 + \frac{k_2}{2} (c_{xx} + c_{yy} + c_{xy} + c_{yz})^2 \\ & + k_1 c_{xy}^2 + \frac{k_2}{2} (c_{xx} + c_{yy} + c_{xy} + c_{yz})^2 \\ & \left. + k_1 c_{yz}^2 + \frac{k_2}{2} (c_{xx} + c_{yy} + c_{xy} + c_{yz})^2 \right]. \end{aligned} \quad (39.44)$$

To get the total energy of all the springs connected to atom 1, we must make one addition to the values in Eq. (39.43). Even though we have only x - and y -components of the strain, there are still various energies associated with the next-nearest neighbours of the atom. Thus additional energy is

$$k_2(c_{xx}^2 + c_{yy}^2). \quad (39.45)$$

The elastic constants are related to the energy density ϵ by Eq. (39.11). The energy we have calculated is the energy associated with one atom, or rather, it is twice the energy per atom, since one-half of the energy of each spring should be assigned to each of the two atoms it joins. Since there are 10^{23} atoms per unit volume, ϵ and C_{ijkl} are related by

$$\epsilon = \frac{C_{ijkl}}{2a^4}.$$

To find the elastic constants C_{ijkl} , we need only to expand out the springs in Eq. (39.44), adding the terms of (39.45)—and compare the coefficients of v^2 with the corresponding coefficient in Eq. (39.13). For example, collecting the terms

in ϵ_{12} and in ϵ_{23} , we get the factor

$$(k_1 + 2k_2)\sigma^2.$$

so

$$C_{xxz} = C_{yyz} = \frac{k_1 + 2k_2}{\sigma}.$$

For the remaining terms, there is a slight complication. Since we cannot distinguish the product of two terms like $\epsilon_{12}\epsilon_{23}$ from $\epsilon_{23}\epsilon_{12}$, the coefficient of such terms in our energy is equal to the sum of two terms in Eq. (39.13). The coefficient of $\epsilon_{12}\epsilon_{23}$ in Eq. (39.13) is $2k_3$, so we have that

$$(C_{xxx} + C_{yyz}) = \frac{2k_3}{\sigma}.$$

But because of the symmetry in our crystal, $C_{xxx} = C_{yyz}$, so we have that

$$C_{xxx} = C_{yyz} = \frac{k_3}{\sigma}.$$

By a similar process, we can also get

$$C_{xxy} = C_{yyx} = \frac{k_3}{\sigma}.$$

Finally, you will notice that any term which involves either ϵ_x or ϵ_y only once is zero—as we concluded earlier from symmetry arguments. Summarizing our results:

$$\begin{aligned} C_{xxx} &= C_{yyz} = \frac{k_1 + 2k_2}{\sigma}, \\ C_{xxy} &= C_{yyx} = \frac{k_3}{\sigma}, \\ C_{xyx} &= C_{yxy} = C_{xyz} = C_{zyx} = \frac{k_3}{\sigma}, \\ C_{zyx} &= C_{xyz} = 0. \end{aligned} \quad (39.49)$$

We have been able to relate the bulk elastic constants to the atomic properties which appear in the constants k_1 and k_2 . In our particular case, $C_{xyx} = C_{xyz}$. It turns out—as you can perhaps see from the way the calculations went—that these terms are always equal for a cubic crystal, no matter how many force terms are taken into account, provided only that the forces act along the line joining each pair of atoms—that is, so long as the forces between atoms are like springs and don't have a sideways component as you might get from a cantilevered beam (and yet the net is covariant overall).

We can check this conclusion with the experimentally measured values of the elastic constants. In Table 39-2 we give the observed values of the three elastic coefficients for several cubic crystals.* You will notice that C_{xxx} and C_{xyx} are, in general, not equal. This means σ that in metals like sodium and potassium the interatomic forces are not along the line joining. In other words, as we assumed in our model, Diamond does not work either, because the forces in carbon are equivalent forces and have some directional properties—the bonds would prefer to be at the tetrahedral angle. The cubic crystals like Lithium, Boron, and iron boride, and so on, do have nearly all the physical properties consistent in our model, and the table shows that the constants C_{xxx} and C_{xyx} are almost equal. It is not clear why silver sulfide should not satisfy the condition that $C_{xyx} = C_{xyz}$.

* In the literature you will often find that a different notation is used. For instance, people may write $C_{xxx} = C_{111}$, $C_{xyx} = C_{112}$, and $C_{xyz} = C_{113}$.

Table 39-2

The Flow of Dry Water

40-1 Hydrostatics

The subject of the flow of fluids, and particularly of water, fascinates everybody. We can all remember, as children, playing in the bath tub or in mud puddles with the streams of water. As we get older, we watch streams, waterfalls, and whirlpools, and we are fascinated by the substance which seems so mysterious relative to solids. The chapter on fluid mechanics may very well profit a student using it as the subject of his chapter project. The action of a child trying to catch a stream flowing in the street and his surprise at the strange way the water works is very old, but it's amazing how our attempts over the years to understand the flow of fluids. We have tried to nail the water up in our understanding by getting the laws and the equations that describe the flow. We will describe these attempts in this chapter. In the next chapter, we will describe the unique way in which water has broken through the chain and escaped our attempts to understand it.

We suppose that the elementary properties of water are already known to you. The main property that distinguishes a fluid from a solid is that a fluid cannot maintain a shear stress for any length of time. If a shear is applied to a fluid, it will move under the shear. Thicker liquids like honey move less easily than fluids like air or water. The measure of the ease with which a fluid yields is its viscosity. In this chapter we will consider only situations in which the viscous effects can be ignored. The effects of viscosity will be taken up in the next chapter.

We begin by considering hydrostatics, the theory of liquids at rest. When liquids are at rest, there are no shear forces (even the viscous liquids). The law of hydrostatics, therefore, is that the stresses are always normal to any surface inside the fluid. The normal force per unit area is called the pressure. From the fact that there is no shear in a static fluid it follows that the pressure stress is the same in all directions (Fig. 40-1). We will let you entertain yourself by proving that if there is no shear on any plane in a fluid, the stress must be the same in any direction.

The pressure in a fluid may vary from place to place. For example, in a static fluid at the earth's surface the pressure will vary with depth, because of the weight of the fluid. If the density ρ of the fluid is considered constant, and if the pressure at some arbitrary zero level is called p_0 (Fig. 40-2), then the pressure at a height h above this point is $p = p_0 + \rho gh$, where g is the gravitational force per unit mass. The equation

$$p = p_0 + \rho gh$$

is, therefore, a constant in the static fluid. This relation is familiar to you, but we will now derive a more general result of which it is a special case.

If we take a small cube of water, what is the net force on it from the pressure? Since the pressure at any place is the same in all directions, there can be a net force per unit volume only because the pressure varies from one place to another. Suppose that the pressure is varying in the x -direction, and we make the coordinate directions parallel to the cube edges. The pressure on the face at x gives the force $p_x A_x$ (Fig. 40-3), and the pressure on the face at $x + Ax$ gives the force $p_{x+Ax} A_x$.

$[p_{x+Ax}/(p_x/A_x)] A_x \approx Ax$, so that the resultant force is $(\partial p/\partial x) Ax^2 p_x/2$. If we take the remaining pairs of faces of the cube, we easily see that the pressure force per unit volume is ∇p . If there are other forces in addition, such as gravity, then the pressure must balance them to give equilibrium.

40-4 Circulation

40-5 Vortex tubes

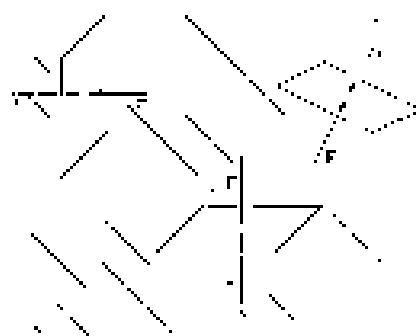

Fig. 40-1. In a static fluid the force per unit area across any surface is normal to the surface and is the same for all orientations of the surface.

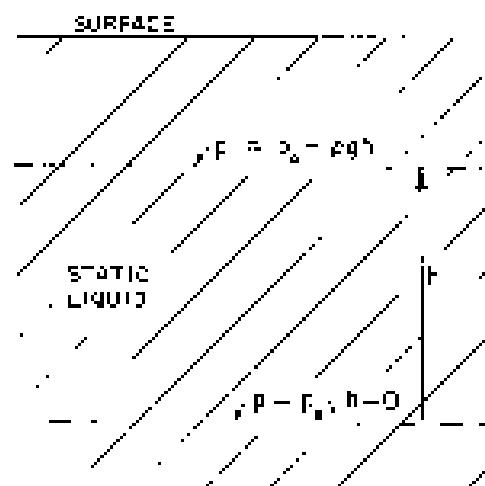

Fig. 40-2. The pressure in a static liquid.

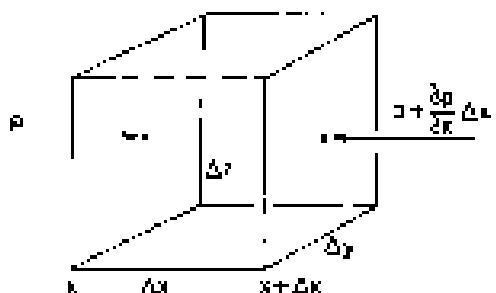

Fig. 40-3. The net pressure force on a cube $\sim = \nabla p$ per unit volume.

Let's take a circumstance in which such an additional force can be described by a potential energy, as would be true in the case of gravitation; we will let ϕ stand for the potential energy per unit mass. (For gravity, for instance, ϕ is just g .) The force per unit mass is given in terms of the potential by $-\nabla\phi$, and if ρ is the density of the fluid, the force per unit volume is $-\rho\nabla\phi$. For equilibrium this force per unit volume added to the pressure force per unit volume must give zero:

$$-\nabla p - \rho\nabla\phi \sim 0. \quad (40.1)$$

Equation (40.1) is the equation of hydrostatics. In general, it has no solution. If the density varies in space in an arbitrary way, there is no way for the forces to be in balance, and the fluid cannot be in static equilibrium. Convection currents will start up. We can see this from the equation since the pressure term is a pure gradient, whereas for variable ρ the other term is not. Only when ρ is a constant is the potential term a pure gradient. Then the equation has a solution:

$$\rho + \rho\phi = \text{const}$$

Another possibility which allows hydrostatic equilibrium is for ρ to be a function only of p . However, we will leave the subject of hydrostatics because it is not nearly so interesting as the situation when fluids are in motion.

40-2. The equations of motion

First, we will discuss fluid motions in a purely abstract, theoretical way and then consider special examples. To describe the motion of a fluid, we must give its properties at every point. For example, at different places, the water filet or call the fluid "water" is moving with different velocities. To specify the character of the flow, therefore, we must give the three components of velocity at every point and for any time. If we can find the equations that determine the velocity, then we would know how the liquid moves at all times. The velocity, however, is not the only property that the fluid has which varies from point to point. We have just discussed the variation of the pressure from point to point. And there are still other variables. There may also be a variation of density from point to point. In addition, the fluid may be a conductor and carry an electric current whose density varies from point to point, its magnitude and direction. There may be a temperature which varies from point to point, or a magnetic field, and so on. So a number of fields needed to describe the complex situation will depend on a few hydrodynamic problems. There are instabilities, phenomena when vortices and instabilities play a dominant role in determining the behavior of the fluid, the subject is called hydrodynamics, and great attention is being paid to it at the present time. However, we are not going to consider these more complicated situations because there are already interesting phenomena at a lower level of complexity, and even the more elementary level will be considered enough.

We will take the situation where there is no unipolar field, our no conductivity, and we will not worry about the temperature because we will suppose that the density and pressure determine the unique feature, the temperature at any point. As a matter of fact, we will reduce the complexity of our work by making the assumption that the density is a constant. We imagine that the fluid is essentially incompressible. Putting it another way, we are supposing that the variations of pressure are so small that the changes in density produced thereby are negligible. If that is not the case, we would encounter phenomena in addition to the ones we will be discussing here. For example, the propagation of sound or of shock waves. We have already discussed the propagation of sound and shocks to some extent, so we will now make our consideration of hydrodynamics from these other phenomena by making the approximation that the density ρ is a constant. It is easy to determine when the approximation of constant ρ is a good one. We can say that if the velocities of flow are much less than the speed of a sound wave in the fluid, we do not have to worry about variations in density. The escape that water makes in our attempt to understand it is not related to the approximation of

constant density. The equations that do permit the escape will be discussed in the next chapter.

In the zeroth theory of fluids one must begin with an equation of state for the fluid which connects the pressure to the density. In our approximation, this equation of state is simply

$$\rho = \text{const.}$$

This idea is the D'Alembert relation for one variable. The new relation expresses the conservation of mass. - if fluid flows away from a point, there must be a decrease in the amount left behind. If the fluid velocity is v_i , then the mass which flows in a unit time across a unit area of surface is the component of v normal to the surface. We have had a similar relation in electricity. We also know from electricity that the divergence of such a quantity gives the rate of decrease of the density per unit time. In the same way, the equation

$$\nabla \cdot (v \rho) = - \frac{\partial \rho}{\partial t} \quad (40.1)$$

expresses the conservation of mass for a fluid. (A third axiomatic equation of continuity.) In one representation, which is the most appropriate fluid approximation, ρ is a constant, and the equation of continuity is simply

$$\nabla \cdot v = 0. \quad (40.2)$$

The fluid velocity v like the magnet + light B has zero divergence. (The hydrodynamic variables are often closely analogous to the electrodynamic variables; that's why we studied electricity first. Some people argue the other way: they think that one should study hydrodynamics first so that it will be easier to understand electricity afterwards. But electrodynamics is really much easier than hydrodynamics.)

We will get our next equation from Newton's law which tells us how the velocity changes because of the forces. The mass of an element of volume of the fluid times its acceleration must be equal to the force on the element. Taking an element of unit volume, and writing the force per unit volume as f , we have

$$\rho \times (\text{acceleration}) \leftrightarrow f.$$

We will write the force density as the sum of three terms. We have already considered the pressure force per unit volume, $-p v$. Then there are the "external" forces which act at a distance—the gravity or electricity. When they are conservative forces with a potential per unit mass, ϕ , they give a force density $-\rho \nabla \phi$. (If the external forces are not conservative, we would have to write f_{ext} for the calculated force per unit volume.) Then there is another "internal" force per unit volume, which is due to the fact that in a flowing fluid there can also be a shearing stress. This is called the viscous force, which we will write f_{vis} . Our equation of motion is

$$v \times (\text{acceleration}) \leftrightarrow -\nabla p - \rho \nabla \phi + f_{vis}. \quad (40.3)$$

For this chapter we are going to suppose that the liquid is "thin" in the sense that its viscosity is negligible, so we will omit f_{vis} . When we drop the viscosity term, we will obtain a simple approximation, which describes some ideal stuff rather than real water. John von Neumann was well aware of the tremendous difference between what happens when you don't know the various terms and when you do, and he was also aware that, during most of the development of hydrodynamics until about 1930, the main interest was in solving useful nonviscous problems with the approximation which he almost nothing to do with, except, like the mathematician T. C. J. Stoker who wrote such articles as a man who should "say what?" Such articles have not an enormous majority of the time. It is because we are leaving this present set of our calculations in the chapter, that we have given it the title "The Flow of Dry Water." We are postponing a discussion of viscosity to the next chapter.

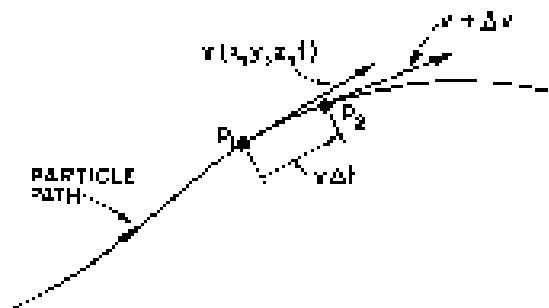

Fig. 40-4. The acceleration of a fluid particle.

If we leave out f_{ext} , we have in Eq. (40.4) everything we need except an expression for the acceleration. You might think that the formula for the acceleration of a fluid particle would be very simple, for it seems obvious that if v is the velocity of a fluid particle at some place in the fluid, the acceleration would just be $\partial v / \partial t$. It is not, and for a rather simple reason. The derivative $\partial v / \partial t$ is the rate at which the velocity $v(x, y, z, t)$ changes at a fixed point in space. What we need is how fast the velocity changes for a particular piece of fluid. Imagine that we mark one of the drops of water with a colored speck so we can watch it. In a small interval of time Δt , this drop will move to a different location. If the drop is moving along some path as sketched in Fig. 40-4, it might in Δt move from P_1 to P_2 . In fact, it will move in the x -direction by an amount Δx , in the y -direction by the amount Δy , and in the z -direction by the amount Δz . We see that, if $v(x, y, z, t)$ is the velocity of the fluid particle which is at (x, y, z) at the time t , then the velocity of the same particle at the time $t + \Delta t$ is given by $v(x + \Delta x, y + \Delta y, z + \Delta z, t + \Delta t) = v(t)$

$$\Delta x = v_x \Delta t, \quad \Delta y = v_y \Delta t, \quad \text{and} \quad \Delta z = v_z \Delta t.$$

From the definition of the partial derivatives—recall Eq. (2.7)—we have, to this order, that

$$\begin{aligned} \Delta v &= v(x + \Delta x, y + \Delta y, z + \Delta z, t + \Delta t) - v(x, y, z, t) \\ &= \Delta v(x, y, z, t) + \frac{\partial v}{\partial x} \Delta x + \frac{\partial v}{\partial y} \Delta y + \frac{\partial v}{\partial z} \Delta z + \frac{\partial v}{\partial t} \Delta t. \end{aligned}$$

The acceleration $\Delta v / \Delta t$ is

$$= \frac{\partial v}{\partial t} + v_x \frac{\partial v}{\partial x} + v_y \frac{\partial v}{\partial y} + v_z \frac{\partial v}{\partial z}.$$

We can write this symbolically—treating ∇ as a vector—as

$$(v \cdot \nabla)v + \frac{\partial v}{\partial t}. \quad (40.5)$$

Note that there can be an acceleration even though $\partial v / \partial t = 0$ so that velocity at a given point is not changing. As an example, water flowing in a circle at a constant speed is accelerating even though the velocity at a given point is not changing. This occurs, of course, when the velocity of a particular piece of water which is initially at one point on the circle has a different direction a moment later; there is a centripetal acceleration.

The rest of our theory is just mathematics. Finding solutions of the equation of motion we get by putting the acceleration (40.5) into Eq. (40.1). We get

$$\frac{dv}{dt} = (v \cdot \nabla)v + \frac{\partial v}{\partial t} + \nabla \cdot v, \quad (40.6)$$

where viscosity has been omitted. We can rearrange this equation by using the following identity from vector analysis:

$$(v \cdot \nabla)v = (\nabla \times v) \times v + \frac{1}{2}\nabla(v \cdot v).$$

If we now define a new vector field Ω as the curl of v ,

$$\Omega = \nabla \times v. \quad (40.7)$$

The vector identity can be written as

$$(\nabla \cdot \nabla) v = \Delta v - \frac{1}{2} \nabla v^2,$$

and our equation of motion, (40.6) becomes

$$\frac{\partial v}{\partial t} + \Omega \times v - \frac{1}{2} \nabla v^2 = -\frac{\nabla p}{\rho} - \nabla \phi. \quad (40.8)$$

You can verify that Eqs. (40.6) and (40.8) are equivalent by checking that the components of the two sides of the equation are equal—and making use of (40.7).

The vector field Ω is called the vorticity. If the vorticity is zero everywhere, we say that the flow is irrotational. We have already defined in Section 3-3 a thing called the circulation of a vector field. The circulation around any closed loop in a fluid is the line integral of the fluid velocity, at a given instant of time, around that loop:

$$(\text{Circulation}) = \oint_C v \cdot d\mathbf{s}$$

The circulation per unit area for an infinitesimal loop is then using Stokes' theorem—equal to $\nabla \times v$. So the vorticity Ω is the circulation around a unit area, perpendicular to the direction of Ω . It also follows that if you get a little piece of driftwood floating about, at any place in the liquid it will rotate with the angular velocity $\Omega/2$. Try to see if you can prove that. You can also check it out for a number of waves on a swimming pool; it is equal to twice the local tangential velocity of the water.

If we are interested only in the velocity field, we can eliminate the pressure from our equations. Taking the curl of both sides of Eq. (40.8), remembering that p is a constant and that the curl of any gradient is zero, and using Eq. (40.7), we get

$$\frac{\partial \Omega}{\partial t} + \nabla \times (\Omega \times v) = 0. \quad (40.9)$$

This equation, together with the equations

$$\Omega = \nabla \times v \quad (40.10)$$

and

$$\nabla \cdot v = 0, \quad (40.11)$$

describes completely the velocity field v . Mathematically speaking, if we know Ω at some time, then we know the curl of the velocity vector, and we also know that its divergence is zero, so given the physical situation we have all we need to determine v everywhere. (It is just like the situation in magnetism, where we had $\nabla \cdot B = 0$ and $\nabla \times B = \mu_0 i e^2$.) Thus, a given Ω determines v just as a given j determines B . Then, knowing v , Eq. (40.9) tells us how to change Ω from which we can get the new Ω for the next instant. Using Eq. (40.10), again we find the new v , and so on. You see how these equations reduce all fluid dynamics to calculating the flow. Note, however, that this procedure gives the velocity field only; we have lost all information about the pressure.

We point out one special consequence of our equations. If $\Omega = 0$ everywhere at any time t , v after that vanishes, so that Ω is still zero everywhere at $t + \Delta t$. We have a solution to the equations; the flow is permanently irrotational. If a flow was started with zero rotation, it would always have zero rotation. The equations to be solved then are

$$\nabla \cdot v = 0, \quad \nabla \times v = 0.$$

They are just like the equations for the electric or magnetic fields in free space. We will come back to them and look at some special problems later.

40-2 Steady flow—Bernoulli's theorem

Now we want to return to the equation of motion, Eq. (40.5), but limit ourselves to situations in which the flow is "steady." By steady flow we mean that at any one place in the fluid, the velocity never changes. The fluid at any point is always replaced by new fluid moving in exactly the same way. The velocity picture always looks the same—it is a static vector field. In the same way that we drew "field lines" in magnetostatics, we can now draw lines which are always tangent to the fluid velocity as shown in Fig. 40-5. These lines are called *streamlines*. For steady flow, they are exactly the actual paths of fluid particles. The steady flow line structure pattern changes in time, and the streamline pattern at any instant does not represent the path of a fluid particle.

A steady flow does not mean that nothing is happening; atoms in the fluid are moving and changing their velocities. It is only that $\partial u/\partial t = 0$. That is, if we take the dot product of $\partial u/\partial t$ with the equation of motion, the term $(\partial u/\partial t) \cdot u$ drops out, and we are left with

$$u \cdot \nabla \left[\frac{p}{\rho} + \phi + \frac{1}{2} u^2 \right] = 0. \quad (40.12)$$

Fig. 40-5. Streamlines in steady flow form.

The equation says that for a small displacement in the direction of the fluid velocity, the quantity inside the brackets doesn't change. Now in steady flow all components are along streamlines, so Eq. (40.12) tells us that for all the points along a streamline, we can write

$$\frac{p}{\rho} + \frac{1}{2} u^2 - \phi = \text{const (streamline).} \quad (40.13)$$

This is *Bernoulli's principle*. The constant may in general be different for different streamlines, and we know is that the left-hand side of Eq. (40.13) is the same all along a given streamline. Unfortunately, we may notice that for steady irrotational motion, for which $\phi = 0$, the equation of motion (40.8) gives us the relation

$$\nabla \left[\frac{p}{\rho} + \frac{1}{2} u^2 \right] = 0,$$

so that

$$\frac{p}{\rho} + \frac{1}{2} u^2 + \phi = \text{const (everywhere).} \quad (40.14)$$

It's just like Eq. (40.13) except that now the constant has the same value throughout the fluid.

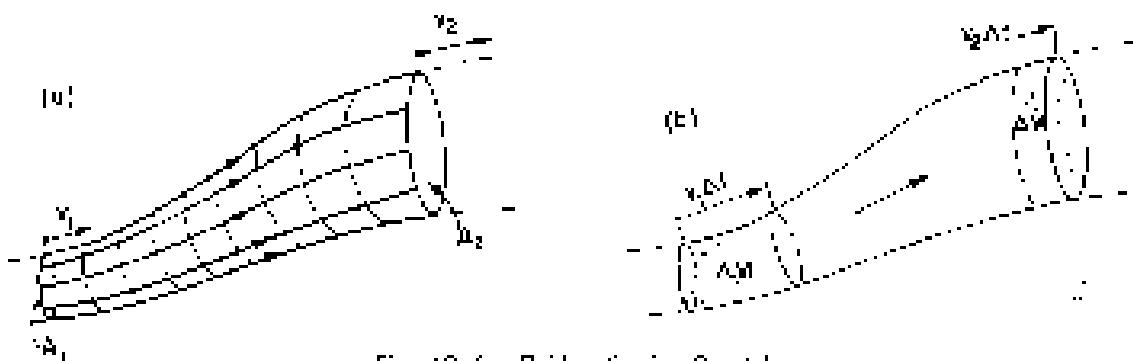

Fig. 40-6. Fluid motion in a flow tube.

The theorem of Bernoulli is in fact nothing more than a statement of the conservation of energy. A conservation law such as this gives us a lot of information about a flow without ever actually having to solve the equations of motion. Bernoulli's theorem is an important and simple idea that we would like to show you how it can be derived in a way that is different from the formal calculations we have just used. Imagine a bundle of adjacent streamlines which form a stream tube as sketched in Fig. 40-6. Since the walls of the tube consist of streamlines, no fluid flows out through the walls. Let's call the area at one end of the stream

mass ΔM , the fluid velocity there v_1 , the density of the fluid ρ_1 , and the potential energy ϕ_1 . At the other end of the tube, we have the corresponding quantities ρ_2 , v_2 , ϕ_2 , and ΔM . Now after a short interval of time Δt , the fluid at A_1 has moved a distance $v_1 \Delta t$, and the fluid at A_2 has moved a distance $v_2 \Delta t$ [Fig. 10-6(a)]. The conservation of mass requires that the mass which enters through A_1 must be equal to the mass which leaves through A_2 . These masses ΔM at the two ends must be the same:

$$\Delta M = \rho_1 A_1 v_1 \Delta t = \rho_2 A_2 v_2 \Delta t.$$

So we have the equality

$$\rho_1 A_1 v_1 = \rho_2 A_2 v_2 \quad (10.15)$$

This equation tells us that the velocity varies inversely with the area of the stream tube if c is constant.

Now we calculate the work done by the fluid pressure. The work done on the fluid entering at A_1 is $\rho_1 P_1 A_1 \Delta t$, and the work given up at A_2 is $\rho_2 P_2 A_2 \Delta t$. The net work per unit mass between A_1 and A_2 is, therefore,

$$\rho_2 P_2 A_2 \Delta t - \rho_1 P_1 A_1 \Delta t$$

which must equal the increase in the energy of a mass ΔM of fluid in going from A_1 to A_2 . In other words,

$$\rho_2 P_2 A_2 \Delta t - \rho_1 P_1 A_1 \Delta t = \Delta M(E_2 - E_1), \quad (10.16)$$

where E_1 is the energy per unit mass of fluid at A_1 , and E_2 is the energy per unit mass at A_2 . The energy per unit mass of the fluid can be written as

$$E = \frac{1}{2} v^2 + \phi + U,$$

where $\frac{1}{2} v^2$ is the kinetic energy per unit mass, ϕ is the potential energy per unit mass, and U is an additional term which represents the internal energy per unit mass of fluid. The internal energy might also be called the thermal energy in a compressible fluid, or mechanical energy in a solid. All these quantities are ΔM from point to point. Using this form for the energy in (10.16) we have

$$\frac{\rho_2 d(M) \Delta t}{\Delta M} = \frac{\rho_2 d(v_2) \Delta t}{\Delta M} = \frac{1}{2} (v_2^2 - v_1^2) + \phi_2 - \phi_1 + U_2 - U_1 = C,$$

But we have seen that $\Delta M = \rho A \Delta t$, so we get

$$\frac{\rho_2}{\rho_1} + \frac{1}{2} \frac{v_2^2}{v_1^2} - \phi_1 + U_1 = \frac{\rho_2}{\rho_1} + \frac{1}{2} \frac{P_2^2}{P_1^2} + \phi_2 - U_2, \quad (10.17)$$

which is the Bernoulli result with an additional term for the internal energy. If the fluid is incompressible, the internal energy term is the same on both sides, and we see again that Eq. (10.14) holds along any streamline.

We consider now some simple examples in which the Bernoulli integral gives us a description of the flow. Suppose we have water flowing out of a hole near the bottom of a tank, as drawn in Fig. 10-7. We take a situation in which the flow speed v_{top} at the hole is much larger than the flow speed near the top of the tank. In other words, we imagine that the diameter of the tank is so large that we can neglect the drop in the liquid level. (We could make a more accurate calculation if we wished.) At the top of the tank the pressure is P_0 , the atmospheric pressure, and the pressure at the sites of the jet is also P_0 . Now we write an ordinary equation for a streamline, such as the one shown in the figure. At the top of the tank, we take ϕ equal to zero and we also take the gravity potential ϕ to be zero. At the open end, and $\phi = -gh$, so that

$$P_0 = P_0 - \frac{1}{2} \rho v_{top}^2 - \rho g h,$$

or

$$v_{top} = \sqrt{\frac{2 P_0}{\rho}}. \quad (10.18)$$

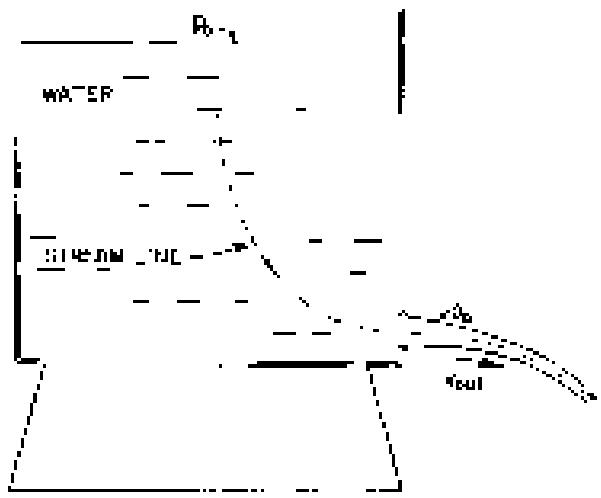

Fig. 40-7. Flow from a tank.

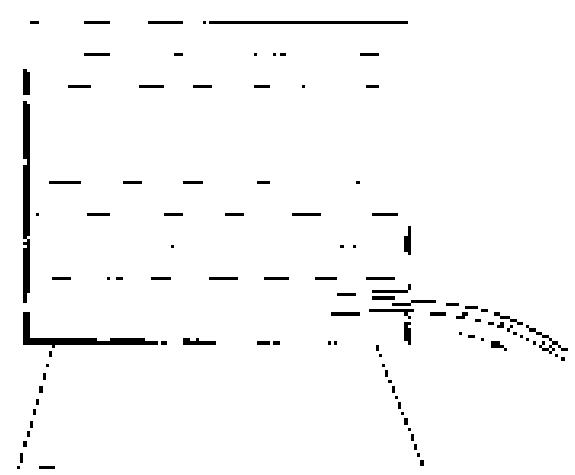

Fig. 40-8. With a constricted discharge tube, the stream contracts to maintain the area of the opening.

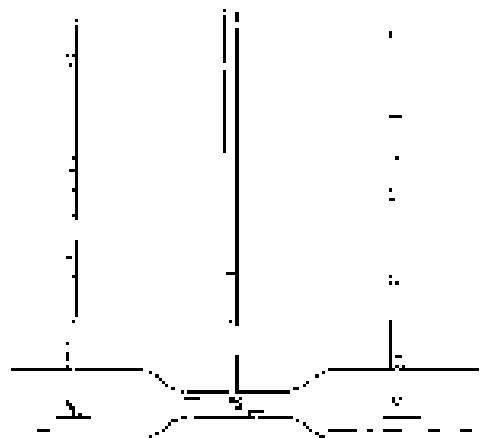

Fig. 40-9. The pressure is lowest where the velocity is highest.

This velocity is just what we would get for something which falls the distance h . It is not too surprising, since the water at the top gains kinetic energy at the expense of the potential energy of the water at the top. Do not get the idea, however, that you can figure out the rate that the fluid flows out of the tank by multiplying this velocity by the area of the hole. The fluid velocities as the jet leaves the hole are not all parallel to each other but have components directed toward the center of the stream—the jet is converging. After the jet has gone a little way, the contraction stops and the velocities do become parallel. So the total flow is the velocity times the area of the jet. In fact, if we have a discharged opening which is just a round hole with a sharp edge, the jet contracts to 62 percent of the area of the hole. The reduced effective area of the discharge varies for different shapes of discharge tubes, and experimental contractions are available as tables of efflux coefficients.

If the discharge tube is constricted, as shown in Fig. 40-8, it is possible to prove in a most beautiful way that the efflux coefficient is exactly 50 percent. We will give you a hint of how the proof goes. We have used the measureless of energy to get the velocity, Eq. (40-18), but there is also a measure of conservation to consider. Since there is an outflow of momentum in the discharge jet, there must be a force applied over the cross section of the discharge tube. Where does the force come from? The force must come from the pressure on the walls. As long as the efflux hole is an all-around flow free of walls, the fluid velocity and the walls of the tank will be very small. Therefore the pressure on every fiber is almost exactly the same as the static pressure for a fluid at rest—*from* Eq. (30-14). Then the static pressure at any point on the side of the tank must be matched by the static pressure at the point on the opposite wall, except at the points on the wall opposite the discharge tube. If we calculate the static pressure exerted on through the jet by the pressure, we can show that the efflux coefficient is 1/2. We cannot use this method for a discharge tube like that shown in Fig. 40-9, however, because the velocity increases along the wall right near the discharge area gives a pressure fall which we are unable to eliminate.

Let's look at another example—a horizontal pipe with changing cross section, as shown in Fig. 40-9, with water flowing in one end and out the other. The law of conservation of energy, namely Bernoulli's formula, says that the pressure is lower in the constricted part where the velocity is higher. We can easily demonstrate this effect by measuring the pressure at different areas sections with small vertical columns of water attached to the flow tube through holes small enough so that they do not disturb the flow. The pressure is then measured by the height of water in these vertical columns. The pressure is found to be less at the constriction than it is on either side. If the area beyond the constriction comes back to the same value it had before the constriction, the pressure rises again.

Bernoulli's formula would predict that the pressure downstream of the constriction should be the same as it was upstream, but actually it is noticeably less. The reason that our prediction is wrong is that we have neglected the frictional viscous forces which cause a pressure drop along the tube. Despite this pressure drop the pressure is definitely lower at the constriction. This is because the water goes faster than it is on either side of it, as predicted by Bernoulli. The speed must certainly exceed v_1 to get the same amount of work through the constriction, since ΔE is zero. So the water accelerates as it goes from the wide to the narrow part. The force that gives this acceleration comes from the drop in pressure.

We can check our results with another simple demonstration. Suppose we have an orifice discharge嘴 which throws a jet of water outward as shown in Fig. 40-10. If the efflux velocity were exactly $\sqrt{2gh}$, the distance x from the mouth to a level even with the surface of the water in the tank, experimentally, it fails somewhat short. Our prediction is roughly right, but again viscosity friction which has not been included in our energy conservation formula has resulted in a loss of energy.

Have you ever held two pieces of paper close together and tried to blow them apart? Try it! They come together. The reason, of course, is that the air has a higher speed going through the restricted space between the sheets than it does when it gets outside. The pressure between the sheets is lower than atmospheric pressure, so they come together rather than separating.

40-4 Circulation

We saw at the beginning of the last section that if we want to move up past the fluid with no circulation, the flow satisfies the following two equations:

$$\nabla \cdot v = 0, \quad \nabla \times v = 0. \quad (40.29)$$

They are the same as the equations of electrodynamics or magnetostatics in empty space. The divergence of the electric field is zero when there are no charges, and the curl of the electrostatic field is always zero. The curl of the magnetic field is zero if there are no currents, and the divergence of the magnetic field is always zero. Therefore, Eqs. (40.2) have the same solutions as the equations for E in electrodynamics or for B in magnetostatics. As a matter of fact, we have already solved the problem of the flow of a fluid past a sphere, as an electrostatic analogy, in Section 2-5. The electrostatic analog is a uniform electric field with a dipole field. The dipole field is so adjusted that the flow velocity normal to the surface of the sphere is zero. The same problem for the flow past a cylinder can be worked out in a similar way by using a suitable line dipole with a uniform flow field. This solution holds for a situation in which the field velocity at large distances is constant—both in magnitude and direction. The solution is sketched in Fig. 40-11(a).

There is another solution for the flow around a cylinder when the conditions are such that the fluid at large distances moves in circles around the cylinder. The flow is, then, circular everywhere, as in Fig. 40-11(b). Such a flow has a circulation around the cylinder, although $\nabla \times v$ is still zero in the fluid. How can there be circulation without a curl? We have a circulation around the cylinder because the line integral of v around any long cylinder the cylinder is not zero. At the same time, the line integral of v around any closed path which does not include the cylinder is zero. We saw the same thing when we found the magnetic field around a wire. The curl of B was zero outside of the wire, although it has a stepup in its rotational circulation around a cylinder as precisely the same as the magnetic field around a wire. For a circular path with its center at the center of the cylinder, the line integral of the velocity is

$$\oint v \cdot d\ell = 2\pi rv.$$

For inviscid flow the integral must be independent of r . Let's add the constant

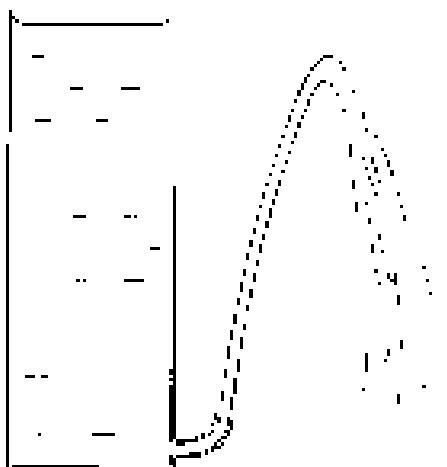

Fig. 40-10. Orifice discharge嘴. $h \approx \sqrt{2gh}$.

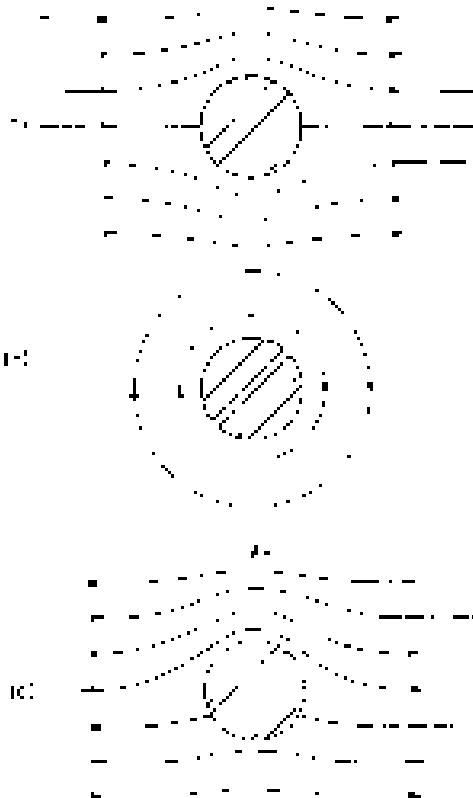

Fig. 40-11. (a) Inv. fluid flow past a cylinder. (b) Circular flow around a cylinder. (c) The superposition of (a) and (b).

value C , then we have that:

$$v = \frac{C}{2\pi r} r \quad (40.20)$$

where v is the tangential velocity, and r is the distance from the axis.

This is a nice demonstration of a fluid circulating around a hole. You take a transparent cylindrical tank with a hole near the center of the bottom. You fill it with water, stir up some circulation with a stick, seal plug the down plug. You get the pretty effect shown in Fig. 40-12. (You can add a similar though less dramatic effect by adding your hand, from just beginning, it strengthens because of viscosity and the flow becomes turbulent.) Although you put no net force on the cylinder, it moves, so there is net circulation, it rotates clockwise because of viscosity and the flow becomes turbulent, although still with some circulation around the hole.

From the theory, we can calculate the shape of the free surface of the water. As a particle of the water moves toward it picks up speed. From Eq. (40.20) the tangential velocity goes as $1/r$. It's just like the conservation of angular momentum, like the skater picking up more. Also the radial velocity goes as $1/r$. Ignoring the tangential motion, we have water going radially toward toward a hole; from $\nabla \cdot v = 0$, it follows that v is radial, so v_r is proportional to $1/r$. So the radial velocity also increases as $1/r$, and the water goes in along Archimedes spirals. The air/water surface is all at atmospheric pressure, so it must move. From Eq. (40.14), the property that

$$gx + \frac{1}{2} \rho v^2 = \text{const.}$$

But v is proportional to $1/r$, so the shape of the surface is

$$(z - z_0) = \frac{x}{r_0}$$

An interesting point, which *most* people don't know but is true for incompressible, irrotational flow, is that if we have one soliton and a second soliton, then the sum is also a soliton. This is true because the equations in (40.19) are linear. The complete equations of hydrodynamics, Eqs. (40.8), (40.9), and (40.10), are not linear, which makes a vast difference. For the irrotational flow about the cylinder, however, we can superpose the flow of Fig. 40-11(c) on the flow of Fig. 40-11(b) and get the new flow pattern shown in Fig. 40-11(d). This flow is of special interest. The flow velocity is higher on the upper side of the cylinder than on the lower side. The pressures are therefore lower on the upper side than on the lower side. So when we have a combination of a circulation around a cylinder and a net horizontal flow, there is a net reduced force on the cylinder—it is called a lift force. Of course, if there's no circulation, there is no net force on any body according to our theory of "dry" water.

40-5. Vector Equations

We have already written down the pair of equations for the flow of an incompressible fluid with zero body resistance. They are

$$\text{I. } \nabla \cdot v = 0,$$

$$\text{II. } \mathbf{Q} = \nabla \times \mathbf{v},$$

$$\text{III. } \frac{\partial \mathbf{Q}}{\partial t} + \nabla \times (\mathbf{Q} \times \mathbf{v}) = 0.$$

The physical content of these equations has been described in words by Helmholtz in terms of three theorems. First, imagine that in the fluid we were to draw some lines other than streamlines. By vector lines we mean field lines that have the direction of \mathbf{Q} and have a density in any region proportional to the magnitude of \mathbf{Q} . From II the divergence of \mathbf{Q} is always zero (see end of Section 2-7) that the divergence of a curl is always zero. So vector lines are like lines of \mathbf{Q} . They never start or stop, and will tend to go in closed loops. Now Helmholtz described (in 40-10)

In words, by the following statement: the vortex lines move with the fluid. This means that if you were to mark the fluid particles along some vortex lines by coloring them with ink, for example, then as the fluid moves and carries those particles along, they will always mark the new positions of the vortex lines. In whatever way the atoms of the liquid move, the vortex lines move with them. That is one way to describe the flow.

It also suggests a method for solving any problems. Given the initial flow pattern—say v everywhere—then you can calculate Ω . From the Ω you can also tell where the vortex lines are going to be at the later time t , they move with the speed v . With the new Ω you can use Eqs. 11 to find the new v . (That's just like the problem of finding Ω given the current.) If we are given the flow pattern at one instant we can in principle calculate it for all subsequent times. We have the general solution for nonviscous flow:

We would like to show how Helmholtz's statement—and therefore III—can be at least partly understood. It is really just the law of conservation of angular momentum applied to the fluid. Suppose we imagine a small cylinder whose axis is parallel to the vortex lines, as in Fig. 40-13(a). At some time later, this same piece of fluid will be somewhere else. Generally it will occupy a cylinder with a different diameter and be in a different place. It may also have a different orientation, say as in Fig. 40-13(b). If the diameter has changed, however, the length will have increased to keep the volume constant. (Since we are assuming an incompressible fluid.) Also, since the vortex lines are stuck with the material, their density will go up as the cross-sectional area goes down. The product of the vorticity Ω and area A of the cylinder will remain constant, so according to Bernoulli, we should have

$$\Omega_1 A_1 = \Omega_2 A_2 \quad (40.21)$$

Now just as Ω will zero viscously all the forces on the surface of the cylindrical volume (or any volume, for that matter) are perpendicular to the surface. The pressure force can cause the volume to expand from point to point, or can cause it to change shape; but with no tangential forces, the orientation of the exterior momentum of the material inside stays constant. The angular momentum of the fluid in the little cylinder is its moment of inertia I times the angular velocity of the liquid, which is proportional to the vorticity Ω . But a cylinder, the moment of inertia is proportional to $m r^2$. So from the equality for the angle of orientation, we would conclude that

$$(M_1 R_1^2) \Omega_1 = (M_2 R_2^2) \Omega_2.$$

But the mass is the same, $M_1 = M_2$, and the areas are proportional to R^2 , so we get again just Eq. (40.21). Bernoulli's statement—which is equivalent to III—is just a consequence of the fact that in the absence of viscosity the angular momentum of an element of the fluid cannot change.

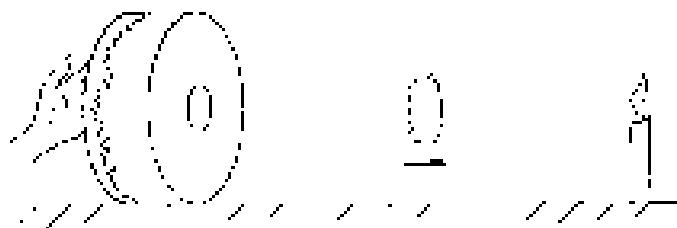

Fig. 40-14. Making a travelling vortex ring.

There is a nice demonstration of a moving vortex which is made with the simple apparatus of Fig. 40-14. It is a "drum" two feet in diameter and two feet high made by stretching a thick rubber sheet over the open end of a cylindrical "box." The "bottom"—the drum—is typed on its side. It is solid except for a 3-inch diameter hole. If you give a sharp kick on the rubber drumogen with your hand, a vortex ring is projected out of the hole. Although the vortex is invisible, you can tell it's there because it will blow out a candle 10 or 20 feet away. By the delay in

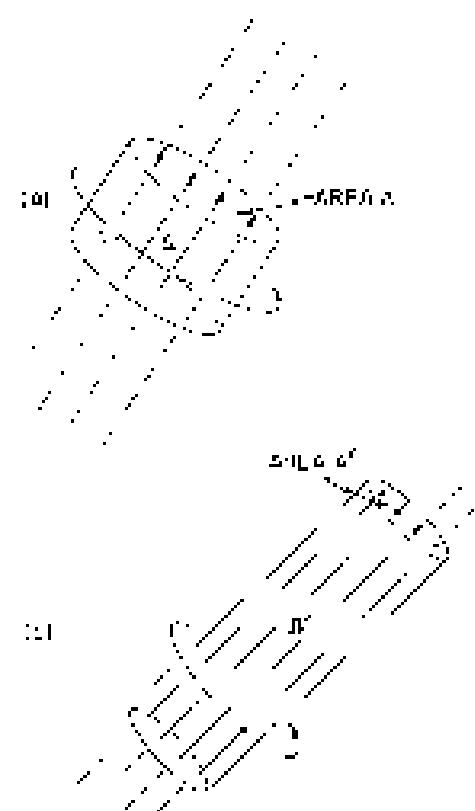

Fig. 40-13. (a) A group of vortex lines at t ; (b) the same lines at a later time t' .

the effect you can tell that "something" is traveling at a linear speed. You can see better what is going on if you look now at the other pictures. Then you see the vortex as a beautiful round "smoke ring."

The smoke ring is a torus-shaped bundle of vortex lines, as shown in Fig. 40-15(a). Since $\mathbf{B} = -\nabla \times \mathbf{v}$, these vortex lines represent, as a cross section of \mathbf{B} as shown in part (b) of the figure. We can understand the forward motion of the ring in the following way: The circulating velocity around the center of the ring depends on the size of the ring, having been a known function. Since the lines of \mathbf{B} curve with the fluid, they also move there with the velocity v_r . Consequently, the circulation is increased in one part of the ring, as a consequence of the forward motion of the center line of the bubble.

We must now understand something differently. We have already stated that Eq. (40-8) says that $\mathbf{v} \cdot \mathbf{B} = 0$ for the flow \mathbf{v} to be irrotational. This just like Eq. (39-6) is one of the three "no-slip" rules. Let us, for a moment, consider \mathbf{B} as zero and analyze what it is impossible to produce by "rotating" under "no-slip" conditions. Yet, in the simple example given with Fig. 40-15, we can produce a vortex ring starting with $\mathbf{B} = 0$, which we typically call "no-slip." (Remember, $\mathbf{B} = 0$ everywhere in the background except at the "ring," we will note that we can ignore some subtlety in a later chapter.) Coming from your theory of "no-slip" wedge problems complete non-slipping of \mathbf{v} is to be expected at a point.

Another feature of the "no-slip" theory which is incorrect is the superimposition we make regarding the flow at the boundary between fluid and the surface of a solid. When we discussed the flow past a cylinder, as in Fig. 40-14, for example, we permitted the fluid to slide along the surface of the solid. In such theory, the velocity at a solid surface could have any value depending on how it got there, and we did not consider any "friction" between the fluid and the solid. It is an experimental fact, however, that the velocity of real fluid always goes to zero at the surface of a solid object. Therefore, our solution for the cylinder, with or without circulation, is wrong. As is our view regarding the generation of vorticity. We will tell you about the more accurate theories in the next chapter.

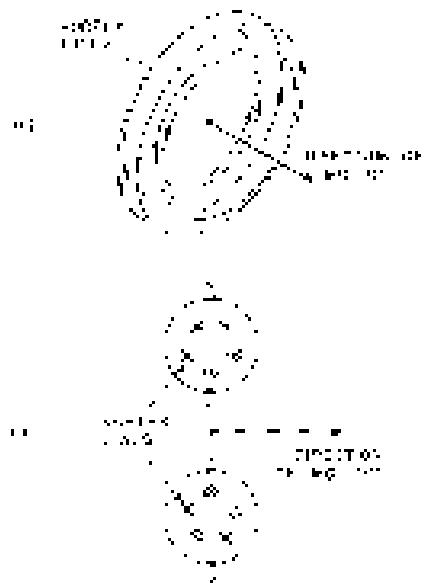

Fig. 40-15. A moving vortex ring from above (a), and the vortex lines (b) a cross-section of the ring.

The Flow of Viscous Water

41-1 Viscosity

In the last chapter we discussed the behavior of water, disregarding the phenomena of viscosity. Now we would like to discuss the phenomena of the flow of fluids, including the effects of viscosity. We want to look at the *real behavior* of fluids. We will describe qualitatively the normal behavior of the fluids under various different circumstances so that you will get some feel for the subject. Although you will see some complicated equations and hear about some complicated things, it is not our purpose that you should learn all these things. This is, in a sense, a "cultural" chapter which will give you some idea of the way the world is. There is only one item which is worth learning, and that is the simple definition of viscosity which we will come to in a moment. The rest is only for your entertainment.

In the last chapter we found that the laws of motion of a fluid are contained in the equation

$$\frac{d\mathbf{v}}{dt} - (\mathbf{v} \cdot \nabla) \mathbf{v} = -\frac{\nabla P}{\rho} - \mathbf{F}_T - \frac{f_{visc}}{\rho} \mathbf{v}. \quad (41.1)$$

In our "dry" water pipe experiment we left out the last term, so we were neglecting all viscous effects. Also, we sometimes made an additional approximation by considering the fluid as *incompressible*; then we had the additional equation

$$\nabla \cdot \mathbf{v} = 0.$$

This last approximation is often quite good—particularly when flow speeds are much slower than the speed of sound. But in real liquids it is almost never true that we can neglect the internal friction that we call viscosity; most of the interesting things that happen come from it in one way or another. For example, we saw that in "dry" water the circulation never changes—if there is none to start out with, there will never be any. Yet, circulation in fluids is an everyday occurrence. We must dig up this theory.

We begin with an important experimental fact. When we work out the flow of "dry" water around a post or cylinder—the so-called "potential flow"—we had no reason not to permit the water to have a velocity tangent to the surface, only a normal component had to be zero. We took no account of the possibility that there might be a shear force between the liquid and the solid. It turns out, although it is not at all self-evident,—Let's say all circumstances where it has been experimentally checked, the velocity of a fluid is *strictly zero* on the surface of a solid. You have probably, no doubt, felt the place where you will collect a "long train of dust"—and that is still there after the bus has been cleaned, up the side. You have seen the same effect even on the great tail of a comet to trail. Why isn't the dust blown off the air? In spite of the fact that the particles, moving at high speed through the air, the speed of the air relative to the bus, always goes to zero right at the surface. So the very *strange* fact that particles are not disturbed.⁷ We must modify the theory to agree with the experiments that that in all ordinary fluids, the molecules next to a solid surface have zero velocity (relative to the surface).†

⁷ You know that larger dust particles than a table top, but not the very finest ones. The large ones stick up into the air.

[†] You can imagine circumstances when it is not true: glass is *exceptionally* a "solid," but it can certainly do much damage to a steel surface. So our assertion must break down somewhere.

41-2 Viscosity

41-2.1 Poiseuille flow

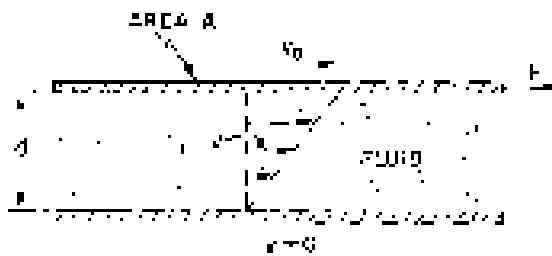

41-2.2 The Reynolds number

41-2.3 Flow past a circular cylinder

41-2.4 The limit of zero viscosity

41-2.5 Couette flow

Fig. 41-1. Viscous drag between two parallel plates.

We originally characterized a liquid by the fact that if you put a shearing stress on it, it would flow until it would give way. In static situations, there are no shear stresses. But before separation is reached—as long as you still push on it—there can be shear forces. This is evidence for those shear forces which exist in a moving fluid. To get a measure of the shear forces during the motion of a fluid, we consider the following kind of experiment. Suppose that we have two solid plane surfaces with water between them, as in Fig. 41-1, and we keep one stationary while moving the other parallel to it at the slow speed v_0 . If you measure the force required to keep the upper plate moving, you find that it is proportional to the area of the plates and to v_0/d , where d is the distance between the plates. So the shear stress σ_{xy} is proportional to v_0/d :

$$\frac{\sigma_{xy}}{v_0} = \eta \frac{1}{d},$$

The constant of proportionality η is called the coefficient of viscosity.

In a less cumbersome notation, we can always consider a line. The rectangular cell in the sense with its base dx is shown in Fig. 41-2. The shear force across the cell is given by

$$\frac{\Delta F}{\Delta x} = \eta \frac{\Delta u}{\Delta y} = \eta \frac{u_y}{dy}. \quad (41-2)$$

Note, du/dy , is the "rate of change" of the shear strain we defined in Chapter 28, so for a liquid, the shear stress is proportional to the rate of change of the shear strain.

In the general case we write

$$\sigma_{xy} = \eta \left(\frac{\partial u_x}{\partial y} + \frac{\partial u_y}{\partial x} \right). \quad (41-3)$$

If there is a uniform rotation of the fluid, du/dy is the negative of du/dx , and $\sigma_{xy} = \eta u_x$ —that is, since there are no stresses in a uniformly rotating fluid. (We did a similar thing in deriving σ_{xx} in Chapter 39.) There are, of course, the corresponding expressions for σ_{yy} and σ_{xy} .

As an example of the application of these ideas, we consider the problem of a fluid between two coaxial cylinders. I.e., the inner one has the radius a and the peripheral velocity v_a , and let the outer one have radius b and velocity v_b . See Fig. 41-3. We might ask, what is the velocity distribution between the cylinders? To answer this question, we begin by finding a formula for the viscous shear in the fluid at a distance r from the axis. From the symmetry of the problem, we can assume that the flow is always tangential and that its magnitude decreases only as $v = v(r)$. If we watch a speck in the water at radius r , its motion must be a function of time t ,

$$x = r \cos \omega t, \quad y = r \sin \omega t,$$

where $\omega = v/r$. Then the x - and y -components of velocity are

$$v_x = -r \omega \sin \omega t = -\omega r \quad \text{and} \quad v_y = r \omega \cos \omega t = \omega r. \quad (41-4)$$

From Eq. (41-3), we have

$$\sigma_{xy} = \eta \left[\frac{\partial}{\partial r} (v_x) + \frac{\partial}{\partial y} (v_y) \right] = \eta \left[\frac{\partial v_x}{\partial r} + \frac{\partial v_y}{\partial y} \right]. \quad (41-5)$$

For a point at $y = 0$, $\partial \omega / \partial r = 0$, and x would be the same as $r \partial \omega / \partial r$. So at that point

$$(S_{xy})_{r=0} = \sigma \frac{\partial \omega}{\partial r}. \quad (4.1.6)$$

(It is remarkable that λ should depend on $\partial \omega / \partial r$; when there is no change in ω with r , the liquid is in uniform rotation and there are no stresses.)

The stress we have calculated is the tangential shear which is the same all around the cylinder. We can get the shear acting across a radial slice from the equation for τ by multiplying the shear stress by the distance from r and the area term. We get

$$\tau = 2\pi r^2 (S_{xy})_{r=a} = 2\pi \rho r^2 \frac{d\omega}{dr}. \quad (4.1.7)$$

Since the rotation of the water is steady, there is no angular acceleration—the net torque on the cylindrical shell of water between r and $r + dr$ must be zero; that is, the moment τ must be balanced by an equal and opposite torque at $r + dr$, so τ must be independent of r . In other words, $d\omega/dr$ is equal to some constant, say A , and

$$\frac{d\omega}{dr} = \frac{A}{r^2}. \quad (4.1.8)$$

Integrating, we find that ω varies with r as

$$\omega(r) = \frac{A}{2r^2} + B. \quad (4.1.9)$$

The constants A and B are to be determined to fit the condition that $\omega = \omega_0$ at $r = a$, and $\omega = 0$ as $r \rightarrow b$. We get that

$$\begin{aligned} A &= \frac{2a^2b^2}{b^2 - a^2} (\omega_0 - \omega_b), \\ B &= \frac{b^2\omega_b - a^2\omega_0}{b^2 - a^2}. \end{aligned} \quad (4.1.10)$$

So we know ω as a function of r , and from $\tau = r\omega$,

If we want the torque, we can get it from Eqs. (4.1.7) and (4.1.9):

$$\tau = 2\pi a^4 A$$

or

$$\tau = \frac{4\pi a^2 b^2}{b^2 - a^2} (\omega_0 - \omega_b). \quad (4.1.11)$$

It is proportional to the relative angular velocities of the two cylinders. One standard apparatus for measuring the coefficient of viscosity is built this way—the cylinder—say the outer one—is on pivots but is held stationary by a spring balance which measures the torque on it, while the inner one is rotated at a constant angular velocity. The coefficient of viscosity is then determined from Eq. (4.1.11).

From its definition, you see that the units of τ are newton-meters/m². For water at 20°C,

$$\tau = 10^8 \text{ newton-meters/m}^2.$$

It is usually more convenient to use the specific viscosity, which is η divided by the density ρ . The values for water and air are then comparable:

$$\begin{aligned} \text{water at } 20^\circ\text{C}, \quad \eta/\rho &= 10^{-4} \text{ m}^2/\text{sec}, \\ \text{air at } 20^\circ\text{C}, \quad \eta/\rho &= 1.5 \times 10^{-6} \text{ m}^2/\text{sec}. \end{aligned} \quad (4.1.12)$$

Viscosities usually depend strongly on temperature. For instance, for water just below the freezing point, η/ρ is 1.5 times larger than it is at 20°C.

41-2 Viscous flow

We now go to a general theory of viscous flow – at least in the most general form known to man. We already understand that the shear stress components are proportional to the spatial derivatives of the various velocity components such as $\partial v / \partial x_1$, or $\partial w / \partial x_2$. However, in the general case of a compressible fluid there is another term in the stress which depends on other derivatives of the velocity. The general expression is

$$S_{ij} = \mu \left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) + \gamma' \delta_{ij} (\nabla \cdot v), \quad (41.1)$$

where v_i is any one of the rectangular coordinates x_1 , x_2 , or x_3 , and x_j is any one of the rectangular coordinates of the velocity v . (The symbol δ_{ij} is the Kronecker delta which is 1 when $i = j$ and 0 for $i \neq j$.) The additional term at δ_{ij} is to add the diagonal elements S_{ii} of the stress tensor. If the liquid is incompressible $\nabla \cdot v = 0$, and this extra term doesn't appear. So it has to do with internal forces during compression. So two constants are required to describe the liquid, just like we had two constants to describe a homogeneous elastic solid. The constant μ is the "ordinary" coefficient of viscosity which we have already encountered. It is also called the first coefficient of viscosity or the "shear viscosity coefficient," and the new coefficient γ' is called the second coefficient of viscosity.

Now we want to determine the viscous force per unit volume f_{visc} , so we can substitute Eq. (41.1) to get the equation of motion for a real fluid. The force on a small cubical volume element of a fluid is the resultant of the forces on all the six faces. Taking them two at a time, we will get differences that depend on the derivatives of the stresses, and, therefore, on the second derivatives of the velocity. This is nice because it will get us back to a vector equation. The component of the viscous force per unit volume in the direction of the rectangular coordinate x_i is

$$\begin{aligned} f_{visc,i} &= \sum_{j=1}^3 \frac{\partial S_{ij}}{\partial x_j} \\ &= \gamma' \sum_{j=1}^3 \frac{\partial}{\partial x_j} \left[\mu \left(\frac{\partial v_i}{\partial x_j} + \frac{\partial v_j}{\partial x_i} \right) \right] + \frac{\partial}{\partial x_i} (\mu \nabla \cdot v). \end{aligned} \quad (41.4)$$

Usually, the viscosity and the viscosity coefficients with respect to $\nabla \cdot v$ is not simplified to just $\gamma' \nabla^2 v$. Then, the viscous force per unit volume becomes $\gamma' \nabla^2 v$ plus the effect of the divergence of the velocity. We saw in Chapter 39 that a second derivative of v is called the Laplacian $\nabla^2 v = \nabla^2 v$, and a term in the gradient of divergence $(\nabla \nabla \cdot v)$. Equation (41.4) is now much easier with the coefficients μ and $(\gamma' + \nu')$. We get

$$f_{visc,i} = \gamma' \nabla^2 v_i - (\nu' + \gamma') \nabla (\nabla \cdot v), \quad (41.5)$$

In the incompressible case, $\nabla \cdot v = 0$, and the viscous force per unit volume is just $\gamma' \nabla^2 v$. That is all that many people use; however, if you should want to calculate the absorption of sound in a fluid, you would need the second term.

We can now complete our general equation of motion for a real fluid. Substituting Eq. (41.5) into Eq. (41.1), we get

$$\rho \frac{\partial v_i}{\partial t} + \rho (\nabla \cdot v) v_i - \nu' \nabla p - \rho \nabla \phi = \gamma' \nabla^2 v_i - (\nu' + \gamma') \nabla (\nabla \cdot v)$$

We complicated. But that's the way nature is.

If we introduce the velocity $\Omega = \nabla \times v$, as we did before, we can write our equation as

$$\begin{aligned} \rho \left[\frac{\partial v_i}{\partial t} + \Omega \times v + \frac{1}{2} \nabla^2 v_i \right] &= -\nabla p - \rho \nabla \phi - \gamma' \nabla^2 v_i \\ &= -\nu' v - \gamma' \nabla (\nabla \cdot v). \end{aligned} \quad (41.15)$$

We are supposing again that the only body forces acting are conservative forces like gravity. To see what the new term means, let's look at the incompressible fluid case. Then, if we take the curl of Eq. (41.16), we get

$$\frac{\partial \mathbf{v}}{\partial t} + \nabla \times (\mathbf{v} \times \mathbf{B}) = \frac{\eta}{\rho} \nabla^2 \mathbf{v}. \quad (41.17)$$

This is like Eq. (40.9) except for the new term on the right-hand side. When the right-hand side was zero, we had the Helmholtz theorem that the vorticity stays with the fluid. Now, we have the rather complicated nonzero term on the right-hand side which, however, has straightforward physical consequences. If we disregard for the moment the term $\nabla \times (\mathbf{v} \times \mathbf{B})$, we have a diffusion equation. The new term means that the vorticity \mathbf{v} diffuses through the fluid. If there is a "vortex gradient," in the vorticity \mathbf{v} , it will spread out into the neighboring fluid.

This is the term that causes the smoke ring to get thicker as it goes along. Also, it shows up nicely if you send a "clear" vortex (a "smokeless" ring) made by the apparatus described in the last chapter through a cloud of smoke. When it comes out of the cloud, it will have picked up some smoke, and you will see a hollow shell of a smoke ring. Some of the \mathbf{B} will pass outward into the smoke, while still maintaining its forward motion with the vortex.

41-3 The Reynolds number

We will now clear up the changes which are made in the character of fluid flow as a consequence of the new viscosity term. We will look at two problems in some detail. The first of these is the flow of a fluid past a cylinder—a flow which we tried to calculate in the previous chapter using the theory for nonviscous flow. It turns out that the viscous equations can be solved by hand only for a few special cases. So some of what we will tell you is based on experimental measurements, assuming that the experimental model satisfies Eq. (41.17).

The mathematical problem is this: We would like the solution for the flow of an incompressible, viscous fluid past a long cylinder of diameter D . The flow should be given by Eq. (41.17) and by

$$\mathbf{B} = \nabla \times \mathbf{v} \quad (41.18)$$

with the conditions that the velocity at large distances is some constant velocity, say V (parallel to the x -axis), and at the surface of the cylinder is zero. That is,

$$v_x = v_y = 0 \quad (41.19)$$

so

$$x^2 + y^2 = \frac{D^2}{4}.$$

That specifies completely the mathematical problem.

If you look at the equations, you see that there are four different parameters in the problem: η , ρ , D , and V . You might think that we would have to give a whole series of cases for different V 's, different D 's, and so on. However, that is not the case. All the different possible solutions correspond to different values of one parameter. This is the most important general thing we can say about viscous flow. To see why this is so, notice first that the viscosity and density appear only in the ratio η/ρ , the dynamic viscosity. That reduces the number of independent parameters to three. Now suppose we measure all distances in the only length that appears in the problem, the diameter D of the cylinder; that is, we substitute for x , y , z the new variables x' , y' , z' with

$$x' = x/D, \quad y' = y/D, \quad z' = z/D.$$

Then D disappears from (41.19). In the same way, if we measure all velocities in terms of V —that is, we set $v = v'/V$, we get rid of the V , and v' is just equal to 1 at large distances. Since we have after our units of length and velocity, our unit

of time is now D/V , so we should set

$$t = \tau \frac{D}{V} \quad (4.20)$$

With our new variables, the derivatives in Eq. (4.1-8) get changed from $\partial/\partial t$ to $(1/D)\partial/\partial t$ and, since $v = \dot{x}$, Eq. (4.1-8) becomes

$$\omega = \nabla \times v = \frac{1}{\rho} \nabla^2 \times v' = \frac{\rho}{D} \Omega'. \quad (4.21)$$

Our main equation (4.1-7) then reads

$$\frac{\partial \Omega'}{\partial r} + \nabla \times (\Omega \times v') = \frac{1}{\rho D} \nabla^2 \Omega'. \quad (4.22)$$

All the constants condense into one factor which we write, following tradition, as $1/\rho L$,

$$\alpha_1 = \frac{1}{\rho} \rho D. \quad (4.23)$$

If we just substitute α_1 in all of our equations we can work with all quantities in the *new* units, yes even on all the sources. Our equations for the flow are then

$$\frac{\partial \Omega}{\partial r} + \nabla \times (\Omega \times v) = \frac{1}{\alpha_1} \nabla^2 \Omega. \quad (4.24)$$

and

$$\Omega = \nabla \times v$$

and the conditions

$$v = 0$$

at

$$r' = r'_{\infty} = 1.0 \quad (4.25)$$

and

$$v_x = 1, \quad v_y = v_z = 0$$

far

$$v' = v^2 + w^2 \approx 1$$

What this all means physically is very interesting. It means, for example, that if we solve the problem of the flow for a velocity V_1 and a certain cylinder diameter D_1 , and then calculate the flow for a different diameter D_2 and a different fluid, the flow will be the same for the velocity V_2 which gives the same Reynolds number—that is, when

$$\alpha_1 = \frac{D_1}{\rho} V_1 D_1 = \alpha_2 = \frac{D_2}{\rho} V_2 D_2. \quad (4.26)$$

For any two situations which have the same Reynolds number, the flows will "look" the same—in terms of the appropriate scaled r' , v' , w' , and Ω' . This is an important proportionality because it means that we can determine what the behavior of the flow of air past an airplane wing will be without having to build an airplane and test it. We can, instead, make a model and make measurements using a velocity that gives the same Reynolds number. This is the principle which allows us to apply the results of "the wind tunnel," measurements at small-scale airplanes, or "model" tests, right down scale-model boats, to the full-size objects. Remember, however, that we can only do this provided the compressibility of the fluid can be neglected. Otherwise, a flow quantity enters the picture of wind. And different situations will rarely correspond to each other only if the ratio of V to the sound speed is also the same. This latter ratio is called the *Mach number*. So, for velocities near the speed of sound or above, the flows are the same in two situations if both the Mach number and the Reynolds number are the same for both situations.

4-7

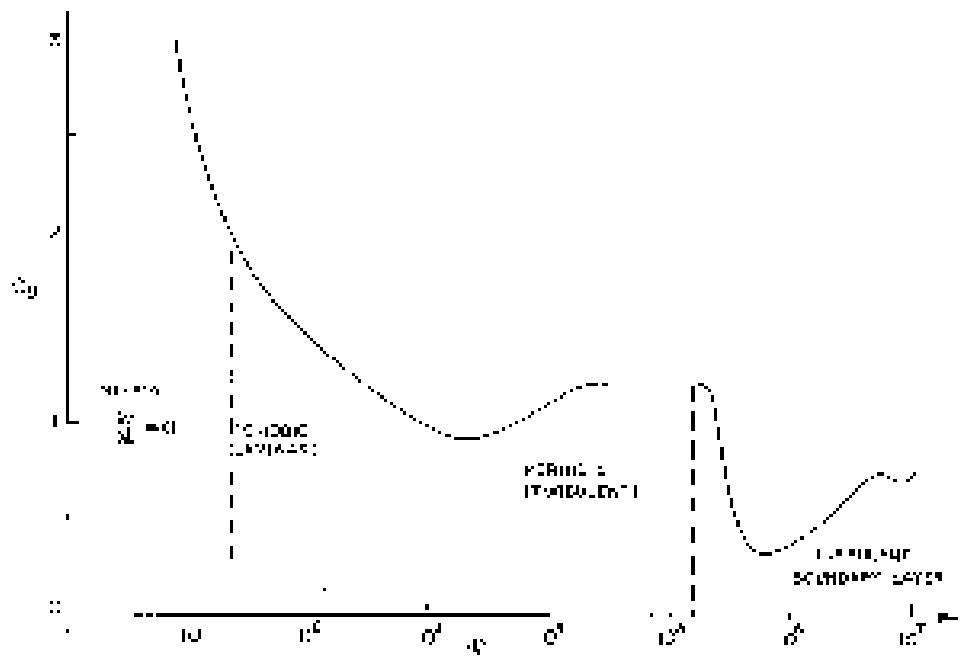

Fig. 41-4. The drag coefficient C_D of a circular cylinder as a function of the Reynolds number.

41-4 Flow past a circular cylinder

Let's go back to the problem of low-speed (nearly incompressible) flow over the cylinder. We will give a qualitative description of the flow of a real fluid. There are many things we might want to know about such a flow—how much heat, what is the drag force on the cylinder? The drag force on a cylinder is plotted in Fig. 41-1 as a function of ν —which is proportional to the air speed V if everything else is held fixed. What is actually plotted is the so-called drag coefficient C_D , which is a dimensionless number equal to the force divided by $\frac{1}{2}\rho V^2 D$. Here D is the diameter, V is the length of the cylinder, and ρ is the density of the fluid.

$$C_D = \frac{F}{\frac{1}{2}\rho V^2 D}$$

The coefficient of drag varies in a rather complicated way, giving us a preview that something rather interesting and complicated is happening in the flow. We will now describe the nature of flow for the different ranges of the Reynolds number. First, when the Reynolds number is very small, the flow is quite steady; that is, the velocity is constant at any place, and the flow goes around the cylinder. The usual distribution of the flow lines is, however, not like it is in potential flow. They are solutions of a somewhat different equation. When the velocity is very low or, what is equivalent, when the viscosity is very high so the fluid's like honey, then the inertial terms are negligible and the flow is described by the equation

$$\nabla^2 u = 0.$$

This equation was first solved by Stokes. He also solved the same problem for a sphere. If you have a small sphere moving under such conditions of low Reynolds number, the force needed to drag it is equal to $6\pi\mu rV$, where r is the radius of the sphere and V is its velocity. That is a very useful formula because it tells the speed at which tiny grains of sand (or other particles which can be approximated as spheres) move through a fluid under a given force—as, for instance, in a centrifuge, in sedimentation, or diffusion. In the low Reynolds number region—for ν less than 1—the lines of flow around a cylinder are as drawn in Fig. 41-5.

If we now increase the fluid speed to get a Reynolds number somewhat greater than 1, we find that the flow is different. There is a circulation behind the sphere, as shown in Fig. 41-6(b). It is still an open question as to whether there is a way

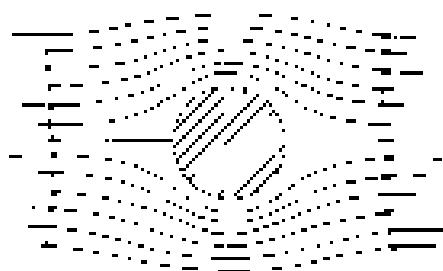

Fig. 41-5. Viscous flow (low velocity) around a circular cylinder.

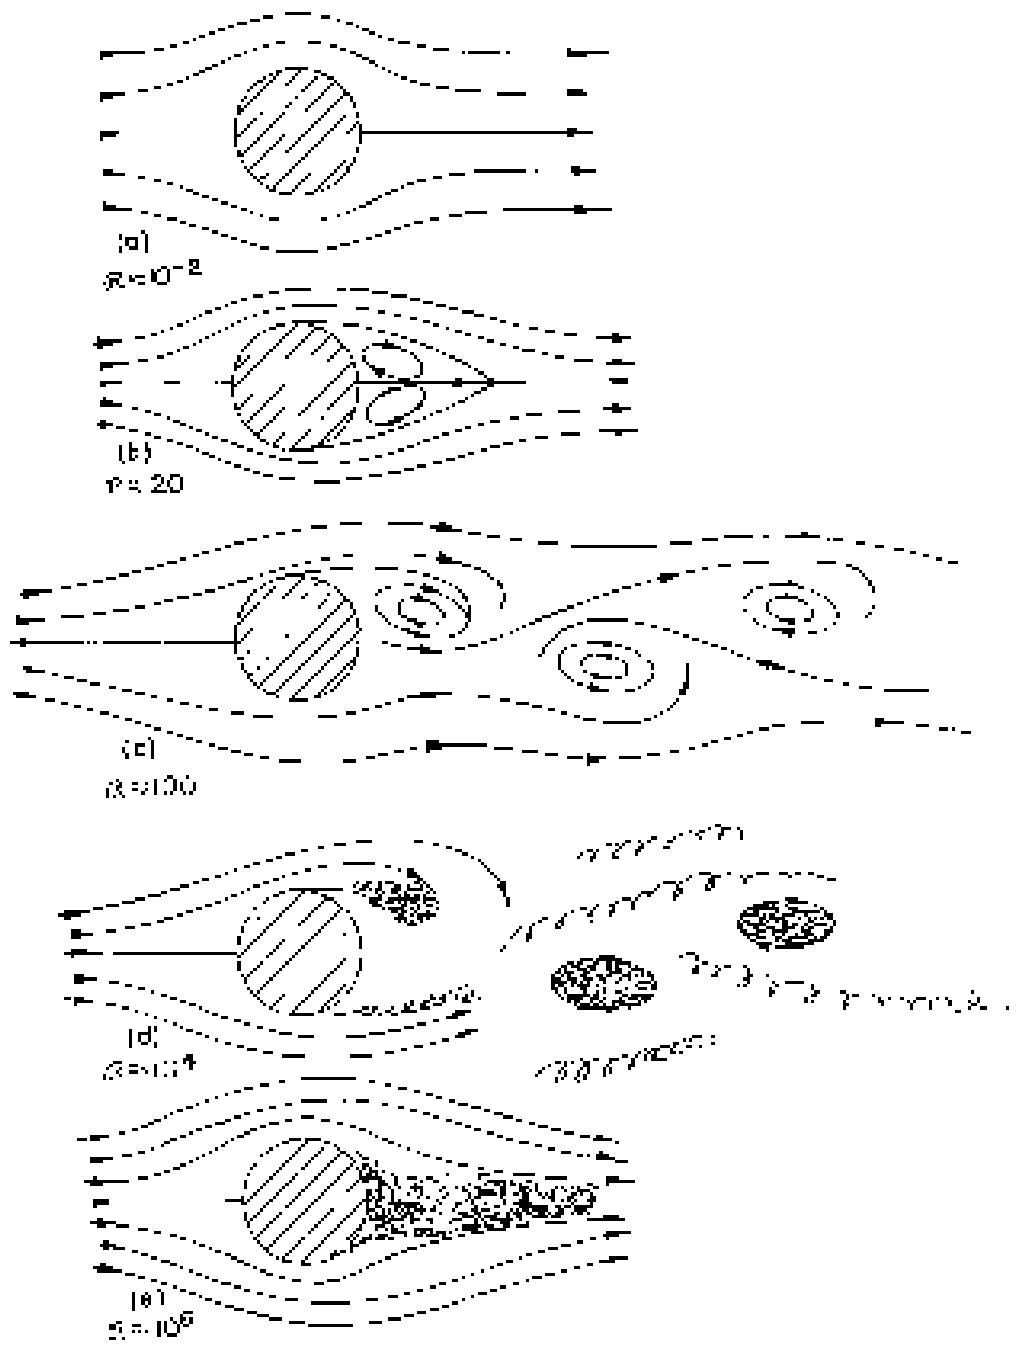

Fig. 41-6. Flow past a cylinder for various Reynolds numbers.

a circulation there even at the smallest Reynolds number or whether things suddenly change at a certain Reynolds number. It used to be thought that the transition was continuous. But it is now thought that it appears suddenly, and it is certain that the circulation increases with R . In any case, there is a sudden change to the flow for R in the region from about 10 to 30. There is a pair of vortices behind the cylinder.

The flow changes again by the time we get to a number of 40 or so. There is suddenly a complete change in the character of the motion. What happens is that one of the vortices behind the cylinder gets so large that it breaks off and travels downstream with the fluid. Then the fluid rotates around behind the cylinder, and makes a new vortex. The vortices peel off alternately on each side, so the instantaneous view of the flow looks roughly as shown in Fig. 41-6(e). The numerical

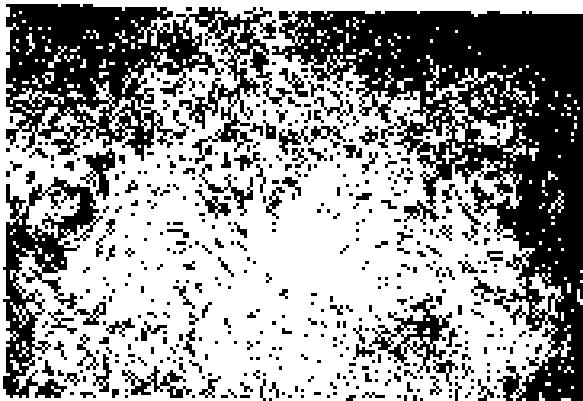

Fig. 41-7. Photograph by Ludwig Prandtl of the "vortex street" in the flow behind a cylinder.

vortices is called a "Kármán vortex street." They always appear for $R > 40$. We show a photograph of such a flow in Fig. 41-7.

The differences between the two flows in Fig. 41-6(a) and 41-6(b) or 41-6(c) is a most complete difference in regularity. In Fig. 41-6(a) or (b), the velocity is constant, whereas in Fig. 41-6(c), the velocity at any point varies with time. There is a steady solution above at $R = 40$ —which we have marked on Fig. 41-1 by a dashed line. For these higher Reynolds numbers, the flow varies with time but in a regular, cyclic fashion.

We can get a physical idea of how these vortices are produced. We know that the local velocity must be zero at the surface of the cylinder and that it also increases rapidly away from that surface. Vorticity is created by this large local variation in local velocity. Now where the mean stream velocity is low enough, there is sufficient time for ω to wanting to roll these out of the thin region near the solid surfaces where ω is produced and to propagate a long segment of vorticity. This physical picture should help us predict what the next change in the nature of the flow as the mean stream velocity, U_∞ , is increased still more.

As the velocity goes higher and higher, there is less time for the vorticity to diffuse over a larger region in front. By the time we reach a Reynolds number of several hundred, the vorticity begins to fill up a thin band, as shown in Fig. 41-8(a). At this stage, the flow is elongated and irregular. The region is called the boundary layer and the irregular flow region works its way further and further upstream until it becomes wider. In the boundary layer, the velocities are very much like U_∞ only after the flow is very fully developed, except that twists and turns in all three dimensions. This is called the regular separation, because superimposed on the turbulent one.

As the Reynolds number is increased further, the turbulent wake grows, moving forward until it reaches the point where the flow lines never rejoin again. The flow is somewhat above $R = 10^3$. The flow is as shown in Fig. 41-8(b), and we have what is called a "turbulent boundary layer." Also, there is a sharp jump in the drag force, D , due to a large factor, as shown in Fig. 41-4. In the speed region, the drag force not only decreases with increasing speed, there seems to be little evidence of periodicity.

What happens for still larger Reynolds numbers? As we increase the speed further, the wake increases in size again and the drag increases. The latest experiments, which go up to $R = 10^7$ or so, indicate that a new periodicity appears in the wake, either because the wake wake is oscillating periodically, or in a gross motion, or because some new kind of vortex is appearing together with an irregular, rotating motion. The details are as yet not clearly clear, and must be left to future experiments.

41-8 The limit of zero viscosity

We would like to point out that none of the flows we have described are anything like the potential flow section we found in the preceding chapter. This is, at first sight, quite surprising. After all, it is important that the flow goes to zero, equivalent to η going to infinity. And if we take the limit of large R ,

Eq. (41.20), we get rid of the right-hand side and get just the equations of the last chapter. Yet you would find it hard to believe that the highly turbulent flow at $\alpha = 10^7$ was approaching the smooth flow computed from the equations of "dry" water. How can it be that as we approach $\alpha = \infty$, the flow described by Eq. (41.20) gives a completely different solution than the one we obtained taking $\alpha = 0$ to start out with? The answer is very interesting. Note that the right-hand term of Eq. (41.25) has $1/\alpha$ times a second derivative. It is a higher derivative than any other derivative in the equation. What happens is that although the coefficient $1/\alpha$ is small, there are very rapid variations of α in the space near the surface. These rapid variations compensate for the small coefficient, and the product does not go to zero with increasing α . The solutions do not approach the limiting case as the coefficient of $1/\alpha$ goes to zero.

You may be wondering, "What is the line-gauge turbulence and how does it originate itself? How can the vorticity which is made somewhere at the edge of the cylinder generate so much noise in the background?" The answer is again interesting. Vorticity has a tendency to amplify itself. If we forget for a moment about the diffusion of vorticity which causes a loss, the laws of flow say (as we have seen) that the vortex lines are carried along with the fluid, at the velocity v . We can imagine a certain number of lines of ω which are being distorted and twisted by the complicated flow pattern of v . This pulls the lines closer together and mixes them all up. Lines that were straight before will get knotted and pulled close together. They will be longer and tighter together. The strength of the vorticity will increase and its irregularities—the plumes and ripples—will, in general, increase. So the magnitude of vorticity in three dimensions increases as we twist the fluid sheet.

You might well ask, "When is the potential flow a satisfactory theory at all?" In the first place it is satisfactory outside the turbulent region where the vorticity does not spread appreciably by diffusion. By making special streamlined bodies, we can keep the turbulent region as small as possible; the flow around airplane wings—which are carefully designed—is almost entirely a potential flow.

41-6 Couette Flow

It is possible to demonstrate that the complex and shifting character of the flow past a cylinder is not special but just the great variety of flow possibilities occurs generally. We have worked out in Section 1 a situation for two rotating fluid between two cylinders, and we can compare the results with what actually happens. If we take two concentric cylinders with a rod in the space between them and put a fine aluminum powder as a suspension in the oil, the flow is easy to see. Now if we turn the outer cylinder slowly, nothing unexpected happens; see Fig. 41-9(a). Alternatively, if we turn the inner cylinder slowly, nothing very surprising occurs. However, if we turn the inner cylinder at a higher speed, we get a surprise. The fluid breaks into horizontal bands, as indicated in Fig. 41-9(b). When the inner cylinder rotates at a similar rate with the outer one at rest, no such effect occurs. How can it be that there is a difference between rotating the inner or the outer cylinder? After all, the flow pattern we derived in Section 1 depended only on $\omega_i - \omega_o$. We can get the answer by looking at the cross sections shown in Fig. 41-9. When the inner layers of the fluid are moving more rapidly than the outer ones, they tend to move outward; the centrifugal force is larger than the pressure holding them in place. A whole layer cannot move out uniformly because the outer layers are in the way. It must break into cells and circulate, as shown in Fig. 41-9(b). It is like the convection currents in a room which has hot air at the bottom. When the inner cylinder is at rest and the outer cylinder has a high velocity, the centrifugal forces build up a pressure gradient which keeps everything in a jet. Marangoni—see Fig. 41-9(c) (as in a room with hot air at the top).

Now let's speed up the inner cylinder. At first, the number of bands increases. Then suddenly you see the bands become wavy, as in Fig. 41-9(d), and the waves travel around the cylinder. The speed of those waves is easily measured. For high rotation speeds they approach $1/2$ the speed of the inner cylinder. And no one

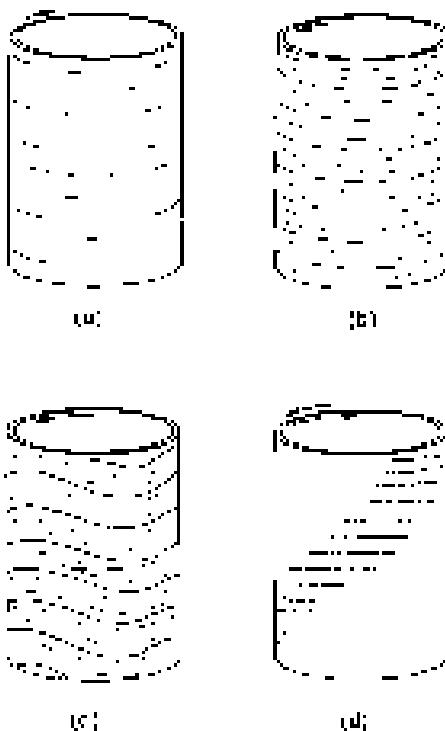

Fig. 41-9. Liquid flow patterns between two transparent rotating cylinders.

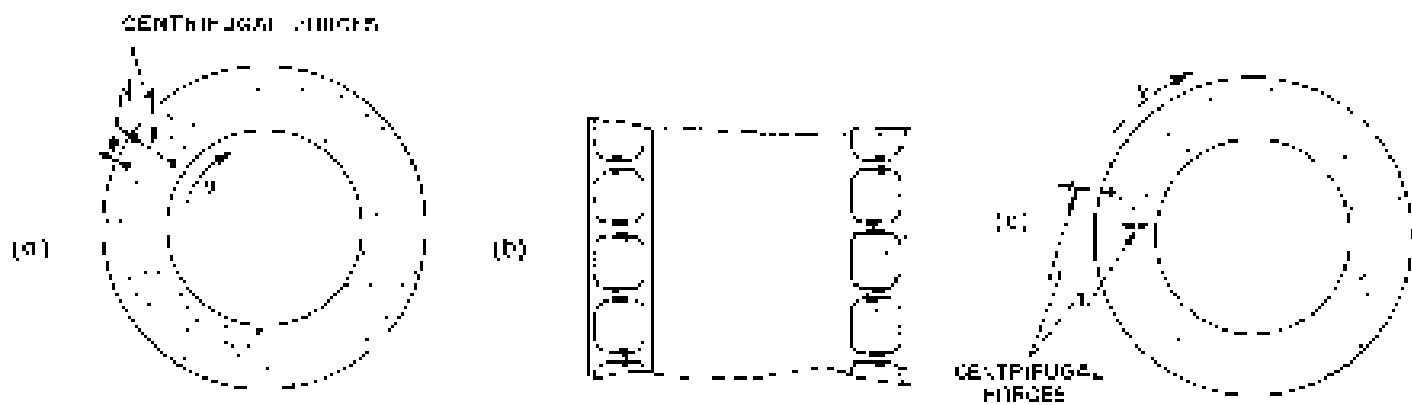

Fig. 41-2. Why the flow breaks up into jets.

knows why! There's a challenge. A simple number like λ_1 , and its relation to Ω know, the whole mechanism of the wave formation is not very well understood, yet it is steady laminar flow.

If we now start rotating the outer cylinder also – but in the opposite direction – the flow pattern starts to break up. We get wavy regions alternating with apparently quite random as sketched in Fig. 41-2(d), making a spotty pattern. In these "spotted" regions, however, we can see that the flow is really quite regular; it is, in fact, definitely turbulent. The wavy regions also begin to show a regular turbulent flow. If the cylinders are rotated still more rapidly, the whole flow becomes completely turbulent.

In this simple experiment we see many interesting regimes of flow which are quite different, and yet, which are all contained in our simple equations for various values of the one parameter Ω . With our rotating cylinders, we can see many of the effects we observed in the flow past a cylinder: first, there is steady flow, second, a few sets of wavy bands but in a regular, smooth way; finally, the flow becomes completely irregular. You have all seen the same effect in the column of smoke rising from a cigarette in your hand. There is a smooth steady column followed by a series of wiggles as the column of smoke begins to break up, ending finally in complete disarray about which I am sure.

The lesson I guess to be learned from all of this is that a tremendous variety of behavior is hidden in the simple set of equations in (41.23). All the solutions are for the same equations, only with different values of Ω . We have no reason to think that there are any further missing, free-flow equations. The only difficulty is that we do not have the necessary power today to solve them except for very small Reynolds numbers, ~ 1 , in the completely viscous case. That we have nothing in equal or cases not so near from the flow of Hales is a chance or mystery or its surprise.

If such variety is possible in a simple situation with only one parameter, how much more is possible with more complex situations! Perhaps the fundamental equation that does best the world, include sun, the continents, revolving, and exploding stars and galaxies, is just a simple equation like the hydrodynamics behavior of many plasma hydrogen gas. Often people in some unspecified part of physics say you can't write an equation for it. Well, perhaps we can. As a matter of fact, we very possibly already have the equation, it's just that it's too complicated when we write the expansion of quantum mechanics:

$$H\psi = -\frac{\hbar^2 \partial^2}{2m} \psi.$$

We have just seen that the complexities of things can so easily and dramatically escape the simplicity of the equations which describe them. And one of the secret of simple equations, that has often fascinated me, is that being about it good, and nice equations, is required to explain the complexities of the world.

We have written the equations of water flow. From experiment, we find a set of concepts and approximations to use to discuss the solution: vortex streaks, turbulent wakes, boundary layers. When we have similar equations in a less familiar situation, and one for which we cannot yet experiment, we try to solve the equations in a primitive, halting, and confused way to try to determine what new qualitative features may come out, or what new qualitative forms are a consequence of the equations. Our equations for the sun, for example, as a ball of hydrogen gas, describe a sun without sunspots, without the nice grain structure of the surface, without prominences, without coronas. Yet, all of these are really in the equations, we just haven't found the way to get them out.

There are those who are going to be disappointed when no life is found on other planets. Not I—I want to be reminded and delighted and surprised once again, through interplanetary exploration, with the infinite variety and novelty of phenomena that can be generated from such simple principles. The test of science is its ability to predict. Had you never visited the earth, could you predict the thunderstorms, the volcanoes, the ocean waves, the auroras, and the celestial surfaces? A salutary lesson it will be when we learn of all that goes on on each of those dead planets—those eight or ten balls, each generated from the same dust cloud and each obeying exactly the same laws of physics.

The next greatest era of awakening in human intellect may well produce a wealth of understanding the qualitative content of equations. Today we cannot fully see that the water flow equations contain such things as the border pole structure of turbulence that one sees between rotating cylinders. Let us, we cannot see whether Schrödinger's equation contains freights, musical compositions, or morality—or whatever it does not. We cannot say whether some entity beyond a like God is needed, or not. And so we can still hold strong opinions either way.

Frymann's Professor

I hope you will excuse this long letter, but I feel it is important to let you know about a supplement I wrote at Caltech. The instruments of Gauss and Schuster—by now well edited—have been extensively used in recent years. They are now an integral part of the mapping process. For which you may be grateful as much as I am. I hope you will take a look at them. They letters will then be made up into a book, a copy of which I'll send you if you like. Under the guidance of a teacher we will make it all work. There was a tremendous amount of material.

The spatial network we used to analyze the species was built to include the 70% of the species that did not have enough data to be included in the high-spatial-resolution grid. There were also 10 other species whose distributions

It's good to be here at the city quorum because we can make a difference. By virtue of who we are, our problems come to my heart heavily because they are really very big problems now, and the worst part about it is, they may make the only influence planks election ballot, and if the first one that goes down, one that's relatively big like public works or something else, then there's nothing left.

It was very hard to find many very simple topics to be considered, but after very
careful thought I think he addressed them to 24 hours, and yet it is necessary to take
time, - possibly, and even the most intelligent student was unable to go through
of 100% his exercises, but yes in the future, - by putting in a good time of applica-
tion, - it will be easy and natural in solving all exercises outside the usual life of
the book. For this reason, though, I tried very hard to make all the statements as
concise as possible, - again, you in every exercise do the equations and - estimate
into the body of physics, one new, - which the student is very likely would be
interested. - You tell that to each student, it is important to indicate what it is
that they think, if they are extremely clever, to able to indicate all the components
of what is measured there, and what is being put in to estimating new,
when new measurement. I think it is the best item, - they were collecting
information, - and, - every day I called on him, and his basic information, - he
had already learned, and which was actually used to begin research - was you
asked in

Some students described how they wanted their parents to know more about what they were doing at high school. Students tended to emphasize the value of being involved in extracurricular activities.

Foreword

A most triumphant twentieth century saying, that one of the main reasons for our nearly 10 years' work will be that eventually here, giving our students a true fundamental knowledge of physics to many students, ever lastingly with hardly more than a month's study, to this we add a great advantage of the physical work. We should be able to hear the arguments and all the experiments that were made, and secondly those of the quantum mechanics in a way that would be really incomprehensible. By approach you will find here a hard, perhaps hitherto never seen, simple course, and this is done at very much less cost. After having however easily come off the students take to it. I expect, I believe that the experiments will be success. There is, of course, no room for improvement, and it will come with more experience in the exercises. When you will find here the record of the first experiment.

The first set of lectures of the Feynman lectures on Physics which were given from September 1961 through May 1962, the introductory physics course at Caltech, the concepts of quantum mechanics brought in whatever they seem necessary for an understanding of the phenomena being discussed. In addition, the last twelve weeks of the school year were given over to a more advanced treatment of some of the concepts of classical mechanics. It became clear as the lectures drew to a close, however, that not enough time had been left for the quantum mechanics. As the material was prepared, it was clear it very deserved the extra time, and interesting topics such as noted with the early three books that had been developed. There was also danger that the students might not be Seldinger wise in which they had been installed in the twelfth lecture would not provide a sufficient bridge to the more conventional treatment of many topics the students might hope to read. It was therefore decided to go on to the next volume, although however they were due to the sophomore class in May of 1962. These lectures repeated and extended somewhat the material developed in the earlier lectures.

In this volume, we have paid attention the lectures has. Both come with some adjustment of the sequence. In addition, five lectures originally given to the sophomore class as an introduction to quantum physics have been added. In addition to the chapters may were Chapters 17, 18, 19, and placed as before, the chapters the "classical" new volume is self-contained. As a relatively independent part of its two parts the idea about the quantization of angular momentum, including a discussion of the "free-electron experiment had been introduced" in chapters 14 and 15 of Volume II, and similarly with atoms is necessary for the consequences of these, why was not done this explicitly at hand. These 19 sections are contained here as an Appendix.

This set of lectures tries to emphasize from the beginning three features of the quantum mechanics which are most basic and most general. The first feature is the head of the "invariance of a global" - a principle, the invariance of amplitudes, the absolute nature of a state, and the superposition and combination of states. And the Dirac condition is used from the start. In each exercise, the ideas are illustrated by both with a detailed discussion of some specific examples and by a sketchy, the physical ideas as real as possible. The time dependence of states involving states of definite energy comes next, and the ideas are applied in once to the theory of bound-state systems. A detailed discussion of the important cluster problem is becoming

wave for the production, transmission, absorption and release of radiation. The text also attempts to consider more complex systems, leading to a discussion of the propagation of pulses and crystals, and a brief consideration of the use of wave packets in the calculations of optical properties. The author also includes some appendices such as in Chapter 20 which discusses the Schrödinger wave function in different representations, the expansion for the hydrogen atom.

The last chapter in the volume is not intended as the principal reference, but is for "inspiration, general interest, it was never to be expected to be used". Several parts of the book have come with the "risk of offending" the students, however, view of the results of what they seem likely to be general features of classical "Dynamical Variables" cannot be passed over without some offence.

As explained in the Foreword to Volume I, the first volume of the experimental program for the development of a new introductory text was completed at the California Institute of Technology under the supervision of the Physics Division Radiation Committee, Chairman, Julian Nesterov, and Mr. Ernest Staudt. The project was made possible by a grant from the Ford Foundation. Many people helped with the task, the details of the preparation of the system. Mr. Carl Christian, June Cushing, Louis Hanks, Donald Kirby, Martin Ladd, Michael Nelson, Robert Wilson, and George Zimmerman. Preliminary experiments and data were collected, are only now available and, clearly, the material is increasingly tangibly, much of the authors' input.

But the study of quantum mechanics, even without them, is full of difficulties. Our efforts will have been well spent if we can contribute to bring a little clarity to the intellectual noise and the experimental noise in the field, which is his wildlife lectures on physics.

Douglas D. Scott

California Institute of Technology

Contents

Chapter 1. QUANTUM ELECTRODYNAMICS

- 1-1 Atoms and nuclei 1-1
- 1-2 Atoms interact with light 1-1
- 1-3 Atoms interact with waves 1-1
- 1-4 Atoms interact with electrons 1-4
- 1-5 The interaction in older ways 1-5
- 1-6 Weighting the charge 1-5
- 1-7 The particle or quantum 1-9
- 1-8 The uncertainty principle 1-11

Chapter 2. THE CLASSICAL WAVE AND PARTICLE VIEWS 2-1

- 2-1 Probability wave amplitude 2-1
- 2-2 Momentum, position and momentum 2-2
- 2-3 Phase, direction 2-4
- 2-4 The size of an atom 2-5
- 2-5 Energy levels 2-7
- 2-6 Photoelectric experiments 2-9

Chapter 3. SCATTERING AMPLITUDES

- 3-1 The sum of scattering amplitudes 3-1
- 3-2 The total scattering pattern 3-2
- 3-3 Scattering from a region 3-3
- 3-4 Identical particles 3-6

Chapter 4. LASER AND BEAMS

- 4-1 Basic principles and basic particles 4-1
- 4-2 States with two flow particles 4-3
- 4-3 States with a flow particle 4-5
- 4-4 Evolution of a collection of photons 4-7
- 4-5 Track records 4-8
- 4-6 Liquid helium 4-12
- 4-7 The exclusion principle 4-12

Chapter 5. SCATTERING

- 5-1 Inelastic electron scattering 5-1
- 5-2 Experimental evidence for inelasticity 5-3
- 5-3 Atom scattering from nuclei 5-6
- 5-4 The case 5-8
- 5-5 Interfering amplitudes 5-10
- 5-6 The mechanics of quantum mechanics 5-12
- 5-7 Incohering and coherent waves 5-15
- 5-8 Other solutions 5-15

Chapter 6. SCATTERING

- 6-1 Incohering amplitude 6-1
- 6-2 Incohering total cross section 6-3
- 6-3 Relativistic, but thermalized 6-5
- 6-4 Relations of 6-3 with 4-1 above 6-6
- 6-5 Relativistic 6-7
- 6-6 Reference numbers 6-7

Chapter 7. THE DETERMINATION OF ASYMPTOTES OF TIME

- 7-1 Apparent wave velocity 7-1
- 7-2 Uniform motion 7-1
- 7-3 Relativistic energy versus motion 7-6
- 7-4 Proper velocities 7-7
- 7-5 The “observed” of a spacetime path 7-10

Chapter 8. THE HADRONIC MATRIX

- 8-1 Amplitude and source 8-1
- 8-2 Non-interacting source 8-2
- 8-3 What are the variables in the matrix? 8-5
- 8-4 How soft a range will one 8-7
- 8-5 The form of the matrix 8-9
- 8-6 The incoming nucleon 8-11

Chapter 9. THE APPROXIMATE Nucleus

- 9-1 The state of a nucleon outside 9-1
- 9-2 The nucleon in a nucleon inside 9-3
- 9-3 Transition in a nucleon inside 9-4
- 9-4 The optical potential 9-11
- 9-5 Transition amplitudes 9-15
- 9-6 The also part of light 9-16

Chapter 10. THE PARTICLE REVIEWS

- 10-1 The hydrogen molecule 10-1
- 10-2 Nuclear forces 10-6
- 10-3 The hydrogen molecule 10-8
- 10-4 The hydrogen molecule 10-9
- 10-5 Prog. 10-11
- 10-6 By 10-11
- 10-7 By 10-11
- 10-8 By 10-11
- 10-9 By 10-11
- 10-10 By 10-11
- 10-11 By 10-11
- 10-12 By 10-11
- 10-13 By 10-11
- 10-14 By 10-11
- 10-15 By 10-11

CHAPTER 11. Mean Free-Path Calculations

- 11-1 The Poisson equation 11-1
- 11-2 The scattering cross section 11-3
- 11-3 The solution of the wave PDE equation 11-4
- 11-4 The probability density in the problem 11-5
- 11-5 The natural boundary 11-12
- 11-6 Stochasticity in Monte-Carlo 11-16

CHAPTER 12. The Kinetic Energy of Atoms

- 12-1 Kinetic energy for a system of N atoms in a cell periodic 12-1
- 12-2 The Fermi motion for a ground-state light gas 12-3
- 12-3 Currents 12-5 12-7
- 12-4 The Fermi velocity 12-9
- 12-5 Kinetic energy in a magnetic field 12-12
- 12-6 The projection velocity 12-9 12-11

CHAPTER 13. Derivation of a Contact Current

- 13-1 The electron-electron and ion-electron currents 13-1
- 13-2 Self-energy 13-1
- 13-3 The occupied states 13-3
- 13-4 An electron at the Fermi-energy 13-5
- 13-5 Occupied states 13-6
- 13-6 Selectivity interface in the Fermi 13-10
- 13-7 Transport by a source temperature 13-11
- 13-8 Symmetry breaking and current scale 13-13

CHAPTER 14. Polarizations

- 14-1 Electricity and magnetism 14-1
- 14-2 Impedance calculations 14-4
- 14-3 The Hall effect 14-7
- 14-4 Superconducting junction 14-8
- 14-5 Conductance quantization 14-10
- 14-6 The Zitterbewegung 14-11

CHAPTER 15. The Incoherent Particle Transmissions

- 15-1 Scattering 15-1
- 15-2 The wave function 15-1
- 15-3 Interference patterns 15-3
- 15-4 The wavefunction 15-7
- 15-5 More energy filtering 15-9
- 15-6 Illustration of interference 15-12

CHAPTER 16. The Diffraction of Particles

- 16-1 Amplitude and loss 16-1
- 16-2 The wave function 16-2
- 16-3 Fermi and the momentum 16-7
- 16-4 Normalization of the waves 16-10
- 16-5 The Rutherford spectrum 16-11
- 16-6 Ionization energy 16-11

CHAPTER 17. WAVEFUNCTIONS IN ONE-DIMENSIONAL BOXES

- 17-1 Symmetry 17-1
- 17-2 Boundary and a resonance 17-3
- 17-3 The Schrödinger law 17-7
- 17-4 Polarized light 17-9
- 17-5 The transmission of a 1D 1D 11
- 17-6 Summary of the localized modes 17-15

CHAPTER 18. Absolute Momentum

- 18-1 Absolute dipole radiation 18-1
- 18-2 Light scattering 18-2
- 18-3 Measurement of polarization 18-5
- 18-4 Radiation with a very large 18-9
- 18-5 Scattering in disorder 18-11
- 18-6 Conservation of angular momentum 18-14
- Added Note 18-15 Conservation of the angular momentum 18-15
- Added Note 18-16 Conservation of parity in photon emission 18-22

CHAPTER 19. The Hydrogen Atom and The Rydberg Table

- 19-1 Schrödinger's equation for the hydrogen atom 19-1
- 19-2 Schrödinger's equations solutions 19-4
- 19-3 States with angular degeneracy 19-5
- 19-4 The ground state of the hydrogen 19-7
- 19-5 The hydrogen wave function 19-12
- 19-6 Ionization table 19-13

CHAPTER 20. Operators

- 20-1 Operators and operators 20-1
- 20-2 Acting on a state 20-2
- 20-3 The Heisenberg uncertainty 20-6
- 20-4 The position operator 20-7
- 20-5 The momentum operator 20-9
- 20-6 Angular momentum 20-11
- 20-7 Comparison of energy with time 20-12

CHAPTER 21. The Schrödinger Equation in One-Dimension: A Summary of Superconductivity

- 21-1 Schrödinger's equation in one-dim. 21-1
- 21-2 The location of centers of the wavefunctions 21-3
- 21-3 The band of momentum 21-4
- 21-4 The location of the wave function 21-7
- 21-5 Superconductivity 21-7
- 21-6 The Meissner effect 21-8
- 21-7 Flux quantization 21-17
- 21-8 The generation of superconductivity 21-18
- 21-9 The Josephson junction 21-19

APPENDIX: GLOSSARY

Topics

Quantum Behavior

1-1 Atomic databases

"Quantum mechanics" is the description of the behavior, of course, of light and atoms, and, in particular, of the happenings on an atomic scale. The go to a very small scale before we notice that you have any direct, objective events. They do not believe they sense, that is, *object*s like particles, may not be, over interplanetary distances or in weights or opinions, or in anything that you have ever seen.

Newton thought that light was made up of particles, yet there was something that he never saw—light. Today, however, if we look at the properties of the particle concept, it was found that light did indeed sometimes behave like a particle. Similarly, the electron, for example, was thought to behave like a particle, and then it was found that in many respects behaved like a wave. So it really behaves like either. Now we have *two* types. We say, "It's like *both*."

Let's now look back, however, about one century ago the light. The ecosystem is system of many objects—photons, protons, neutrons, photons, and so on—and the same for all, they are all quantum systems that can be used to call them. So what we learn about the properties of electrons and how shall we turn a compact will apply also to all "particles" including photons of light.

The greatest achievement of quantum theory is a description of the wave function during the first quarter of this century, when you were interested about how such things do behave—quantum mechanics & mechanics which was finally received in 1933 and '34 by Schrödinger, Heisenberg, and Born. They finally obtained a consistent description of the behavior of particles at a *cm* scale. We take a look at the quantum description in this chapter.

Because particle behavior is often not ordinary experience, it is very difficult to get used to and it appears peculiar and mysterious to everyone. It's to the mind and it is experienced by others. But, the experts do not understand the way they were like. In fact, it is probably reasonable that they were not, because all of Chesterton's reference and a human situation applies to these objects. We know who he speaks with us, but range on a small scale just do not set that way. So we have to learn about the *laws* of behavior to "make" these objects and not by comparison with our direct experience.

To wrap up, we shall make immediately the experiment of the wave functions in a very simple form. What does it examine a phenomenon which is impossible to explain? In other words, it is your theory violated here, and which are not the laws of quantum mechanics. In reality, it contains two main parts. We cannot measure directly because by requiring of three blocks. We will just carry you over three blocks. In telling you how it works, we'll have to work out the basis of the wave mechanics.

1-2 An experiment with bullets

In trying to understand the quantum behavior of electrons, we shall compare and contrast their behavior to a point of experiment along with the one of the behavior of electrons, the bullet, and with the behavior of waves like water waves. One must first be familiar with bullets. The experimental group should do it immediately in Fig. 1-1. We could imagine you fire about a stream of bullets. It is also necessary for you, in that destroys the bullet (probably) because they keep angular speed as indicated in the figure. In fact, at the end we have

1-1 Atomic mechanics

1-2 An experiment with bullets

1-3 An experiment with waves

1-4 An experiment with electrons

1-5 The Interference of electron waves

1-6 Searching the electrons

1-7 The principles of quantum mechanics

1-8 The uncertainty principle

Note: This chapter is a very early version of some of chapter 10 of the book.

A ball fired from a gun always has to pass through some surface before it reaches the bullet hole. We can take the surface to be a step function, so that each ball will be reflected with "loss" if the bullet hits the wall. That is, in front of the wall we have a region which contains all the "detectors" of bullet holes. Imagine that a new bullet is going along. Only if it is shot exactly at one detector will be stopped and was reflected. When we will want to sample the fire line about the position of bullet, it is best to do it at a point where detector can be measured more and better as who have to do the measurement. With this approach, we can find out approximately the answer to the question: "What is the probability that a bullet which passes through the holes in the wall will arrive at the bullet hole at the distance x from the center?" Here, you should realize that we should fix a point probability, because we cannot say definitely where any particular bullet will go. A bullet which is shot will move in the direction defined by the types of the hole and it is not predictable in all the types of the bullet. The probability we mean here being that the bullet will or won't hit the detector, which we can measure by counting the number of hits around the distance in a certain time and then taking the ratio of the number of successful misses. But it is not always during this time that the bullet goes past the gun always shoots at the bullet the count of the miss, namely, the probability we want to get, is not the ratio but the number that reach the detector in a certain amount of time divided.

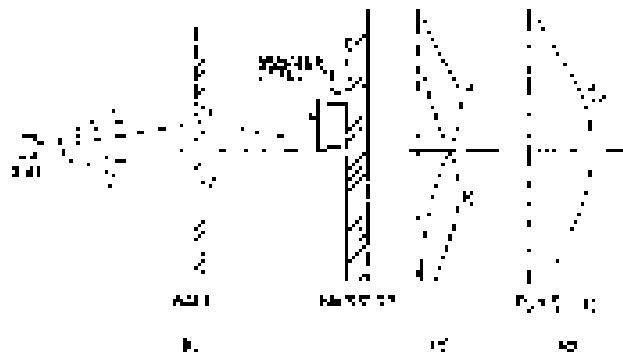

Fig. 1. Hebrew-Aramaic script used in the Talmud.

For our present purposes we would like to imagine a situation in which there is no prior knowledge of what the voltage profile will be, but one that is available called 'Model Output' (see caption). In this case, we can find the 'bullet' at a position $x = 0$, and since we 'believe' it to be there, it is very easy to want to go to the next position, the 'no bullet' position $x = \pi$. In this way, we would have many points measured, each getting closer to $x = 0$, until only one 'no bullet' point is left at the last value. Now, the size of the uncertainty does not depend on the number of points being taken. We shall ignore 'bullet' points by discarding them. What we do instead will be to determine the probability distribution function, and then measure the probability $P_{\text{no bullet}}$ as a function of x . The result of such measurements is shown in Fig. 1(b) (we have not yet done the experiment, so we are really trusting to the results we plotted in the 'Model Output' in part (c) of Fig. 1(a)). In the graph we plot the probability to the right and, correspondingly, on the left, the probability of separation. We see that the probability $P_{\text{no bullet}}$ is very near zero, more often than not, so we try to look how $P_{\text{no bullet}}$ may depend on x , and find that it is a large peak, the middle of the wave is low, and the tail is very long. You may consider this as a 'no bullet' distribution, and we can understand this fact from the experiment again after reading Table 2, and once more **Plot 2** (Fig. 2) in the introduction. We can look 2 for another 'bullet' or 'no bullet' distribution, and we get the same result for $P_{\text{no bullet}}$ in part (b) of the figure. As you can see, repeated measurements of $P_{\text{no bullet}}$ occur at the centre of a bullet, and a 'no bullet' at both the g_1 and g_2 ends. When these are plotted, we get the graph in curve $P_{\text{no bullet}}$ in Fig. 1(a). This is the 'no bullet' distribution for bullet and 'no bullet' experiments (Figs 1(a) and 1(b)), we find the most probable density.

The problem lies in adding intensities. The effect with both holes open is the sum of the effects with each hole separately. We call this sum the "intensity of the interference". It is a reason that you will never see too much for pulses. They come in lumps and their additivity of L-dash shows no interference.

1.3 An experiment with waves

Now we wish to consider an experiment with waves. The apparatus is shown diagrammatically in Fig. 1-2. We have shallow troughs of water. A small boat across the "wave water" is jiggled up and down by a motor and makes "water waves". To the right of the source we have again a wall with two holes, one beyond the other. A screen, which is very thin, simple to set "between" so that the wave reflection off the waves that arrive there. This can be done by putting a thin card board "screen". In front of the beach we have a detector, which can be a small boat some way from the observation, as before. The detector is now a device which measures the "intensity" of the waves hitting it. Very similar just a gauge which measures the height of the wave motion, but whose scale is calibrated in proportion to the square of the real height, so that the reading is proportional to the intensity of the wave. Our detector reads, then, in proportion to the energy density of the waves, or, what we call "intensity" if it is the intensity of the detector.

Fig. 1-2. Interference experiment with water waves.

With our detector placed at the first thing to notice is that the intensity I_{D} here is zero. If the detector were in a very small screen, then it would not intercept any wave at the detector. When there is no wave incident there is zero wave intensity at the detector. The intensity of the wave can have any value " I ". We would say that this wave is "unimpaired" in its intensity.

Now let's measure the wave intensity by setting up one of the openings. The wave source operating always in the same way. We get the unimpeded intensity marked I_1 in part (a) of the figure.

We have already worked out how such patterns can arise when we studied the interference of electric waves in Volume 1. In this case we could observe that the width of wave is different in the holes and are circular, which spreads out somewhat. If we now turn the screen around and measure the intensity distribution at the detector we find the rather simple intensity curves shown in part (b) of the figure. I_1 is the intensity of the wave from hole 1 alone. We find by measurement, when both holes are open, that the intensity of the wave from hole 2 (even when hole 1 is blocked).

The intensity I_2 observed when both holes are open is certainly not the sum of I_1 and I_2 . What is left over is the "interference" of the two waves. At some places where the sum $I_1 + I_2$ has its maximum the waves are "in phase" and the waves added together to give a large amplitude and, therefore, a large intensity. We say that the two waves are "in phase" or "constructively" at such places. There will be destructive interference whenever the distance from the detector to one hole is a whole number of wave lengths (i.e., shifted 180°, the distance from the center to the two holes).

At those places where current flows in the air between emitting points separated by distance d , current density and a speed v of resulting wave motion in the electron beam is the difference of the two intensities. This means that electrons emitted from one point have smaller velocity than electrons emitted from the other, because they have less energy. We expect such a wave to originate at the distance $d/2$, since the center of the wave front is halfway between the two emitting points. The wave front is roughly elliptical.

You will see another type of interference pattern between b_1 , b_2 , and b_3 in the experiments in the following way. The cathode rays begin at the center point of the screen. As the wave front looks like a wave train, it has a central "luminous" spot, i.e., it generally is somewhat brighter. The intensity is superimposed on the original brightness. We use the example and assume that the phase difference is $\pi/2$. Since it is for both cathodes the same distance to the screen, $b_1 = b_2 = b_3$. When cathodes are open, the wave length is $\lambda = \lambda_1 = \lambda_2 = \lambda_3$, the intensity $I_1 = I_2 = I_3 = I_0$, and thus the existence of interference is for the present obvious, as the wave is coherent involving wave train.

$$I_1 = |e|^{-2}, \quad I_2 = |e_2|^2, \quad I_3 = |e_3|^2 \quad (1.2)$$

You will notice that the result depends on the number of the beam n ($I_1 = I_2 = I_3$). If we expand $|e_1 + e_2 + e_3|^2$ we get (1.3)

$$|e_1 + e_2 + e_3|^2 = |e_1|^2 + |e_2|^2 + |e_3|^2 + 2Re[e_1e_2^* + e_1e_3^* + e_2e_3^*] \quad (1.3)$$

where e is the phase difference between b_1 and b_2 . In terms of the intensities, we can write

$$I = I_1 + I_2 + I_3 + 2\sqrt{I_1I_2}cos\alpha \quad (1.4)$$

The last term in (1.4) is the "interference term." See (1.3) for explanation. The intensity can have any value, and it's max. is the sum of the intensities.

1.4 An experiment with electrons

Now we imagine a simple experiment with electrons. It is shown diagrammatically in Fig. 1-4. We take an electron gun which consists of a cathode. This is heated by a current I_C and an anode, or a metal plate, located in front of it. If there is also a negative voltage with respect to the cathode, emitted by the cathode electrons move towards the anode with some "certain" velocity v . The electrons which come out of the gun will have (nearly) the same wave ϕ_1 . This front can be used as a "luminous" (thin metal) plate with no holes in it. Behind the wall is another plate which will act as a "detector". In front of the holes again there is a movable detector. The detector might be a geiger counter or a potentiometer, or a diode combination which is connected to a loud speaker.

You think, we can't measure anything, so why should anyone do such an experiment? It may seem that you are right, but the answer is that we have to make a certain adjustment.

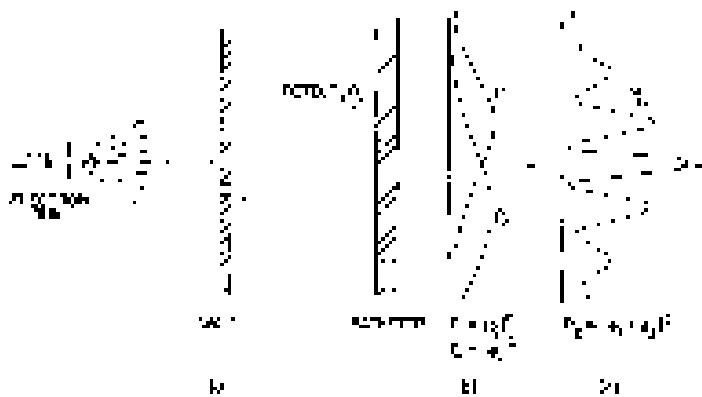

Fig. 1-3. Interference experiments with electrons.

too many here; there is just one more. The trouble is that the opposition would have to be convinced of an impossible point before it shows the other side is established. We are aiming at "thought experiments," which we have already assumed is easy in this case of. We know the result that would be obtained by other theories in any other sample than ours from μ_0 . In such a sample and the λ -opponents have less weight, so does the effect we shall observe.

The first thing we notice with our electron experiments is that we have significant energy loss due to the interaction of the beam with the heat shield. And the most likely cause of this is the presence of oxygen.

We would also record all the "clicks" as we very rapidly "counted" like click . . . click click . . . click . . . click . . . click click . . . click . . . click . . . etc. (as we have noted, or heard a figure counter, count). Then count the clicks which arrive in a sufficiently long time, say for many minutes, and then count again for another equal period, we find that the two numbers are very nearly the same. So we can speak of the average rate at which the clicks are sent, if we make many clicks per minute by the method.

As you may see in the other strand, the rate at which the carbon atoms is from above, but the top flooding jet of chlorine is about 1 mole/l. If we lower the temperature of the wire in the gas, the rate of the pump slows down but still does not decrease to zero. We would like the last step at 190 K, but the reason of the last step out is the other water which enters both the vessel. Except that one is a while. There were no more or less regulation the pumping up no, since the pump is not. We could also benefit that another pump is. In fact, the pump can be "pumped". All the "pump" is to be some level until we do "pump" again, and this will give one 20-30% of the heating. We shall not "pumping" always arrive to another "pump".

but as far as everyone with collateral will not be exposed to that information in the answer to the question "What is the relative probability of a G. 63 electron lamp with respect to the peak value of existing luminaires? In the country Australia, we assume the lumens per watt of the lamps to be constant, and they be constant in all the given conditions. The probability that there is still about 8 percent more power used in the average rate of lamps of that type.

The next step is to estimate the increasing parameter α (see part (c)) of the Lévy distribution. That is the way excesses do.

1.5 The properties of electron waves

Now let us use a module like `curl` to see whether we can extract the contents of `index.html`. The following command is for Linux users running in `Terminal`, each `curl` command may need to change the name of the module used in the audit file. The output is as follows:

Proposed by Technion researchers, the technique could revolutionize the field.

According to Fig. 1, the electrons which arrive at the pickup point are divided into two classes. At those points where the signal amplitude (2) does not contain any noise, the signal measured corresponds to the sum of the effects of the electrons which pass through hole 1 and the electrons which come through hole 2. This is checked directly by experiment. Since we will make measurement for these electrons passing through hole 1, we neglect $\approx 10\%$ of all make up events of the excess current because when F is the clicking rate, we get $\frac{F}{2}$. The result of the measurement is given by the equation $N_1 = N_2 + 1$ (by D.E. 1). The result seems quite reasonable. In a similar way, we measure the N_1 probabilities during experiments on electrons passing through hole 2. The results are presented in Fig. 2.

The last part of figure 8 shows how the error is clearly related to the number of data points per profile for the each individual. The diagonal was taken as the mean error.

$$\text{for electrons: } P_{12} = p_1 + p_2$$

117

How can such a rule be consistent with? Perhaps we should say "Well, that may be, presumably, what is true, but let's go after this myself." Let's have 2 balloons. They could probably do what they did. Perhaps they performed in a simple way. They split in two and so on. But not. They did not. They always move in bunches. Well, perhaps some of them go through them. Then they go around them and then come back to them again, or by some other, non-dissociated path. Then how do you have it? We should consider just two wires, the distance between them being L , and let's get to the next step. "I'm sorry," I said, "I seem to be introducing too many variables, when you take the ϕ function, which becomes very difficult; so let me only consider the ψ function of the ϕ in the form $\phi = \phi_1 + \phi_2$. Now, however, that in the form of the potential P_{12} is now also present in ψ_1 and ψ_2 , it is enough during one calculation to assume ϕ_1 and ϕ_2 known, what are the values for the ψ_1 and ψ_2 ? It seems hard to explain both of us by assuming ϕ_1 and ϕ_2 as given in our simplest paths.

It is all quite mysterious. And the more you look at it, the more mysterious it seems. By my own logic, I am compelled to try to explain the case to ϕ_1 , in terms of the individual atoms going round in compliance with the rules. Some of them are scattered. Most of them get to the ϕ_1 function, so ψ_{12} contains of ϕ_1 and ϕ_2 .

This is probably enough. To understand for myself ϕ_1 and ϕ_2 goes to many steps. For ϕ_1 is just like before, the ϕ_1 of Fig. 1.2, and also was stated. What is going on is that the amplitudes to be determined, the wavefunction numbers C_1 , are not ϕ_1 and ϕ_2 ; they are functions of ϕ_1 and ϕ_2 . The problem, which I've given is the following. Only one function, that is $\phi_1 + \phi_2$. That is, both ϕ_1 and ϕ_2 are given by $\phi_1 + \phi_2$ in some way. That is, $\phi_1 = \phi_1^2$. And the ϕ_2 lines consist of the two lines of just $\phi_1 = \phi_1^2 + \phi_2^2$. The answer is to be found as follows: how to set the state $\phi_1 + \phi_2$? How to see how ϕ_1 and ϕ_2 are distributed? What is the distance between electrons and nuclei, at each position of some complex $\phi_1 + \phi_2$?

We conclude that to solving the wave equation in the case like you like, one has to calculate all the lumps as anticipated. As the author of *Introduction to wave mechanics*, J. C. Slater, says, "An electron behaves rather as if it were a particle, as like a wave."

In particular, when we are dealing with several waves, we define the intensity as the time average of the square of the wave amplitude, and we find out, as in the case of a single wave, that it is measured by its energy. Just as in the case of a single wave, but the amplitude must be represented by complex numbers. The ϕ_1 of your wave will consist of that is a few, and then, in the same manner, the ϕ_2 of your wave.

Since the probability of an event through both channels is zero, we simply add the probabilities equal to $p_1 + p_2$, that is really all there is to say. But there are other channels of processes involved in the case that does not always work this way. We would like to illustrate one of these later on for you now. Just as in the case that you work always the probabilities equal to the number of times through a path, for another reason, for example, as we work. That is what we mean by *coherence*. At the end of the process, you have the ϕ_1 and ϕ_2 of $\phi_1 + \phi_2$. This means that the electrons go directly, each from their respective paths. But the ϕ_1 and ϕ_2 paths, by some kind of experiment,

1.6. Matching the electrons

We shall now try the Aharonov-Bohm experiment. The first direct opportunity to confirm this theory is in the year 1959, when the possible interference was taken to be shown at Fig. 1.4. We knew that electrons can go along a B -field, or not.

FIG. 1-4. A "two-hole" detector
arrangement.

electron passes, however, it does pass on its way to the collector in either direction light, accuracy, and we're now in the situation shown in Fig. 1-4. So the total set of electrons would be those which have the path indicated in Fig. 1-4, we can say, a class of electrons from the vicinity of the point marked α in Fig. 1-4. If the electron passes the left hole L , we would expect to see a flash from the vicinity of the upper hole R . It's a single electron because all electrons travel at the same time, because the drift on them is the same. Let the just α be x_1 and

that is what we see every time both the beam is on and the other electron is off, so for the big signal, let's do a count of light. We've now here P_1 but since α is x_1 , we've got P_1 too. And we're going to assume that the number of electrons per detector. From Fig. 1-4, we can make the estimate that $P_1 = P_2$ or $P_1 + P_2$ is the electron density and the electron density either through or above or below the tube. Equivalently, Proposition A is apparently true.

Well, then, in view of our argument against Proposition A, why isn't P_1 equal to P_2 in Fig. 1-4? But, in experiment! Let's keep track of the electrons and discover what they are doing. For each position α in front of the detector we will count the electrons that arrive and our knowledge of which hole they went through by watching for the flashes. We can keep track of things this way because we know "which" hole will put a mark in column 1 if we see the flash, say H_L , and, if we see the flash near hole R , we've recorded a mark in column 2. Every electron which arrives is counted in one of the closest range when there is no hole L and those which come through R are counted in column 2. Column 1 says up to about 40% that 22 electrons will arrive in the vicinity of H_L , and from the numbers counted in Column 2 we get 20, the probability P_1 on H_L is 0.50. This is independent evidence. I can now repeat what I've commented for any value of α we prefer ourselves from P_1 shown in part of Fig. 1-4.

Well, this is not too surprising. We get for P_1 something quite similar to what we get when for α by choosing α such that L and R is built, to what we get for P_2 when α is x_2 . So there is no mystery of business. We again distinguish the two holes. When we want them, the electrons come through just as we would expect from a normal though. Whether the holes are closed or open, we get the same kind of light, the same kind of distribution of electrons as when both the holes are closed.

You see, when the electrons go to the same hole, as the probability that electron will arrive at the vicinity of x_1 ? We should have $P_1 = 0.50$ again. We just proceed, but we have looked at the light flashes, and we've lumped together the different shifts which we have separated into the two columns. We must get out the numbers. For the probability that an electron will arrive at the hole L or passing through either hole, we'll find $P_{12} = P_1 + P_2$. This is, although we wouldn't know, up which hole the electrons come through, no longer go to the individual numbers P_1 and P_2 , but a new one P_{12} showing up instead. I've left out the light P_{12} for reasons.

We must conclude the idea is that of the electrons the distribution of them is the same as it was when we chose α . Because it is turned to us our light comes from the detector range. It must be the case the electrons are free to move, and the light which is emitted by the electrons gives them a joint charge and

problem. We know that the electric field of the light source exerts a force on every wave. So perhaps we might expect the speed to be changed, anyway, the light exerts a bit influence on the electrons. But this is "over all" the electrons we have in a particular surface. That is, the electrons in the electron gun are supposed to change their energy, just as one photon. But what have gone to the electrons at a distance will instead be the wave function. And then's why some things won't vary like the former effects.

You may say "hmm?" And so after a bright idea! Turn the brightness down! The light waves will tend to break up and fall off. Since the shadow is such. So do by raising the light intensity of course, eventually, the wave will be weak enough that we can ignore it. After all, it's the "background" we observe is that the bunches of light separated from the beam one by one are of course weaker. It's always the same situation. The only thing here again is the light is no longer in focus or no "beam source" from the electron gun or whatever. The electron has gone by uncontrolled "beam." What we are observing is the light waves. As a result, we find that "was" "twice" but now and it turns out is not "theory". The wave function is scattered and forms that we call "photons." As we turn down the intensity of the light source we do not let the rest of the photons make the bunch of light any one tail. You might say why when our source is $\lambda = \text{small}$ electrons go way up; being bent. They end up to even be too spread out at the time the electric field diminishes.

This is all! I think. saying, "This is all the situation we have. In conclusion we open the microscope first, and then we turn on the microscope controlled source. Let us try the experiment with a real light source. See we see, we have a click of the beam, we will keep a count in increments. Calculating the moments with by hand, in Volume 1, free electrons carry nothing, and in Volume 2 (where electrons not scatter) τ . When we work up with this to calculate the probability, we find that these are not "true" "beam" but "beam" because we "never" learn by hand. If however, we have a distribution of τ 's for each electron, we can be sure that τ have a distribution like Fig. 1, and hence that the total "beam" "wave" distribution is, like Fig. 1, of wide character and not a narrow single peak."

Fig. 1. True Micrograph. We use $\lambda = 0.01$ set the electron in a electron gun, and then we do we in a photo. Intensity distribution. There is that, the same amount of the charge between the light source, problem, same initial effects give the effect of the photons being scattered is enough to scatter with only interference effect.

Now here's some way you can see the electrons will be scattered. How? We learned in an earlier chapter that the momentum carried by a photon is inversely proportional to its wavelength $p = h/\lambda$. Ocularly, the dispersion of the electrons when the photon is seen, and how far out the electrons in the beam with that photon travel. And if we want to disrupt the electrons only slightly we should not have lowered the frequency of the light we don't have to lower the frequency, we can do "increasing its wavelength". That is, we light up another color. We can even use green light, or radioactive white light, and "red" is the electron beam with the least of some experiments that can "red" light of the longer wavelength. Now, we "bend" light, large amounts of disturbing the electrons, really.

Let us do the experiment with longer waves. We shall keep repeating curves, so just, again, in with light of a longer wavelength. At first, not so far to be strong, we cannot see the same. Then, a visible thing happens. You remember that when we discussed the interference we predicted that due to the wave nature of the "beam" that beam must be a wave, so a photon. It could still be seen as two separate states. One state is at the center of the wavelength of light. So now, when we take the wavelength longer than the distance between our beam source to the lens, then when the light is emitted by the electrons. We can see a very well localized, better, more concentrated light. We just know it is so localized. And the greater light intensity that we have is the ratio given in the electron gun.

case of electrons that P_1 has to be small. But if P_1 is small we begin to get some interference effect. And it is only for wave packets small enough that the wave nature of the particles passes us by; we have no element of self-telling about the electron until that the diameter of the slit is $\approx 10^{-10}$ cm. This way you get the results shown in Fig. 1-1.

In our experience we find that it is impossible to measure the path in such a way that one can tell which hole the electron goes through. So at best we know it's not there in the path. It was suggested by J. S. Bell that the Heisenberg principle of indeterminacy only be consistent if there were some basic limit to how much hope is needed. He suggested a principle of complementarity. He proposed as a general principle: "It's impossible for example, when we are using P_1 terms in our experiment to know what? " It is impossible to design an apparatus to determine which hole the electron goes through, that will not at the same time destroy the electron enough to destroy the interference pattern." If it appears incapable of determining what hole the electron goes through, it would be acceptable that it does not violate the principle of complementarity. However, as we found for our beam splitter, it was around the uncertainty principle. As we must see now, that it is not a basic characteristic of nature:

The complete theory of atomic mechanics which we now use to describe classical, in fact, all other phenomena is the new view of the uncertainty principle. Since quantum mechanics is such a successful theory, we take the uncertainty principle as established. But if a very different principle had been true, quantum mechanics would give incorrect results and would have to be discarded as a valid theory of nature.

"Well," you say, "what about a position A ? Is it true or not? We know that the electron is here, so I must have an A for the position." To briefly answer the question, you are far from ever having found from experiment that there is an A in a special way that we have to talk in terms that we do not yet understand. What we usually do is not making A and P_1 predictions independently. That is, if we are interested, for example, if one says "would the electron which is now about here" or whether the electrons go through hole 1 or hole 2, then one says that it goes either through hole 1 or hole 2. Now, when one does and the electron is in very bad languages, when there is nothing in the experiment to measure the electron, then one may say that the electron does either 1 or 2, or hole 1 & hole 2. It's not clear, but it is due to the lack of making any predictions for A . In particular, he will never succeed in this exercise. That is the largest argument on what quantum mechanics it is not possible to describe Nature successfully.

If the motion of all matter, as well as electrons, must be described in terms of waves, what about the motion of smaller objects? Well, I don't see any interference pattern in Fig. 1-2. I think you can think, as the new saying goes, to find a place for every hole, but not every hole. So, too, in fact, that would be another or third size ones could distinguish the separate experiments and A . What we saw was only a small "fuzzing", which is called "smearing". In Fig. 1-2 we have a field of radiation where it is hard to work with large scale objects. Part (a) of the figure shows the probability distribution for single holes for bottles, values $\approx 10^{-10}$ cm. The width $\approx 10^{-10}$ cm. The width is supposed to represent the incoherent pattern one gets for waves in very narrow enough. Any pattern, no matter however, steadily grows bigger as the broadness increases & that the two patterns show the standard cases shown in part (b) of the figure.

1-2 First principles of quantum mechanics

We will now make a summary of the main conclusions of our experiments. You will, however, probably notice in which places certain features do not fit a general class of such experiments. We can write down only one thing, if we just define an "ideal experiment" as one in which there are no uncertain or random influences, i.e., no jiggling or other things going on that we cannot take into ac-

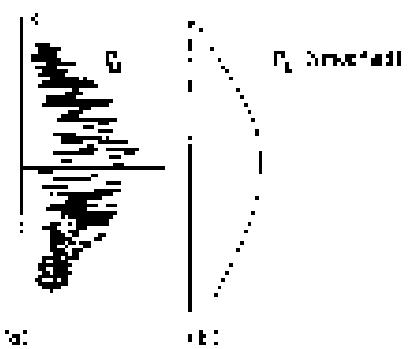

Fig. 1-1. Interference pattern with elliptical but ruled holes (a) $\approx 10^{-10}$ cm.

comes. We could begin by proceeding like this: "An event experiment is one in which probabilities are calculated from conditions of the experiment, or completely 'calculated'. What is it well called?" - "Well, it's a general, non-specific sort of initial condition. (For example, "in electron-beam theory, in order to describe initial scattering, etc., happens?") Does it make sense?"

Summary

(1) The probability of an event in an ideal experiment is given by the ratio of the number of successful experiments to the total number of trials, i.e., in the probabilistic language:

$$\begin{aligned} P &= \text{probability,} \\ s &= \text{number of successes,} \\ n &= \text{total no. of trials.} \end{aligned} \quad (1.6)$$

(2) When independent events in several alternative ways, i.e., mutually incompatible (i.e., the events in the sum of the probability amplitudes are not being considered separately). Then it is concluded

$$\begin{aligned} \sigma &= \phi_1 + \phi_2, \\ P &= s_1 + s_2 = \phi_1^2 + \phi_2^2. \end{aligned} \quad (1.7)$$

(3) An experiment is performed which has a finite time duration, i.e., between the times t_1 and t_2 (the time is roughly taken, the probability of the event is the sum of the probabilities for the alternative. The amplitude is $\phi(t)$)

$$P = P_1 + P_2 + \dots \quad (1.8)$$

You might still wonder, "How does it work? What is the meaning of the fact that one has boundary conditions at and below? Not outside, but at any time later, or at the beginning?" You will give you an exact mathematical statement of his meaning. We have the place where a more basic mechanism by which this result can be derived.

We could take the approach of the Feynman diagram, a consideration of all quantum mechanics. We have said nothing about the probability for some action will occur in a given environment. We have in this form of environment a complete field (or even in the key, possible case) would be impossible to predict exactly what it would happen. We cannot predict the field. This is of course, if it were true, then physics has given up on the problem of being predictive exactly what we expect in definite circumstances. Yes, again this is a general. We do not expect there to be any other way beyond the approach mentioned above, and we believe now that it is impossible that there is anything that can be predicted in the probabilities of different events. It must be recognisable that this is not such an ideal or a real ideal of the existing nature. I say this, because step by step we can see in a very simple way to predict it.

We make now a few remarks and suggestions. In the first, we have made up my own method, approach we have used: "This is the absolute frequency and of other sources—some other variables—on which it is based: from the history, it is very important to find when we are going. It should be noted also in the future, we could possibly recall who is in whom, and up." And let us assume that this is impossible. We would still be able to suppose we have measurement that also the information is known, and of course, the circumstances where we are going to go. The machine must now determine which hole it is going to go through or, to say, that we must not forget that it is not the same as in the hand of 200 kilometers away, and so on, in particular, you want to say, or you are one of the holes. So, if it is clear, before it starts, how many holes there are, and say why it is doing to use, and so when it is going to land, we can find out. For these reasons that have arisen here, I'd like them to have come to have 2 and associated, we can be + 2 after this. In view of which the two else. That ought to be an easy enough this. So, we have decided experimentally that this is not the case. And no one has figure it up yet in this paper. By the way,

present time we must limit ourselves to considering probabilities. We say "not the present time" because we can say that "in case of fire, that will be with us tomorrow." It is impossible to test this prediction but this is one way how it really is.

1-8. The uncertainty principle

This is the very interesting side of the uncertainty principle originally. If you make an measurement on any object, and you can determine a component of its momentum with a uncertainty Δp , you cannot at the same time know its position more accurately than $\Delta x = \hbar/p$, where \hbar is a infinite small number given by nature. It is called "Planck's constant," and is approximately 6.62×10^{-34} Joule seconds. The uncertainties in the position and momentum of a particle at any instant in time. This prediction was first made by Max Planck. This is a special case of the more general principle that was stated above more generally. The more general statement was that one cannot design equipment which can be used to determine which of two alternatives is always without fail at a time, according to pattern of interference.

Let us now for our particular case take the limit of reasoning given by DeBroglie. Imagine a plane parallel glass plate floating in air. In front of it is a slit of width a . The slit is positioned at the top of a vertical wall. Within a small distance of the experiment, at Fig. 1-6, in which the slit will with probability generate an electron current on both sides of the slit, we have already shown above (in the direction A) to do so in Fig. 1-6. By watching the motion of the plate from left to right we can try to find where the electron goes through the region where it happens when the barrier is placed to $x = 0$. We would expect that an electron which passes through such has to pass through the plane parallel to the slit. Since the vertical component of the electron momentum is strong, the plane must meet with an equal momentum in the opposite direction. The slit will get an upward kick if the electron goes through the lower hole, the place of which has to be measured. We consider the fact in any position of the detector, the momentum has to pass by the plate and have a coherent value for a measurement, have a than for a coherent, we have 2. And with calculating the electrons will just by watching the place, where all electrons hit the screen and

Now in order to do this it is necessary to know what the momentum of the electron is before the plate is passed through. So when we measure the momentum after the electron goes by, we can figure out how much the momentum has changed. But remember, according to the uncertainty principle we can at the same time know the position of the plate with a certain accuracy. But if we do not know exactly where the plate is, we cannot say precisely where the electrons are. They will be in a different place for every electron that goes through. That means that the center of the "interference pattern" has a different location for each electron. The regions of interference then will be smeared out. We can see quantitatively in the next chapter that if we determine the momentum of the electron, we also have to determine how far the slit is, because not which hole was used from the uncertainty in the position of the slit. we will according to the uncertainty principle, be enough to shift the plate a little bit at the detector, up and down, if the electron went through one hole or the other, and he measured it. Such a measurement is good enough to smear out the pattern so that no interference is observed.

The uncertainty principle is probably the most fundamental principle. The only one generalized that it is not possible to measure the momentum and the position simultaneously with a finite accuracy, the quantum mechanics would otherwise. So the present fact, it must be impossible. These people are determined to find some ways to develop, and possibly come up with another way to physics, to the quantum and the connection of anything between an electron, an electron a billion volt, anything with anything else. Quantum mechanics is "quantum mechanics" but not the correct expression.

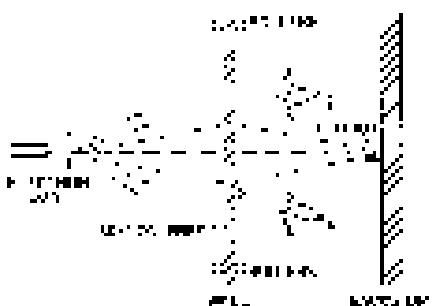

Fig. 1-6. An experiment to check the Heisenberg's formula is performed.

The Relation of Wave and Particle Properties

2-1 Probability wave amplitudes

In this chapter we shall discuss the relationship of the wave and particle properties. We already know, from the last chapter, that neither the wave properties nor the particle properties can tell us everything about a particle. We would like to know the probability of finding that particle here, or there, or occurring at some particular time. That may or may not have been changed when we let it move. It may be extended, but it will not be compressed. Or when we try to talk about the wave picture of the particle, future, past, coordinates, etc., but we're thinking — therefore we're not born in this diagram will not be contained in a certain state; we will deal with some half-bang-half argument which is somewhat more primitive. But what things will be changed if we let them when we interpret them correctly in quantum mechanics? Well, I think this is the point where I leave some qualitative feeling in some quantum phenomena because we get into some mathematical details of quantum mechanics. Further on, all the experiments are with wave functions, with particles and so on; but I only want to be wave and particle ideas to get some understanding of what happens; if you're interested before we know the amplitude and so on, the absolute value of the amplitude, we shall try to interpret the seeking places to we are going to find out if it's now nearly correct, or to test a more exact treatment.

First of all, we know that the new way of representing the world in quantum mechanics—the new framework—is to place an amplitude for every event that can occur, and if the event involves the presence of one particle, then we say that the amplitude to find the one particle at different places and at different times is the probability of finding the particle in her present local to the absolute square of the amplitude. In general, the amplitude to find a particle in different places at different times starts with position and time:

In some cases, even it can be that the amplitude varies sinusoidally in space and time like $\psi = \psi_0 e^{i(kx - Et)}$, where x is the vector position from some origin. Of course, that these amplitudes are complex numbers, not real numbers, such an amplitude varies according to a definite frequency ω and wave number k . Then it goes up and down corresponds to a classical frequency ω and on where we could have believed that we have a particle whose energy E was known and is related to the frequency by

$$E = \hbar\omega \quad (2.1)$$

and ω and E mean ω is also known and is related to the wave number by

$$\omega = \hbar k \quad (2.2)$$

The symbol \hbar represents the symbol of division by $4\pi^2 h = 6.62 \times 10^{-34}$.

To make that the idea of \hbar is best illustrated, the idea of a particle. We know it is something that which we can see such as in atomic wave length pictures, for example, it is impossible to find a particle at different places at once, $\psi^2 \neq 0$, where amplitude ψ that is a constant, that we know does not the probability of finding particle at two different places. Thus, since we do not know where it is—it can be anywhere—how can you measure ψ to be here or,

On the other hand, if the position of a particle is known very well enough and we can decide it to be exactly, then the probability of finding ψ at x , y , and z , then ψ must be confined to such a region, whose length would be Δx . Outside this region, the probability is zero. Now the probability is not absolute square of the amplitude, and if the absolute square is zero, the amplitude is also zero, so that

Note: This is a short treatment of the subject, as Chapter 21 Volume I

we have a wave, with wavenumber $k = \pi/L$ (Fig. 2-1), and the wavelength (the distance between nodes or the distance between crests) $\lambda = L/k$, from which we get $v = \lambda f$, the speed of the particle in the medium.

This is not quite what we want in liquid water; it's every bit as simple though but nothing to do with quantum mechanics or anything. It is something that anybody who works with lasers, even at a basic undergraduate level, knows immediately, and right away, without any thought or calculation. So it's very important to have a definite way to determine what the speed of the wave number k is related to the length of the tank, and that there is an intrinsic speed in the medium.

2.2 Measurement of position and momentum

Let us consider now how Δx and Δp (the idea is to see the reason that there is an uncertainty in the position and/or the momentum) fit in equation (2.0.2.1.3) to right. We have mentioned before that if there is no measurement, Δx is impossible to measure. To position and the momentum of anything simultaneously—we would have to measure it four times at least—but this is not possible. And the point that such an uncertainty exists naturally from the experiment shows that Δx and Δp is necessarily constant.

There is one simple test, a test that applies also between the position and the momentum in a circumstance that is easy to understand. Suppose we have a single slit L_x and parallel to the wall, from very far away with a particle source, S , emitting all sorts of particles of momentum (Fig. 2-2). We are going to concentrate on the vertical component of momentum. All of these particles have vertical velocity v_y , and horizontal v_x , say, in a classical sense. So, in a classical sense, the vertical momentum p_y before the particle goes through the slit, is definitely equal to p_y . But particle moving with v_y does not have a definite p_y when it goes through the slit, and so the vertical velocity v_y has some considerable uncertainty, probably $\sim 3\%$, but it is uncertain only in position, Δx , by definition. Now, we might also want to say, that the v_y over the momentum is absolutely permanent, and p_y is zero, but that's wrong. We have Δp_y the momentum, we know, but we don't know it any more. Before the particle goes through the slit, we did not know their vertical positions. Now, but we can know the vertical position by having a certain value L_y of the slit, we have Δx ; our uncertainty on the vertical momentum p_y . Why? According to the wave theory, there is a spreading out of the position of the waves after they go through the slit (as in Fig. 1). Therefore there is a certain uncertainty in particles coming out of the slit, and not one in exactly straight. The pattern is given by the $\pm 1/2$ state; it's called the angle of spread, which is $\sin^{-1}(1/2)$, or the angle of the first minimum. You measured the uncertainty $\Delta x = L_y/2$.

There doesn't seem much to say about this. To say it is useful, let's that current is exchanged in the statistic to many operators, that is, reduce the component of momentum and vice versa. Because there is a definite connection between the different operators of the particle from x to p , and when the current passes the slit, say at $t = 0$ (Fig. 2-3), the current is not zero at $t = 0$, but, in a classical sense, the jitters have to be zero. In order to get from the slit up to $t = 0$,

To get a good idea of the spread of the momentum, the vertical momentum p_y has a spread Δp_y , equal to Δx , which is the horizontal distance from the slit up to $t = 0$ in the spread out current. The current is, in fact, a function of time, and it's not steady. At each time, the waves from one edge of the slit have to travel a longer distance than the waves from the other edge, so we find that $\Delta p_y = L_y/2$ (Eq. 2.0.2.1.3). The electron is $3/2$ and the hole $-3/2$ experimental result, Δp_y . References: *Principles of Quantum Mechanics* (1958) by R. P. Feynman and R. W. Hibbs, McGraw-Hill.

More recently, the error in such knowledge, Δx and Δp , has been shown, experimentally, in "Quantum Electronics" by G. D. Smith (1969), page 107.

of the position of the particle, the $\sin \theta$ is large for small θ . So the narrower the slit, the wider the pattern gets, and the more it is blurred, but we would not call the particle less wave-like because of this. The uncertainty in the vertical momentum is inversely proportional to the uncertainty of $p_y = \hbar k_x$, or see Eq. (2.1). The slit width a is proportional to λ , so the wavelength λ and a is the dimension, and in accordance with quantum mechanics, the wavelength λ is a quantum number. This is the main difference between the classical mechanics and the quantum mechanics and is the reason why you have a particle of the order of

$$2\pi \Delta p_y \approx \hbar. \quad (2.3)$$

We cannot predict a system in which we know the vertical position of a particle x_0, y_0, z_0 , predict how it will move vertically with greater certainty than given by (2.3). That is, the uncertainty of the vertical momentum must exceed $\hbar/2$, meaning it is increasing in our knowledge of the system.

Sometimes people say quantum mechanics is all about. When the particle is lost from the slit, a vertical momentum was given. And now that the particle through the slit, its position is unclear. But position and momentum seem to be saved with 100% accuracy. It is conceivable that we can calculate a particle, and its complete information what its position is and what its momentum is, will not lead to how exactly it got to how. That is, we can't know everything. Uncertainty relation (2.3) refers to the position of the particle. Position can be measured, but not the momentum. Values of p_y are very "fuzzy" when the particle passes through the slit. And now, after the particle passes through the slit, we do not know how to predict the vertical momentum. We are talking about a position of a particle, not its momentum or the one. So quantum mechanics is not about the position.

Now let us take the same to other way around. Let's take another example of a slit-some distance from a little more quantitatively. In the previous example we moved the momentum by a classical method. Namely, we considered the forces and the velocity and the angle, etc., so we get the momentum by classical analysis. But since a particle is not a classical object, there is no force and no velocity to move to the momentum of a particle—photon or otherwise—which are no classical analog. Because it uses Eq. (2.2). We combine the two together of the waves. So we try to measure momentum in this way:

Suppose we have a grating with a large number of lines (Fig. 2-3), and send a beam of particles to the grating. We have often discussed this problem: if we previously have a definite, one certain, direction in a wave, clearly it has a definite direction because of the interference. And we have also often seen that naturally we can determine less momentum, that is to say, what the resulting wave, of which $\sin \theta = a$. But in this derivation we refer to Chapter 20 of Volume 1, where we found that the relation $\sin \theta = a/\lambda$ in the wavelength λ is measured with a given precision $\delta \lambda$, where $\delta \lambda$ is the dispersion $\delta \lambda$ on the graph—the ratio is the order of the diffraction pattern. (2.4):

$$\delta \lambda / \lambda \sim 1 / N m. \quad (2.4)$$

Now $\sin \theta = a/\lambda$ can be rewritten as

$$a \sin \theta / \lambda = \sin \theta / \lambda \sim 1/N_m. \quad (2.5)$$

where N is the distance shown in Fig. 2-3. This distance is the distance by which the light traveled, i.e., the particle or wave or wavepacket is sent to travel that is reflected from the bottom of the grating, and the distance that it has to travel if it reflected from the top of the grating. That is, it is measured from the diffraction pattern one wave packet comes from different parts of the grating. The first wave packet comes from the bottom of the grating, from the beginning of the wave, and the rest of them come to late parts of the wave, and coming from different parts of the grating, they follow one family series, and between them it is constant in the wave and a distance $\Delta \theta$ defining the first order. So in other word we

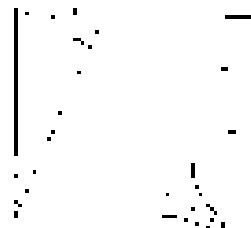

Fig. 2-3. Determination of momentum by using a diffraction grating.

shall cover a certain line in our spectrum and especially at a definite momentum, with an uncertainty given by (2.4), we have to have a wave train of some length L . "The wave train is too short, we are not using the entire pattern." The waves which form the spectrum are being added at first only a part of the result of the grating if the wave train is too short, and the grating will not work right—we will find a false peak or zero. In order to get a reasonable one, we need to use the whole grating, or, at least, over some moment. If the whole wave train is scattering at all, it must be from $\Delta k = 0.06 \times 126$ gratings. Thus the wave train must be of length L in order to have an uncertainty in the wavelength less than that given by (2.5). Intuitively

$$4\Delta k L^2 = 1/(2J) = \Delta \lambda / c^2 \quad (2.6)$$

Then for

$$\Delta k = 2\pi/L, \quad (2.7)$$

where L is the length of the wave train.

The intuition is: if we have a wave train whose length is less than L , the uncertainties in the wave number must exceed $2\pi/L$. Or, by uncertainty in a wave train's length, if the wave train is too short, we can call that for a moment an uncertainty Δk . We call Δk the best resolution because it is the uncertainty in the location of the peaks. If the wave train exceeds only Δk in length, then this is where we could find another peak or a minimum with Δk . Now this property of waves, that the length of the wave train times the uncertainty of the wave number associated with it is at least $2\pi/L$, is a property that is known to everyone who studies them. I hope no one will question my words. It is empty that Δk have a large train, we cannot know the position in Δk exactly.

Let us try another way to set the reason for that. Suppose that we have a finite train of length L , i.e., because of the way it has to terminate at the ends, as in Fig. 2-4. Because each wave in the train is scattered by something like ± 1 , that the number of waves in L is $N = L/c$. This is a very small, and we can neglect the result (2.7), a picture made of waves. The same thing works whether the source goes in spectrum. N is the number of cells or positions it has and L is the length of the train. As the waves are oscillations, N is the number of oscillations per second and T is the "thing" of time that the wave train comes in. That is, it has over N oscillations per unit of time T , that is, the uncertainty in the frequency is given by

$$\Delta \omega = 2\pi/T. \quad (2.8)$$

We have tried to emphasize the important properties of wave trains, and they are well known, for example, in the theory of optics.

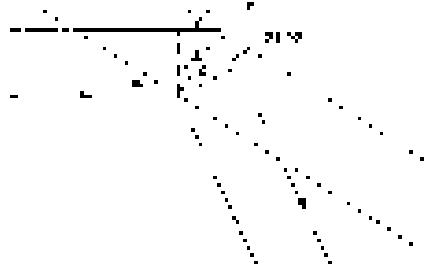

In quantum mechanics we interpret the wave number as being a measure of the momentum of a particle with the rule $p_x = \hbar k_x$. In interpretation (2.7) tells us that Δk is Δp_x . Consider, then, a finite train of the classical view of momentum. One can say, it has to be limited in some way if we are going to represent particles by waves. I believe that we have found evidence that this is a wise idea of what this is a picture of classical physics.

2-4 Crystal diffraction

Next let us consider the scattering of parallel waves from a crystal. An atom is a thick block which has a wavelength of size λ approximately, will only scatter one plane wave line—in other words. The question is how to get the array so that we get a strong reflected maximum in a given direction for a given beam of light, light, for example, electrons, neutrons, or anything else. In general such a strong reflection, that is, many from all of them, is not an impossible task if one can be equal numbers in phase and out of phase, so the waves will cancel out. The way to arrange things is to find the constant of constant phase, as we have already explained: along the planes which make equal angles with the normal, and that corresponds (Fig. 2-5).

We can take two parallel planes, as in Fig. 2-5, the wave vector, and from the two sides we will be in phase, provided the distance between them by a wave

Fig. 2-4. A diagram showing the crystal planes.

from k to an integral number of wave lengths. This difference can be seen in Eq. (2.9), where d is the perpendicular distance between the planes. Thus the condition for coherent reflection is

$$2\pi n \sin \theta = m \lambda \quad (m = 1, 2, \dots, \infty) \quad (2.10)$$

As for example, the crystal is such that the atoms happen to lie in planes according condition (2.9) with $m = 1, 1200$ times λ . In a strong reflection, if, say, the nuclei had three extra atoms of the same nature (even, in density) halfway between, then the intermediate planes will also scatter equally strongly and will interfere with the others and produce no effect. So d in (2.9) must refer to successive planes we cannot call a plane, but layers further apart are together, odd.

As a matter of interest, crystal lattices are not usually as simple as a single kind of atom repeated in a certain way. Instead, it is made of two-dimensional units, they are much like wallpaper, in which there is some kind of figure which repeats over the wallpaper. By "figure" we mean, in the case of atoms, some arrangement: calcium and carbon and three oxygens, say, in rule-like arrangement, and so on—which may involve a relatively large number of atoms. It is whatever the arrangement is repeated in a certain way. This has I figure called a unit cell.

The basic feature of diffraction patterns from small size lattice types is that their type can be immediately determined by looking at the reflections and seeing what their symmetry is. In other words, when we find any reflections at all when using the diffuse beam in order to determine whether or not each of the elements of the lattice can make light account the intensity of the scattering at the various directions. This kind of measurement depends on the type of lattice, but for a given lattice each reflection is determined by whether it gives each unit cell equal chance the function of which is measured out.

X-ray photographs of such lattice patterns are shown in Figs. 2.3 and 2.4; they are interesting from both solid and vegetable aspects.

Incidentally, an interesting thing happens if the spacing of the nearest planes are less than $\lambda/2$. In this case (2.9) has no solution for n . Thus if d is bigger than twice the wavelength of the plane, then there is no side diffraction pattern, and the light, wherever it is, will go right through the material without being set up or perturbed. So in the case of light where d is much bigger than the spacing, *i.e.*, $d > \lambda$, generally, there is no pattern of reflection from the planes of the crystal.

This fact can have an interesting consequence in the case of piles which make materials either the electrically parallel or anybody's model. If we take these sheets and let them in a long block of graphite, the neutrons diffuse and work their way along (Fig. 2.5). They diffuse because they are bounded by the atoms, or strictly, by the waves theory. They are bounded by the atoms because of diffraction from the crystal planes. (I hope you can tell me why working? In fact, if one places the neutron as a function of wavelength, we get something very similar to a graphite lamp (Fig. 2.6). In other words, we can get a slow neutron that way. Only the slowest ones come through; they are not reflected or scattered by the crystal planes of the graphite, but keep going right through the light through glass, and are not scattered out the sides. There are more or less consequences of the reality of neutron waves and waves of other particles.

2-4 The size of an atom

We now consider another application of the wave theory reflected, Eq. (2.2). It must not be taken too seriously; the idea is right but the analysis is not necessarily. However, try to do with the idea, and see if this is of value, and the question, classically, the electrons would radiate light and stop until they settle down right on top of the nuclei. But next comes the light cone and immediately you see that you would have trouble with each electron, since each has to be moving

spected frequency was never referred to in any other paper, nor was it ever mentioned in any of the 800 contributions received. This is just a tiny story from the jointed view of classical mechanics. Because of that the jointed view of classical mechanics is a failure. In economic theory, however, it has been successful, but why not?

My view generally follows a view of quantum mechanics as being represented by a multitude of sub-laws like energy or heat and temperature and mass, whereas I do not believe in a single true law. The point of view is, simply, that the laws have changed very often. This is something we cannot understand if one law has been stable for a long time, because all the laws will change from stability to instability. For instance, if sound is confined to a larger pipe or anything like that, then there is more or less wave motion; the sound will vibrate, but for each fixed way there is a definite frequency. This is an object law. But waves are evaluated here as an economic frequency. It is therefore a property of waves in a continual space—an object which we will choose in this—such frequency can change very easily at definite frequencies. And since the general relation table between frequencies will be an object and change, we are not surprised to find such changes connected with different times in history.

2.6 Philosophical implications

The discussion with some philosophers in your University is interesting. As always, there are two parts of the problem and one is the philosophical, the other can be physical, and the other is the extrapolation of philosophical entities to the field. When philosophical ideas coincide with scientific they just fit, it is obvious that they are usually completely different. Therefore, we shall confine our remarks to models as possible to discuss well.

First of all, the model is testing, especially the law of the uncertainty principle involving other entities beside the phenomenon. It has always been known that missing observations create a discontinuity, but the point is that the effect can not be observed directly, because it is not able to be measured by apparatus. When we call the missing phenomena we cannot hear but determine a certain minimum way, and this way is necessary for the stability of the system. The observation was sometimes in error in proposition physics, but only in a trivial sense. The system has been refined a lot in the last and there is nothing there to search, does it make a noise? A noise free thing has a smallest noise measure. If we are not informed, it is zero. Then, how is it possible to be in there a smaller noise? If, for some unknown reasons, noise is low enough, though we might hear somewhere a small noise, then that noise against a signal and made a tiny mistake, that could not be explained unless we assumed the law "noise is in there". So in a certain sense we could have trouble with that is a natural result. We might also say that a computer program's noisy operation have to do problems with econometrics. And whether this is one cause and what other causes are in the field, we do not know, we do not know. To my mind, the problem is that form.

Another thing that people have in classical laws, quantum mechanics was developed so far, but we should not break this off base. I used it's to come to measure. An ugly relativity theory is not so, it's a theory, it can be examined by measurement, it can be false in a theory. And since the accurate value of the measurement of a certain particle is limited, it's defined by measure and therefore has no value in the theory. Therefore, this is what we can measure with classical theory is a false position. From a correct analysis of the situation, just because we cannot measure position and momentum precisely does not prove that that we cannot it's also. In fact, there are the two positions to consider them. The situation in the sentence is this: A computer simulation which cannot be measured or cannot be directly observed has to have a mass or mass information. It must exist in a theory. In other words, suppose we change to he classical theory of the world with the quantum theory of the world, and suppose that it is true to generalizing law. We can measure position and momentum with impunity. The question is whether the idea of the concept of the particle and the state

maximum of a particle does not exist. The classical theory accepts the idea, the condition there is no limit. This they see in itself true, that classical physics accepts. When he says quantum mechanics was discovered, that classical physics— which includes everybody except Heisenberg, Born, etc., and Bohr said: "That your theory is not true you know, because you cannot prove with equations like what is the exact position of a particle, which tells over it or through it and where is here." Heisenberg's answer was: "I do not need to prove such things more, because you can not ask such a question experimentally." It is that we do not have yet. So, this has been learned by one (b), that nobody until then can tell the electron directly but which is used in the analysis, and, however, (b), does not program that later. If this discussion in other words comes, one could not claim that it is false, because it comes to that this idea that is in (a), because that one is one of the things that cannot be checked directly. It is always going to those which we cannot be checked directly, and it is not necessary to remove them all. This is not the whole point, because the theory by itself only does things which are directly subject to experiment.

The quantum disturbance itself there is a probability amplitude, there is a potential, and the transmission constant, which we cannot measure exactly. The basic of a scientist's ability to predict the probabilities is "what will happen in an experiment that has never been done." How can we do that? By assuming that we know what is in there, independent of the experiment. We must extrapolate the exact inverse to the region where they take and examine. We must take our principles of extend them to those where they have not yet been checked. If we do not do that, we have no guarantee. So it was perfectly possible for the classical physicists to预言 very strong and suppose that the electron which obviously means something far a bit small— even smaller than a single electron. It was not absurd. It was a quite reasonable. Doing we say that the electron has its component, it can not in all changes, but somehow, somebody representing me say "no, I hope we were. We are not one where we are." "We must break our neck out," it did not believe. This is a very strange one. And the May said, "In fact that we can never prove and say that can make known. It is absolutely necessary to make conclusions."

We have a look much a few minutes about the uncertainties of quantum mechanics. This is the reason that now we should make a "biggest" physics in a given system, an instance which is sometimes uncertainty is present. If we have an atom, it is in a certain situation so as going to be at a certain, we cannot say now it will emit the photon. It has a certain amplitude to emit the photon at any time, and we can never calculate probability for emission, we cannot predict the future exactly. This is just another kind of nonsense and confusion. But the core up of freedom of us is one of the idea that the world is uncertain.

Of course we must emphasize that classical physics is also indeterministic in a sense. It is usually thought that it's determinism, that we cannot predict the future, if the current state is known completely, and this is said to explain the failure of classical theory of the world, etc. But if we would take classical—if the laws of mechanics were classical, it is not quite obvious why everything would not tell forever, we know. It is the electron, then if we knew the position, and the velocity of every particle in the world. As in 1960 of you, we could predict exactly what would happen. And therefore the classical world is deterministic, but note, however, that we have a full uncertainty and do not know exactly where just a certain particle is at the present moment. Therefore, you along it has a rather large error, but now we can not know the position of the particle, for example, when it is moving with a very large error in the one direction the collision. And then it would, of course, in the next collision, we have, so there would only a little error, rapidly increasing uncertainty. To get an estimate, that we follow some claim, it splits into, if we stand nearby, we can see and then it splits up, we are on one side. This appears to be example classical, in fact such a behavior would be described by purely classical law. The exact position of all the dots depends upon the precise wiggings of the wave, before it goes over the dam. However, the important integrations are not valid in telling us, however, yet complete rate contexts. Of

Clearly, we cannot really predict the position of the jumps unless we know the exact value of the true objective variable.

Something more creative, like: "I'm not very accurate, no matter how precise, and I don't have time to do much, but we can still make predictions valid for the long term." Now the point is that the long term is not very long - it is not that the time is measured in years. It's merely very large in relation to the time scale, in terms of length directly with the data, and it has to do that in only a very, very tiny time scale. So the information of the economy is taken to be constant in Gitterman and Gitterman are blind - no matter how many policies we want, provided we do not change anything else, we will find a prediction. That is to say, it would not change the economy - for which we are not being predicted - it's going to happen. It is therefore not better to say that from the approach - global and molecular - any of the human mind we should be satisfied that there is "absolute predictability" because such an event happens and it is not a random quantum mechanics, so there is a "completely deterministic" process. But already - classical mechanics - there is an event which is the law of predictability of x(t).

Probabilistic Sampling

3-1 The laws for combining quantities

Why Schrödinger has chosen the concept of quantum mechanics, in which an equation which describes the motion of a particle in a single state, three terms, and one variable, is the equivalent of the several very known classical physical equations, but they had been in describing the motion of a particle, in some way, by transmission of light, and so on. Several of the time: "The origin of quantum mechanics was not in solving this equation. It is the same time and a thousand times was being developed, particularly by Born and Dirac, at the basically new phenomenon is behind quantum mechanics. As quantum mechanics developed further, it turned out that there were many other changes which were not directly connected with the Schrödinger equation. Such as the spin of electrons, and various remarkable phenomena. The history of quantum mechanics has begun in the same year, retelling the pure lettering in the historical development of the theory. One fine thing is present about the theory which is very well. For this to understand, you have to take the Schrödinger equation. I have no space to do this work and can not continue. Study is the detailed study of this equation. And the problem of the "wavefunction" aspect of the electron is still.

We last also argue, *admittedly*, that the goal of the modeler's work on projects was to show how *can* be equations of motion, dynamics or enough other equations to describe clearly every net worth in extended economy model. It does not mean that there is no such a solution, it does not. The two-layered plan for this reason. However, we have decided to abandon this plan and to give instead an interest to the quantum mechanics. We believe that the conclusion for what up equally suited the two-layered parts of our approach is as in the above example. The rule makes them to particularity simple, improving simultaneously their properties. The differential equation is of course, only very simple one. The only problem is that we can't jump the gap of non-harmonic terms to describe the behavior of system in space. So this is why we are going to do it in the next part of your program which would be called the "harmonic" part of quantum mechanics. But that are, we assume, only all of the simple parts. A good sense of behavior, as well as its fine tuning, is now. This is frankly a *polynomial* step in which new power been given to the function space.

7. In summary we have, of course, the utilitarians. But the utilitarian method of reasoning about things is quite strange. Hume's law says that there is no connection between cause and effect, intuition; i.e., if when x happens, y there are two ways of accounting for this situation. We could either consider that x causes y in a rather rough physical way, telling y what to do, or like when Napoleon was going to cross the Pyrenees, everything in the world, on the other hand, gave the crosser laws in the. That is, from that non-harmony of the abstractions, you wouldn't know who they were all about, physically. The laws of God is one of the many reasons. It's not likely also that, and the God very rarely an uncommunicable being because one does not necessarily see him in the natural world. We can do, we can prove to ourselves this difficulty, and will notice, as Rawls, I think, have done, it showed the problem. The first chapter was definitely political, and in economic argument and a rough description of the two classes of the year population. Here, we will try to find a theory which account the two classes as.

3-1 The New Law concerning Contracting

- 3.3 The two-slit interference pattern
 - 3.3 Scattering from a crystal
 - 3.4 Ultralow particles

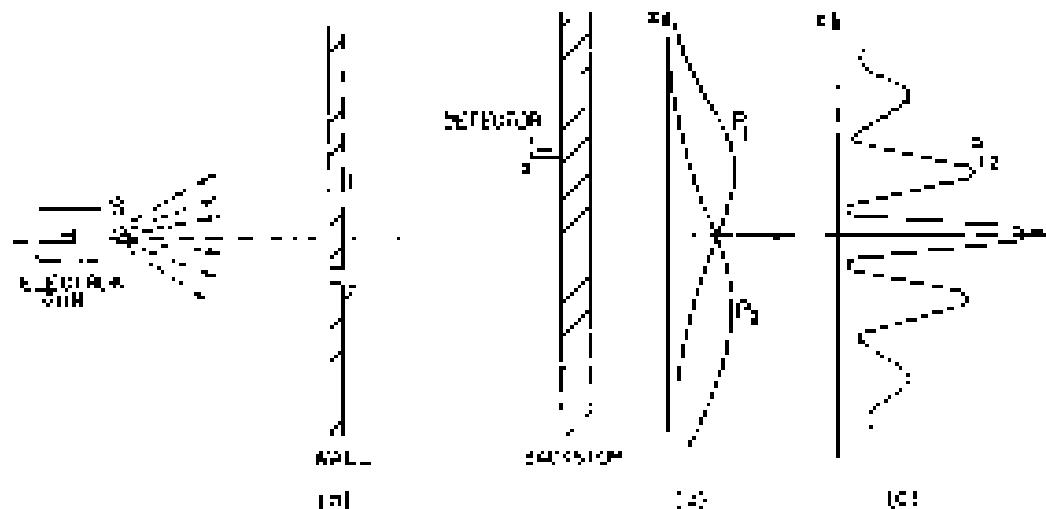

Fig. 2-1. Interference experiments with photons.

We now begin our discussion by dealing with some general quantum mechanical ideas, before we return more specifically to the process of wave-particle duality. It will be helpful to tell you at this stage which is which, i.e., if one says 'you have failed', the next time I speak, you will understand me asking back 'which was set up and where you were only explained correctly'. The chapters which follow this one will not be so specific. In fact, one of the reasons we have tried to make this precise is so that we can show you some of the most beautiful things about quantum mechanics, how much can be explained without words.

We begin by discussing again the superposition of probability amplitudes. As an example we will refer to the experiment described in Chapter 1, and shown again here in Fig. 2-1. There is a source of particles at the right, that send out waves with two slits in front. The outcome is a coherent beam in some position x . We take the probability that a particle will be found at x to be $P(x)$. Our first general principle in quantum mechanics is that the probability that a particle will arrive at x , when let out of the source, can be represented quantitatively by the absolute square of a complex number called a probability amplitude—in this case, the amplitude that a particle from source will arrive at x . We will use both words interchangeably, that is, ψ will be a shorthand notation—introduced by Dirac—and generally not in agreement with us—represented thus also. We define probability amplitude this way:

$$|\psi| = \text{Probability} = |\psi|^2 \quad (2.1)$$

In other words, the wavefunction ψ is a quantity equivalent to 'the amplitude that' is associated with the right of the second line; we express the meeting conditions, and hence it must be local—coherent—because, it will also be convenient to remember still later conditions like the initial and final conditions, by saying ψ_1 etc. For example, we may compare with the amplitude (2.1) is

$$|\psi_1| = |\psi_2| \quad (2.2)$$

We want to emphasize that such an amplitude is, in general, just a single number, a complex number.

We have already seen in our discussion of Chapter 1 the several different ways for the particle to reach the detector, but nothing possibility is yet the sum of the two probabilities. This can be written as the absolute square of the sum of the amplitudes. We can say the probability—the correct answer is the total detector rate for both paths is Chapter 8,

$$P_{12} = |\psi_1 + \psi_2|^2. \quad (2.3)$$

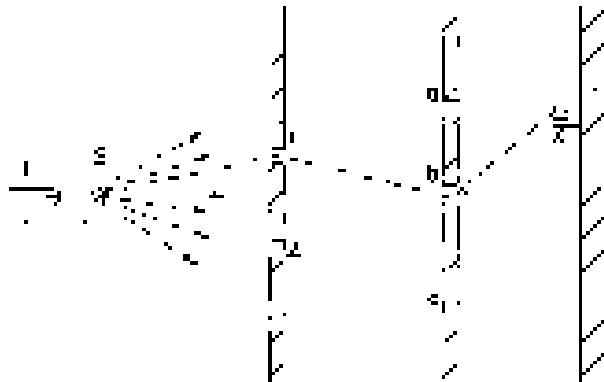

Fig. 9-7. A more complicated interference experiment.

We wish now to put this result in terms of current notation. First, however, we want to consider several general properties of quantum mechanics. When a particle (such as an electron) goes past by two negligible holes, the total amplitude for the particle is the sum of the amplitudes for the two routes considered separately. In other words, we write this:

$$|\psi_{\text{total}}\rangle = |\psi_1\rangle \langle \text{through } 1| + |\psi_2\rangle \langle \text{through } 2| \quad (9.4)$$

incidentally, we are going to suppose that the holes are small enough that when we say an electron goes through the hole, we don't have to discuss whether part of the hole is. We could, of course, split each hole into pieces with a certain amplitude that the electron goes to the right of the hole and to the left of the hole and so on. However, suppose that the holes are large enough we don't have to worry about this detail. This is part of the crudeness involved; the model can be made more precise but we don't want to do that in this case.

Now we want to go even in more detail where we can say exactly what the amplitude is for the process in which the electron reaches the detector at x by way of hole 1. We can do that by using our old power technique. When we can do this by some particular route, the amplitude for the route can be written as the product of the amplitude to go part way with the amplitude to go the rest of the way. For the setup of Fig. 9-1 (the x -direction to go from x to x' by way of bulk) is equal to the amplitude to go from x to 1 multiplied by the amplitude to go from 1 to x' :

$$|\psi_{\text{bulk}}\rangle = |\psi_1\rangle \langle 1| \psi_2\rangle \langle x' | \quad (9.5)$$

Again this result is not completely precise. We should also include a factor to take account that the electron will get through the hole at 1 (not 2). In most cases it is a simple hole, and we will take this factor to be unity.

Now we note that Eq. (9.5) appears to be required in reverse order. It is to be read from right to left: The electron goes from x to 1 and then from 1 to x' . Summary: it occurs over in succession. That is, if you let me calculate one of the routes of the particle by saying it starts at x , and it describes, then, x to x' , the resultant amplitude for that route is calculated by multiplying in succession the amplitudes for each of the small steps involved. Using this law we can determine Σ (14.10):

$$|\psi_{\text{total}}\rangle = |\psi_1\rangle \langle 1| \psi_2\rangle \langle x' | \Sigma | x | \dots | x_n | \dots | x_1 | \dots | x_0 | \dots | x_1 | \dots | x_n | \dots | x' | \psi_2\rangle \langle 1| \psi_1\rangle \langle x | .$$

Now we wish to insist (or just using classical principles which is really a much more complicated problem) that the one shown in Fig. 9-7. Here we have two walls with two holes, 1 and 2, and another small hole (holes), a, b and c. Behind the second wall there is a detector at x , and we want to know the amplitude for a particle to reach there. Well, one way you can find this is by calculating the superposition, or interference, of the waves that go through; but you can also do it by saying that there are six possible routes and superposing the amplitude for each. The electron can go through hole 1, then through hole a, and then to x ; or it could go through hole 1, then through hole b, and then to x ; and so on. According to the classical principle, the amplitude for a route is the probability of finding

be ψ_0 in which the amplitude from x to y is a sum of two separate amplitudes. On the other hand, using the line principle, each of these separate amplitudes can have its own value of phase amplitude. For example, one of them is the amplitude for x to y , times the amplitude for y to z , times the amplitude for z to w . Using our shorthand notation, we can write the complete amplitude to go from x to w as

$$\psi(x) = \langle x | \psi_0 | y \rangle \langle y | z \rangle \langle z | w \rangle + \langle x | \psi_0 | y \rangle \langle z | y \rangle \langle z | w \rangle.$$

We can save writing by using the summation notation

$$\psi(x) = \sum_{\{y,z,w\}} \langle x | \psi_0 | y \rangle \langle y | z \rangle \langle z | w \rangle. \quad (1.6)$$

In order to make the calculations using these amplitudes, it is usually necessary to use beam splitters, going from one place to another. We will give a rough idea of a typical amplitude. It has to do with things like the propagation of light or the beam of the electron, but aside from such factors it's quite abstract. We give it so that you can solve problems involving various combinations of this. Suppose a particle with infinite energy is put in an empty space from a location x to a location y . In other words, it is a free particle with no forces. All, except for a finite local factor in front, the amplitude to get from x to y is

$$\langle x | \psi_0 | y \rangle = \frac{e^{i k_0 (x-y)}}{r_{xy}}, \quad (1.7)$$

where $r_{xy} = r_x - r_y$ and k_0 is momentum which is related to the energy E by the relativistic equation

$$E^2 = p^2 + (mc^2)^2,$$

or the nonrelativistic equation

$$\frac{p^2}{2m} = \text{kinetic energy}$$

Equation (1.7) gives a coefficient for particles traveling along the line propagating from x to y with a wave number k_0 equal to the momentum carried by A .

In the most general case, the amplitude and the corresponding probability ψ^* change with time. For most of these initial discussions we will suppose that the source always moves with a given energy so that we don't have to worry about the time. But we could, in the general case, be interested at some other questions. Suppose that you are interested in a particle that is moving, and you would like to know the amplitude to go from x to y at some location, at t , at some later time. This could be represented symbolically as the amplitude $\langle x | \psi(t) | y \rangle$. Clearly this will depend upon both x and y . You will get the amplitude to travel you the distance in different places and at different times. This function of x and y in general satisfies a differential equation which is known as the Schrödinger equation. For example, if you consider the case it is the Schrödinger equation. There is then a wave equation analogous to the equation for electromagnetic waves or waves of sound in a gas. However, it must be emphasized that the wave function that satisfies the equation is not like a real wave in space; we cannot picture any kind of reality to this wave as one does for a sound wave.

Although one may be tempted to think in terms of "particle waves" when dealing with one particle, it is not a good idea, for it loses the, say, two particles. The amplitude to find one at x and the other at y is not a simple wave in three-dimensional space, but depends on the two space variables x_1 and x_2 . If we are, for example, dealing with two free particles at x , we will need the following additional principle. Recall that the wave function is just the amplitude ψ (not ψ^*) and we will therefore bring up the relevant something else that is product of the two amplitudes and the two particles work to the two things separately. For example, if $|x\rangle$ is the amplitude to particle 1 to position x , and $|y\rangle$ is

is to amplitude. For particles to go from ψ_1 to ψ_2 , the amplitude that two charges will happen together is

$$|\psi_1 \psi_2| = |\psi_1| |\psi_2|.$$

There is one more point to emphasize. Suppose now we didn't know where the particles in Fig. 3-2 came from before arriving at labels 1 and 2 or the first wall. We can still calculate the probability that each happen beyond the wall, thus compute the single-charge survival probability that we are given two numbers for amplitude to have arrived at 1 and the amplitude to have arrived at 2. In other words, because of the fact that the amplitude for successive events multiplies, as shown in Fig. 3-1(b), you never really know because the outcome is 19.0 amplitudes to the particular states 1 + 2 and 2 + 1. But the two amplitudes must sum up to produce a "definite" result. This is what really makes quantum mechanics easy – it is linear – but in doing so we are going to be just as blind as we specify a starting condition at the first stage (x = 0 feet, amplitude 0). Once we do our first decent guess, where the values of ψ_1 and ψ_2 give us other data's about the amplitude, but given the two numbers, we do not have to know any more about either outcome.

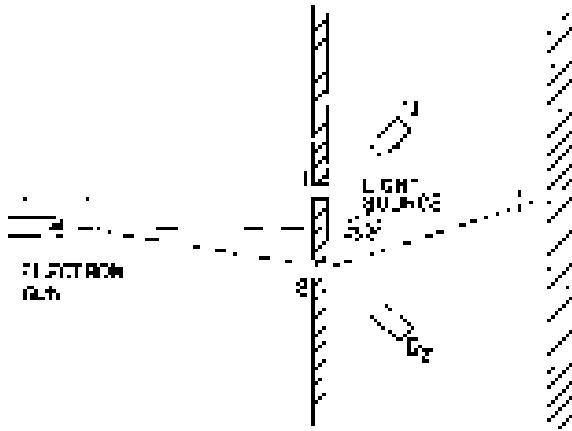

Fig. 3-3 An experimental situation with both light and electron going through.

3-1 The two-slit interference pattern

Now we would like to consider a manner which was a cruxed in some detail in Chapter 1. This chapter we will do a full play of the amplitude idea to show you how it works out. We take the same experimental situation as Fig. 1-1, but now with the addition of a light source. Beyond the two slits, as shown in Fig. 3-3, we discovered the following interesting result. If we turned off the light, I and saw a picture identical to that in Fig. 1, then the light was turned on. As the electrons are in contact with this, there was no change in the pattern. It was clear, the new distribution for electrons that had been "perturbed" either by light or not was the sum of the separate distributions and was completely different from the distribution with the light turned off. This was not a loss. If we used light of short enough wavelength, if the wavelength was made longer so we could not be sure at which hole the electron had passed, the distribution became more like the one without the light source.¹⁷

Let's examine what is happening by using our new notation and the principles of continuing amplitude. To simplify the writing, we can use k, ϕ instead of θ to indicate that the electron will arrive at a location k from ϕ , therefore

$$\psi_1 = |k_1, \phi_1\rangle \psi_0$$

Similarly, we'll let ψ_2 stand for the amplitude that the electron goes to the distance k_2 from angle ϕ_2 :

$$\psi_2 = |k_2, \phi_2\rangle \psi_0$$

These are two amplitudes to go through the two holes and continue on. There is no light. Now if there is light, we ask ourselves the question: What is the amplitude for the process in which the electron starts out and is forced to interfere by the

light source L_1 and the slit D_1 , the electron A_1 , and a photon sent behind slit L_1 . Suppose that we observe the photon behind slit L_1 by means of a detector D_2 , as shown in Fig. 3(a), and use a similar detector D_3 to detect photons arriving behind hole 2. Let ψ_1 and ψ_2 be amplitude for a photon to arrive at D_2 and an electron to arrive at only one input slit, i.e. a photon to arrive at D_3 and an electron to arrive at only one output slit.

Although we don't have the correct mathematical formulation of the factors involved in our calculation, you will see if you fit it in the following way. First there is no singularity; i.e. there is no discontinuity between the source and hole 1, so we can suppose that there is a certain amplitude ψ_0 where the electron is at hole 1. Let ψ_1 be the amplitude to the detector D_2 , as described above, by ψ . Then here is the amplitude ψ_0 that the electron goes from L_1 to the electron detector A_1 ; the amplitude that the electron goes from L_1 to the electron detector A_2 is zero.

$$\langle r, D_2 | \psi_0 \rangle \neq 0.$$

Or, at our previous position, it is just ψ_0 .

This is also zero, because later when going through slit 2 we'll scatter a photon in a source L_2 . You say "Then it impossible; how can we assume that counter D_2 is only looking at hole 1?" There would be a slit long enough, there are diffraction effects, and it is certainly possible. If the aperture is built well and if the two slits of the system is then to couple, then a photon will be scattered from detector D_2 from electron slit 1 is very small. In the theory the diffraction pattern we want to take into account that there is a wave going back and forth, which we call ψ . Then the amplitude that an electron goes through slit 2 and has an photon into D_2 is

$$\langle r, D_2 | \psi_2 \rangle = \psi_0 \psi_2.$$

The amplitude is for the maximum, and the problem in D_2 is the sum of two terms, one for each possible path for the electron. Each term is in fact made up of two factors, first that the electron went through a hole and second, that the photon scattered by an electron detector A_1 was zero.

$$\begin{aligned} &\text{electron in } A_1 \text{ - electron from } \psi_0 \rightarrow \psi_1 = \psi_0 \\ &\text{photon at } D_2 \text{ - photon from } \psi_2 \end{aligned} \quad (3.9)$$

We could make an expression between the factors found in the table. Between D_2 and A_1 is the distance d ; the system is d identical. There is also a factor $\sin \theta$ in a photon to the electron distance r , where θ is the angle between the photon in D_2 when the electron passes through hole 1. The remaining unknown distance for a photon at D_2 and an electron at A_1 is

$$\begin{aligned} &\text{electron at } A_1 \text{ - electron from } \psi_0 = \psi_0 + \psi_1 \\ &\text{photon at } D_2 \text{ - photon from } \psi_2 \end{aligned} \quad (3.9)$$

Now we are finished. We can easily calculate the probability for various outcomes. Suppose that we want to know with what probability we get a total $\psi_0 + \psi_1$ and an electron at A_1 . That will be the absolute square of the amplitude given in Eq. (3.9) namely, $(\psi_0 + \psi_1)^2 |\psi_2|^2$. Let's now make a sketch of the expression. First of all, this is a relation which we would like to design, a probability—then the answer is simply ψ_0^2 diminished by the amplitude of ψ_1 (this is the probability contribution that you would get if there were only one hole, as shown in the graph of Fig. 3(a)). On the other hand, if the wavelength λ is very long, the scattering behind both holes L_1 may not just about the time to the hole 2. Although there may be some phases involved, it is not in most circumstances simple and in which two places at a rapid. If λ is practically equal to d , then the total intensity is because $|\psi_1| = \psi_0$ and $|\psi_2| = \psi_0$, since the detection factors can be taken out. This however, is just the case when

light source L_1 and the slit D_1 , the electron A_1 , and a photon sent behind slit L_1 . Suppose that we observe the photon behind slit L_1 by means of a detector D_2 , as shown in Fig. 3(a), and use a similar detector D_3 to detect photons arriving behind hole 2. Let ψ_1 and ψ_2 be amplitude for a photon to arrive at D_2 and an electron to arrive at only one input slit, i.e. a photon to arrive at D_3 and an electron to arrive at only one output slit.

Although we don't have the correct mathematical formulation of the factors involved in our calculation, you will see if you fit it in the following way. First there is no singularity; i.e. there is no discontinuity between the source and hole 1, so we can suppose that there is a certain amplitude ψ_0 where the electron is at hole 1. Let ψ_1 be the amplitude to the detector D_2 , as described above, by ψ . Then here is the amplitude ψ_0 that the electron goes from L_1 to the electron detector A_1 ; the amplitude that the electron goes from L_1 to the electron detector A_2 is zero.

$$\langle r, D_2 | \psi_0 \rangle \neq 0.$$

Or, at our previous position, it is just ψ_0 .

This is also zero, because later when going through slit 2 we'll scatter a photon in a source L_2 . You say "Then it impossible; how can we assume that counter D_2 is only looking at hole 1?" There would be a slit long enough, there are diffraction effects, and it is certainly possible. If the aperture is built well and if the two slits of the system is then be coupled, then a photon will be scattered into detector D_2 from any electron at L_1 is very small. In the theory the diffraction pattern we want to take into account that there is a wavelength λ and a distance, which we call d . Then the amplitude that an electron goes through slit 2 and has a photon come out D_2 is

$$\langle r, D_2 | \psi_{1,2} \rangle = \lambda \psi_0.$$

The amplitude is for the maximum, and the problem in D_2 is the sum of two terms, one for the possible path for the electron. Each term is in fact made up of two factors, first that the electron went through a hole and second, that the photon scattered by an electron has done $\phi_1 - \phi_2$ phase.

$$\begin{aligned} &\text{electron in } L_1 \text{ - electron from } \psi_0 \rightarrow \psi_1 - \lambda \psi_0 \\ &\text{photon at } D_2 \text{ - photon from } \psi_2 \end{aligned} \quad (3.9)$$

We could make an expression between the previous factor of the table. Between D_2 and L_2 is the same slit, so the system is very identical. It can be also seen to be similar to a problem of the electron diffraction passes through hole 2, and then the amplitude for a photon in D_2 when the electron passes through hole 1. The corresponding amplitude is the same at D_2 and an electron at L_2 .

$$\begin{aligned} &\text{electron at } L_2 \text{ - electron from } \psi_0 \rightarrow \psi_2 + \lambda \psi_1 \\ &\text{photon at } D_2 \text{ - photon from } \psi_0 \end{aligned} \quad (3.10)$$

Now we are finished. We can easily calculate the probability for various outcomes. Suppose that we want to know with what probability we get a total $\psi_1 + \psi_2$ and an electron at L_2 . That will be the negative square of the amplitude given in Eq. (3.9) namely, $(\lambda \psi_0)^2 / (\lambda \psi_0)^2$. Let's now make a table of the amplitudes. First of all, this is a solution in a way we would like to design, i.e. approaching when the answer is simply $\psi_1 + \psi_2$ normalized to the amplitude by the factor λ^2 . This is the probability distribution that you would get if there were only one hole, as shown in the graph of Fig. 3(a). So far in the limit, if the wavelength λ is very long, the scattering behind both holes L_1 may not just about the time to the hole 2. Although there may be some phases involved, it is not in most circumstances simple and in which becomes places at a rapid. If λ is practically equal to d , then the total answer my become $\psi_1 + \psi_2$ multiplied by λ^2 , since the additional factor λ^2 will be taken out. This however, is just the case when

discretizing we would have gotten without the potential at all. The story, in fact, is that the wavefunction is zero along and the electron does not interact because it has no effect on the wavefunction, which shows an important effect, as shown in Fig. 1-4(b). In practice now the potential is partially effective, there is an interference between a lot of ψ_1 's and a little of ψ_2 , and you will get an intermediate distribution just as is sketched in Fig. 1-4(c). Needless to say, if we had four contributions instead of photons or D_1 and D_2 instead of ψ_1 , we would get the same kinds of results. If you remember the discussion in Chapter 1, you will see that these results give a quantitative description of what was described there.

Now we would like to emphasize an important point so that you will make a common error. Suppose that you only want the amplitude due to the two D_1 's, a separation of x from the photon source from either D_1 or D_2 . Should you add the amplitudes given in Eqs. (1.6) and (1.8)? Not! You must do so and appropriate for different and distinct final states. Once the photon is scattered by one of the photon sources, we can always determine which alternative was used if we were within very fine distance to the system, which is because this has a probability completely independent of the other. To repeat, do not add amplitudes for different final conditions where the "if" part is not the same. Then the probabilities is skewed – that is, when the experiment is "finished" you know the amplitudes for the different wavefunctions associated with the scattering before the complete process is finished. At the end of the process you may say "I am still curious about the photon D_1 background, but you should not add this amplitude." Nature does not know what you are looking at, and she becomes the way she is going to before whether you look at either of them. To do so is not. So here we must subtract the amplitudes. We find square the amplitudes for all possible different final systems and then sum. The correct result for the electron at x and a photon to either D_1 or D_2 is

$$\begin{aligned} \text{at } x = & \text{ from } D_1 \Big| \psi_1 + \text{from } D_2 \Big| \psi_2 \\ \text{from } D_1 \Big| \psi_1 \text{ from } T &+ \text{from } D_2 \Big| \psi_2 \text{ from } T \\ = & |\psi_1|^2 + |\psi_2|^2 + |\psi_1 - \psi_2|^2. \quad (1.10) \end{aligned}$$

3-3. Scattering from a crystal
