Our final example is a phenomenon in which we have to analyze the interference of probability amplitudes somewhat carefully. We look at the process of the scattering of neutrons from a crystal. Suppose we have a crystal which has a lot of atoms with nuclei at their centers, arranged in a periodic array, and it attracts nuclear forces more or less. We can label the various nuclei in the crystal by an index i , where i runs over the integers $1, 2, 3, \dots, N$, with N being the total number of atoms. The question is now is the probability of getting a neutron into a certain site with the arrangement shown in Fig. 3-5. It's one particular event, i.e., it's the chance that the neutron arrives at the center C to the right relative to the nucleus B from the source A , etc. It's done, in principle, by my amplitude ψ that is propagated there, multiplied by the amplitude that ψ gets from A to the center C . Let's write that down.

$$\text{amplitude of } C \text{ | neutron from } A, \dots, \langle C | \psi \psi \psi \dots \rangle. \quad (3.1)$$

In writing this equation we have assumed that the scattering amplitude ψ is the same for all atoms. We have been a large number of apparently indistinguishable sources. They are indistinguishable because a low-energy neutron is so slow. From a nucleus we don't knock the atom out of its place. In very almost "perfect" is left of the scattering. As we do in the center discussion, the total amplitude for a neutron in C derives a sum of Eq. (3.1) over all the atoms:

$$\text{amplitude of } C \text{ | neutron from } S = \sum_{i=1}^N \langle C | \psi_i \psi_i \psi_i | S \rangle. \quad (3.12)$$

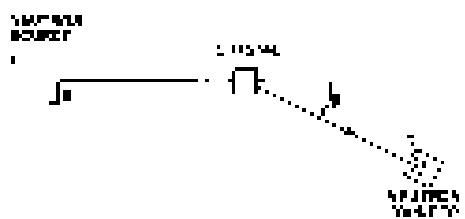

Fig. 3-5. Scattering: the scattering amplitude of a crystal.

however, we are dealing simply about scattering from atoms with different spin positions, the amplitudes are four different phases giving four wave elastic intensities, so that we have already prepared all the cases for the theory of light from a gas, i.e.

The scattered intensity is a function of angle in a plane of unit radius after summing over three-dimensional oscillations with very short interference, and is plotted exactly in sequence to those in Fig. 7-3(a). However, the last two kinds of oscillations do not give this very real intensity, but the incoherent prove discussed above, in general, because of oscillations in all directions. We must pay attention and take up only "physical" cases, i.e., i.e., Well, we have now considered the important property of the atom, i.e., the spin of course, and also the one between the spin which is the total spin, "singlet or product" to the product of the two spin "sums." If the nuclei of the crystal have no spin, the nucleus of course, may take it, however, the result of the total spin of the crystal will be half, you will observe the 100% CBR, as previously scattering described above. The explanation is as follows:

First, the two directions of spin and its phase, and next, the same spin direction of spin can occur in the scattering process. If the incident plane waves have opposite spin, then one of the two can be reflected, and in such case, there are two types, and another in which the spin direction is exchanged. It is difficult to make a good account of the spins corresponding to our discussions of consecutive angular momentum. We can begin to understand the problem if we assume that all the scattering must be set up w. respect to orientation. A beam with these axes will enter with the expected 100% incoherent intensity. There will be no double-peaks, but if it were without spin flip, the setting is changed from the above; w. the two spins fixed in the scattering, we could, in principle, find two channels had done the scattering, since it would be the only ones with open channel. Well, it is certain that such a case, i.e., a case like this, the electrons going out with it, keeping at least, the scattering is nearly the same for the two cases.

To handle this case, the mathematical form of the theory of P must be modified since we haven't used the states and states in that analysis. Let's start with all the axes along the scattering axis, and all the nuclei of the crystal having a fixed z. Then, we would use the amplitude that all the nuclei of the spin of the nucleus, i.e., all spins of the crystal are still down. This is not different from our previous argument. We will let ψ_0 be amplitude of ψ_0 for without spin flip, ψ_0 . The amplitude of scattering from each atom is of course,

$$A_{\text{atom}} = \langle \psi_0 | \psi_0 \rangle = S_{\text{atom}} \cdot S_{\text{atom}}^* = S_{\text{atom}}^2 \quad (7-3)$$

So, all the atomic spins are still down, no atomic absorption, no scattering, no energy loss is absorbed. That is exactly my way to a scattering that is scattering. For this reason, ψ_0 is amplitude in ψ_0 .

We have another case, however, where the spin of each lattice nuclei is down all nuclei started from a spin up in the crystal, one of the spins has to go to the up position to have full calculation. We will again, the same as the state scattering amplitude with spin flip for every atom, and ψ_0 . In this case, it is due to the disagreeable possibility that the reversal spin occurs in scattering. In this case, the crystal for which this probability is very low. The scattering amplitude is then

$$A_{\text{atom}} = \langle \psi_0 | \psi_0 \rangle = S_{\text{atom}} \cdot S_{\text{atom}}^* = S_{\text{atom}}^2 \quad (7-4)$$

If we take the probability of finding the rest of spin down in the crystal is spin up, the ψ_0 , in the absolute square of this amplitude, which is simply S_{atom}^2 times S_{atom}^2 , i.e., S_{atom}^4 . The second factor is this integral over density of the crystal, and all phases. The consequence is that the absolute square of the

probability distribution of final angles in the ensemble has in this case

$$P(\theta) \propto \sum_{i=1}^N \delta(\theta_i - \theta) \delta(\phi_i - \phi)$$

which will show a delta function-like peak at $\theta = \theta_0$ (Fig. 3-6(b)).

Another type of ensemble which we can have is $\langle \cdot \rangle^{\text{exp}}$. Perhaps you don't just require knowledge of the probabilities, in fact what we gave above. Let us consider such an ensemble below. In this case, if we want to measure probability of the sum of the cosines of all angles, we can do it by taking the absolute square of

$$\sum_{i=1}^N \theta_i \leq \pi/2$$

Show this sum. (Figure 3-6(c)) please, this does not have an average value in a different problem. If we do an experiment in which we don't observe the spin in the excited region, then both with class $\langle \cdot \rangle^{\text{exp}}$ and $\langle \cdot \rangle^{\text{ensemble}}$, probabilities add. Now let's calculate the probability of creating a system of angle functions like those in Fig. 3-6(b).

Let's review the physics of this experiment. If you could directly calculate $P(\theta)$ for the initial condition, you might immediately calculate the probability of finding the particle at an angle θ . If you cannot do this, the best way is to calculate the probability amplitude, since this is much harder to calculate than $P(\theta)$, but it is much easier to find the total probability. One thing you should note is probably is that if you were trying to represent the particle by a wave vector, you would probably take it to be something like $\psi(x)$ where x does not change noticeably in the region of interest. You would have to get out the "real" wave function from $\psi(x)$ in terms of energy eigenstates for the \hat{A} symmetry with the same wavelength. But we know that from the scattering. So as indicated earlier, we must take into account the reality of the wave vector. This is useful for our spin problem and problem 3.

3.4 Identical particles

The next experiment we will consider is one which shows some of the basic consequences of quantum mechanics. At first, we discuss a classical situation in which a single atom approaches a differentially heated wire, and we consider the consequences of unitarity, as is always the case in scattering theory. We can ignore the scattering at relatively low energy of such a body, or *over-mass*. We can ignore the other bodies which are more massive and obtain unitarity in this, so we ignore it. In order to be complete however, we will look at the Coulomb-force system in which the approach energy into the wire is too large to enter vertices in opposite directions before the collision, and again in exactly the same way as the collision. See Fig. 3-7(a). The magnitude of the velocity of the system is given by

$v = \sqrt{2E/m}$ where E is the total energy of the system. The reason that the two particles enter the interaction, and each receive a positive charge due to electrostatic springing, there is no electrical repulsion in the gas. The probability will increase at different angles as the different particles pass, and we would also consider the same in spin. The angle dependence of scattering means this is possible. Consider, for instance, scattering at right angles. At 0.001 m/s the most probable angle of scattering indicates that the direction of this collision is 90° out of the center it is essentially. This is an average over all angles for the same distance, the mean square being the inverse square law scattering cross section.

In many ways, scattering of different species can be measured by an experiment as shown in Fig. 3-7(b). The atomic species form a beam, the detector is placed vertically along either the horizontal or vertical axis, and the detector is

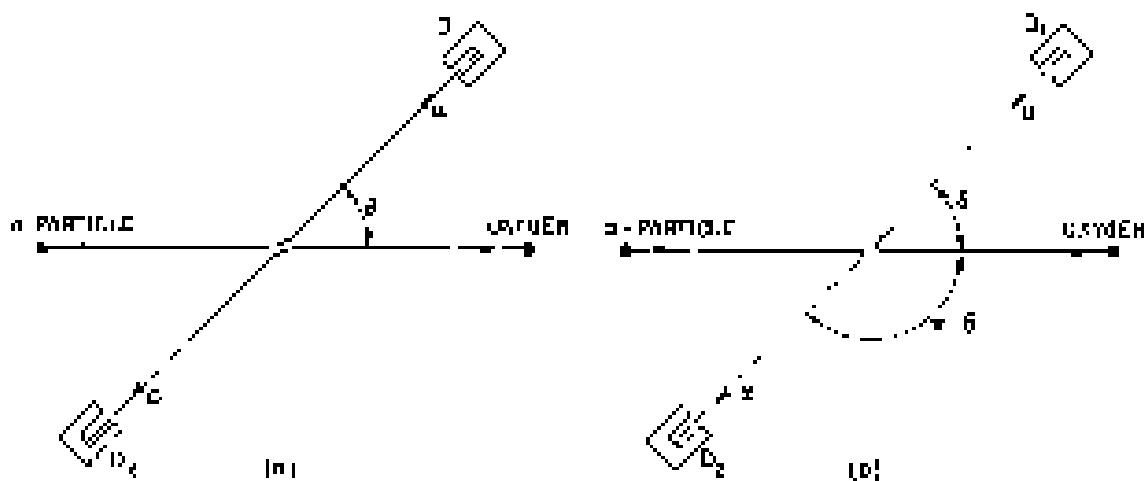

Fig. 3-7 The scattering of α-particles from oxygen nuclei, as seen in the carbon-oxygen system.

only oxygen. Let us check. In the Bohr model, the deuterons would not be scattered; but in the CM system they may. Our experiment consists in measuring the probability of scattering in various directions. It's only by the amplitude of scattering into the counters when they are at the angle θ , does $|f(\theta)|^2$ tell us our experimentally determined probability.

Now we'd like to know experimentally whether our counters would respond to both the deuteron or the oxygen nucleus. Then we'd like to work out what happens when we do not bother to distinguish which particle is scattered. Of course, if we try to put an oxygen in the position C , there must be an α -particle in the opposite side of the angle ($\theta = \pi$, as shown in Fig. 3-7(b)). So $|f(\theta)|^2$ is the amplitude for a scattering channel, the angle θ , when $\alpha \rightarrow D$. The amplitude for response is having through the angle θ a deuteron, the probability for having some particle in the detector at position C :

$$\text{Probability of some particle} = P_C = |f(\theta)|^2 + |f(\pi - \theta)|^2. \quad (3-14)$$

Note that the two states are not necessarily to be added. Even though in this experiment we do not distinguish them, we can't. According to the conservation theorem, we must add the probabilities, not the amplitudes.

The result given above is exact. For a variety of target nuclei (for example, deuterium, carbon, or anything in hydrogen), it's not appropriate to speak of α -particles. For the one case in which both particles are exactly the same, the experimental data disagree with the prediction of (3-14). For example, the scattering problem at 90° is exactly like this: the cross section predicted has nothing to do with the particle being stopped, α -particle or deuteron. If the target is ^{16}O , the projectiles are α -particles (He $_4$), then there is no difference. Only when the target is ^{3}He , so its nuclei are identical with the incoming projectile, does the scattering vary in a peculiar way with angle.

Perhaps you can already see the explanation. There are two ways to pass an α -particle into the deuteron by scattering the deuteron (with angle θ , α projects to a point at angle $\pi - \theta$). Do we know which one before scattering particle or the target particle enters the counter? The answer is: *not*, we cannot. In the case of α -particles with α -particles there are two alternatives that cannot be distinguished. Here, we must let the probability amplitude interfere by selection.

In general, in scattering, an element of cross section, $d\sigma$, described by two angles, one angle θ , as well as the azimuthal angle ϕ . We want to know that an oxygen nucleus at 90° about α , the amplitude is still $f(\theta, \phi)$, $\phi = 0$, however, in Coulomb scattering (and for many other cases), the scattering amplitude is independent of ϕ . Then the elastic total cross section of oxygen nuclei is the same as the amplitude at the angle $\theta = 0$.

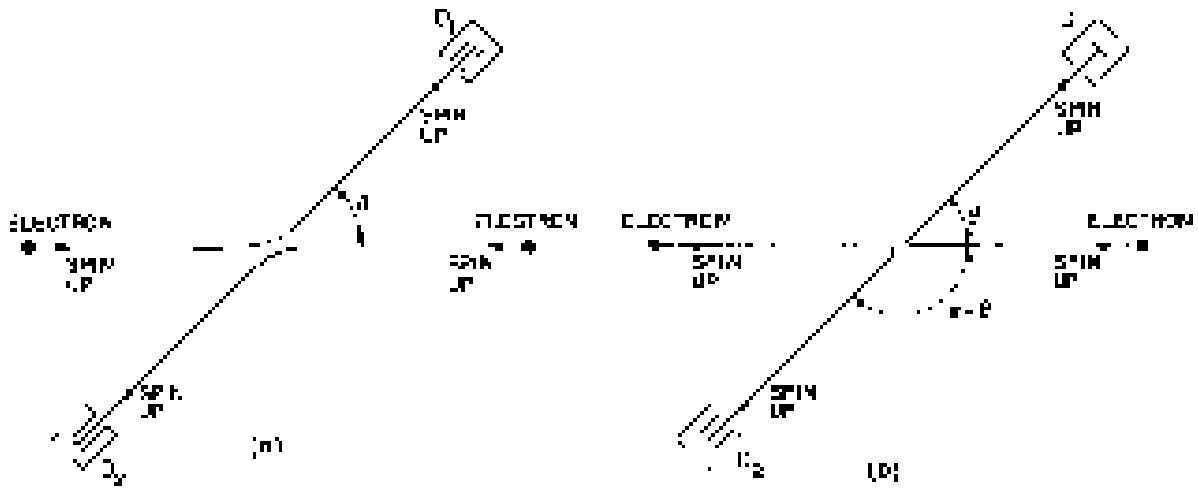

Fig. 3-8. The scattering of an electron by another. If the incoming electron has parallel spin to the scattered, (a), are the probabilities:

so the probability of finding a particle at the center is the sum of the sum:

$$\text{Probability of } \alpha \text{ and } \beta \text{ at } D_1 = |f(\alpha) + f(\beta - \alpha)|^2 \quad (3-15)$$

This is quite a different result than (3-7) in Sec. 3-14! Where do we make a mistake? For example here, if it is true to figure out that $f(\alpha) = \rho/2$, we otherwise have $f(\beta) = f(\beta - \alpha)$, so one finds by in Eq. (3-15) becomes $(\rho/2)^2 + (\rho/2)^2 = 4(\rho/2)^2$.

On the other hand, if they did not interfere, the result of Sec. 3-14 gives only $\rho/4(\pi r^2)^2$. So there is either no interference or else we might have an extra 4π times, in other angles the amplitude to scatter is zero. And we can have the same result in either case as the Coulomb interaction does not depend on spin. In other words the Coulomb interaction is spinless. To get the correct description you must add the amplitudes for the two possible processes. The two processes simply interfere a little, and that is what the license.

An even more surprising thing happens when we look beyond α and β , say, and try scattering electrons on electrons, or protons on protons. Neither of the above results is then correct! For this purpose, we must extend the new rule a little further, namely, let us go to the following. When you have a scattering in which the energy of the incoming electron is exchanged with another electron, the new amplitude α interferes with β and γ and with an opposite phase. If α has the form $\rho/2$, but with a minus sign, at the cost of a plus sign when you exchange β and γ with each other, then the difference, the interfering amplitude, agrees with the positive sign. In other words, the interference amplitude for exchange satisfies $\alpha\beta\gamma = \alpha\gamma\beta$, a sign flip. Except for unimportant factors involved below, the proper equation for electrons in an experiment like the one shown in Fig. 3-8 is

$$\text{Probability of } \alpha, \beta, \gamma \text{ at } D_1 = |f(\alpha) - f(\beta) - f(\gamma)|^2 \quad (3-16)$$

The above statement cannot be qualified, because we have no knowledge of the spins of the last three particles have in spin. The electron could also be considered to be either "up" or "down" with respect to the plane of the scattering. Since energy of the experiment is low enough, the magnetic field is weak, the electrons will be small and the beam will not be deflected. We will assume that this is the case for the present calculation, so that we conclude that the spins are obtained during the collision. Whatever spin the electrons have, we take them all to have you see there are other possibilities. The bombarding and target particles can have both spins up, but between, or opposite spins. If both spins are up, as in Fig. 3-8, if their spins are down, the cross section will be zero, because particles and the denominator for the process is the product of the coefficients for the two probabilities

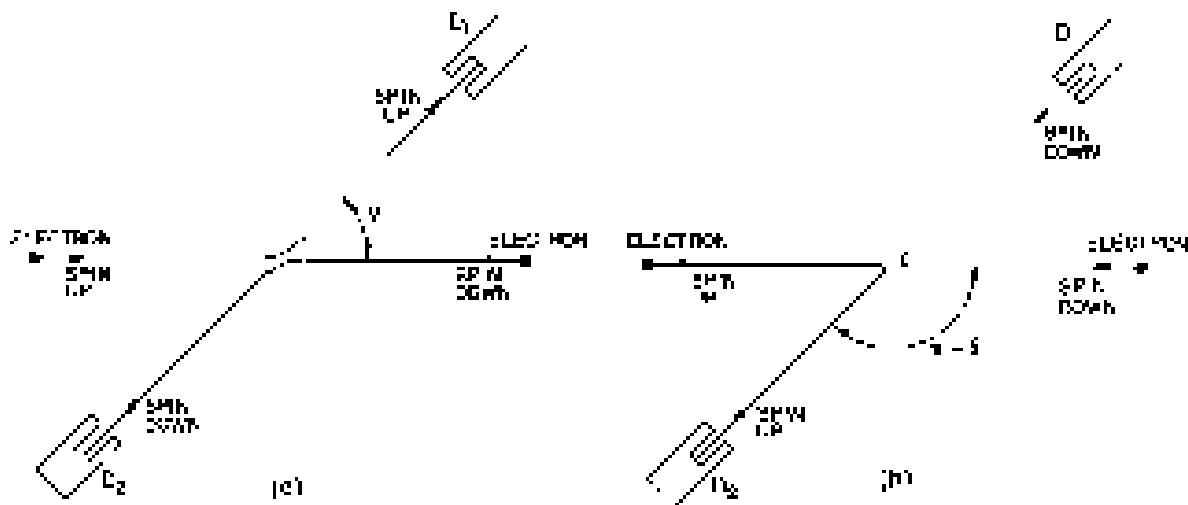

FIG. 3-4. Spin scattering of electrons with antiprotonic atoms.

shown in Figs. 3-4(a) and (b). The probability of detecting an electron in D_1 is given by $P_{D_1}(\theta_1)$.

Suppose, however, the "beamforming" beam is not 100% "up" spin up. Let the electron entering counter D_1 have spin up in spin down, and by measuring this spin we can tell whether it came from the scattering beam or from the target. The two possibilities are shown in Fig. 3-4(b); they are distinguishable in principle, and hence there will be no interference between an addition of the two probabilities. The same argument applies "left" of the original spin measurement; i.e., "The left-down spin is down and the right-hand spin is up."

Show how to use one electron as an atomic test particle in which the electron is a completely unpolarized atom, the addition of the "up" and "down" electron currents with spin up or spin down. If we do not bother to measure the spin at the exit-current point in the source, and we have $\psi(x)$, we still get unpolarized experiments. The results for this experiment are best taken by fitting all of the various ψ possibly since we have done in Fig. 3-3(a). A separate probability is computed for each polarization alternative. The total probability is then the sum of the separate probabilities. Note that for unpolarized beams the result for $\psi(x) = \psi(0)$ is unaltered except for a small weight shift in probability per state. The behavior of identical particles has many interesting consequences, we will discuss them in greater detail in the next chapter.

Table 3-1
Scattering of unpolarized spin one-half particles

Reaction channel	Spin of particle 1	Spin of particle 2	Spin of θ_1	Spin of θ_2	Probability
$\frac{1}{2}$	up	up	up	up	$ f_{11}^{\text{up}} - f_{12}^{\text{up}} + f_{21}^{\text{up}} ^2$
\cdot	down	down	down	down	$ f_{11}^{\text{down}} - f_{12}^{\text{down}} + f_{21}^{\text{down}} ^2$
\mp	up	down	up	down	$ f_{11}^{\text{up}} - f_{12}^{\text{down}} ^2$
\pm	down	up	up	down	$ f_{11}^{\text{down}} - f_{12}^{\text{up}} ^2$
			down	up	$ f_{21}^{\text{down}} - f_{22}^{\text{up}} ^2$

$$\text{Total probability} = |f_{11}^{\text{up}} - f_{12}^{\text{up}} + f_{21}^{\text{up}}|^2 + |f_{11}^{\text{down}} - f_{12}^{\text{down}} + f_{21}^{\text{down}}|^2$$

Elementary Particles

4.1 Basic particles and Fermi particles

In the last chapter we began discussing the basic rules for the interaction of two nucleons in processes with two identical particles. By identical particles we mean things like electrons which can interact with particles one from another. It is agreed, however, that protons (but see Pauli's exclusion principle) are not identical to each other. In fact, it is known that there are two different types of protons which cannot be distinguished statistically (one type of proton is white, while the other is black). The amplitude for an event is then the sum of the two interacting amplitudes; but, interestingly enough, the interference is in such cases *at large* of course, not zero, with the opposite phase.

Suppose we have one black and one white particle incident in the direction α and particle β emerges in the direction β' , as shown in Fig. 4.4(a). Let's call $a(\tau)$ the amplitude for this process; then the probability P_1 of observing such an event is proportional to $|a(\tau)|^2$. Of course it must also be given that particle α is scattered into α' and particle β into β'' , as shown in Fig. 4.4(b). Assuming that there are no special directions defined by spins or such, the probability P_2 for this process is just $|a(\tau - \tau')|^2$ because it is *not* equivalent to the first process with respect to conservation of energy, $\tau = \tau'$. You might also think that the amplitude $b(\tau)$ for the second process is $a(\tau - \tau')$; this is not necessarily so, however, there could be interference due to spin. That is, the amplitude could be

$$a(\tau) + b(\tau).$$

Such an amplitude still gives a probability P_2 equal to $|a(\tau - \tau')|^2$.

Now let's see what happens if α and β are identical particles. Then the two different processes shown in the two diagrams of Fig. 4.4 are not independent. There is an amplitude that either α or β goes into α' and β' , while the other goes into α'' and β'' . This amplitude is the sum of the amplitudes for the two processes shown in Fig. 4.4. If we do nothing else (i.e., if $a(\tau)$), then the amplitude is $e^{i\theta}a(\tau) + b(\tau)$, where θ is the phase between very important because we are trying to be adding two amplitudes. Suppose we have to measure the amplitude by a certain process (such as when we calculate the ratio of the two particles). If we exchange the signs of $a(\tau)$ and $b(\tau)$ in one scattering, then we subtract the before process

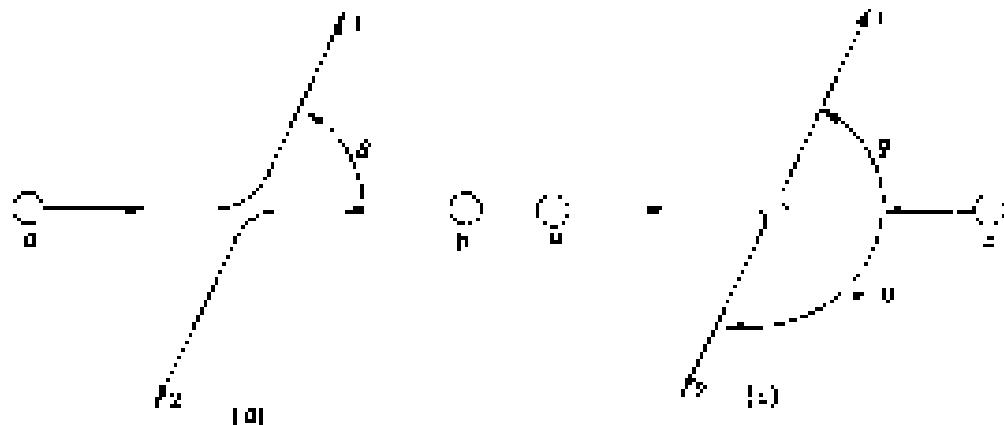

Fig. 4.4. In the scattering of two identical particles the processes (a) and (b) are indistinguishable.

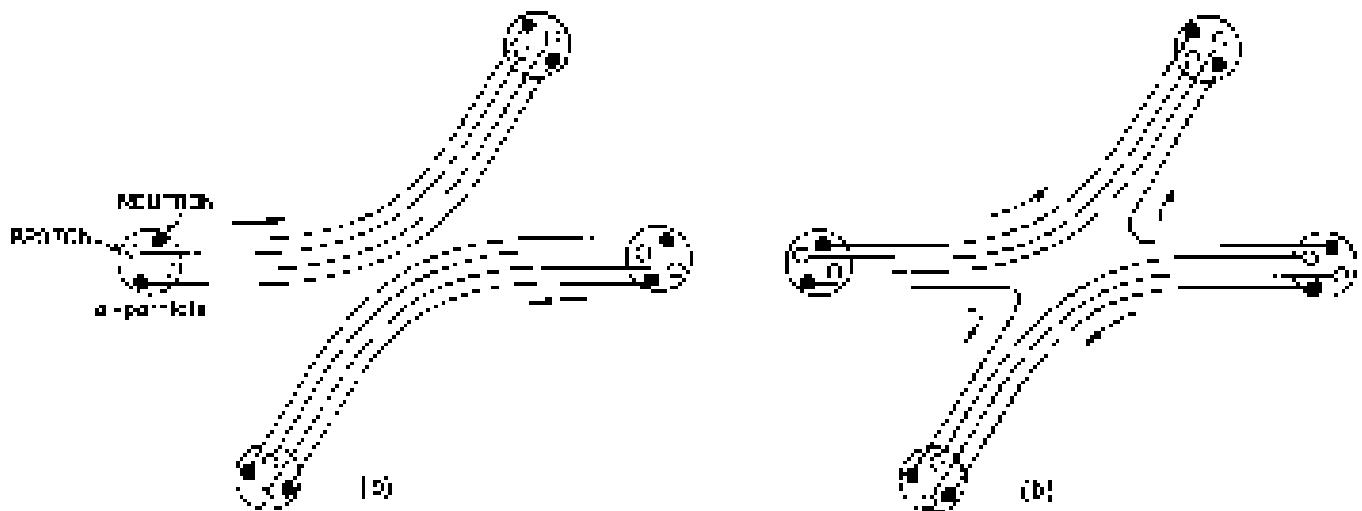

Fig. 4.2. (a) Scattering of two particles. (b) Two-particle exchange. In (b) a reaction is exchanged during the collision.

The first factor in the cross section must bring us back since we wanted the square root to equal to 1. There are only two possibilities: β^2 is equal to 1, or it is equal to -1. Either the exchange does not change or it is being exchanged in conjunction with the exchange sign. There is no room in nature, such far off distances, of course, for either which case the path is exchange sign the initial two particles and total waves must have the same sign as you are talking about just now. The first possibility would give the minus sign, and the second, the plus sign. So the minus sign is one we elect, the minus the deuterons, the nucleons, and the electrons. We have, then, that the amplitude for the scattering of identical particles is:

$$\text{Scattering} = \text{Amplitude direct} + \text{Amplitude exchange}. \quad (4.1)$$

$$\text{For non-identical} \quad \text{Amplitude direct} - \text{Amplitude exchange}. \quad (4.2)$$

For particles with spin like electrons, there is an additional complication. We must specify what is the coupling of the spins along the direction of the incoming. It is only for identical particles with spin zero however, but for any individual electron, when the particles are exchanged, it is one third of the scattering of nucleon-nucleon terms which are a mixture of 2 terms, instead of the 1 we would normally expect.

Now in the existing problem, since when the two particles are moving they come right together, for example, an alpha particle and a proton and the two next ones and two protons. When two alpha particles collide, there are several possibilities. It may be that each particle scatters, thus is a certain amplitude for one of the nucleons will happen to scatter, another particle will scatter, while a nucleon from one other alpha particle traps the other way to trap the two others which come out. Of course the scattering are not like this. It has been an exchange of a pair of nucleons. See Fig. 4.2. The amplitude for scattering is then a sum of a series of non-relativistic amplitudes with the amplitude for scattering with no such exchange, and the amplitudes must be taken into account because there is a certain exchange of one set of Fermi particles. On the other hand, if the relative energy of the two particles is so low that they stay fairly far apart—say, due to the Coulomb repulsion—and there is never any appreciable probability of finding a pair of two internal particles, we can consider the two particles as simple regions, and make no deal with many other, the internal data. In such circumstances there are only two contributions to the scattering amplitude. Either there is no exchange, or all four of the nucleons are scattered in the scattering. Since the protons and the

neutrality of the separate fermi and boson particles; a exchange of one pair between the sets of the incoming annihilation. So long as there are two bound energy in the sets, interchanging the two particles is the same as interchanging fermions or Fermi bosons. There is a change in sign for each switch, so it is not enough that the composite structure such a *ghost* or *spirit*. The composite behaves like a *Bose particle*.

So the rule is that any two objects are *composites*, which is incompatible classically because both are single objects below the Fermi particle or *Bose* particle, depending on whether the bound state is a number or an even number of fermi particles.

All the elementary Fermi particles are *composite*—such as the electron, the proton, the neutron and so on—but $\text{spin} = 1/2$. Classical such Fermi particles are just too thin to form a composite object. The resulting system may be called a *ghost* or *halo-magnet*. For example, the common isotope of helium, the ^4He , has two neutrons and two protons. The $\text{spin} = 1/2$, whence ψ^2 which has three nodes and four minima, see chapter 3.2. We will learn more about conserving angular momentum ... and will see later how this can be enough of a object which has a *ghost* or *halo-magnet* or *ghost particle*, which is every composite object will always have *ghost* incluses it. *Boson* particle.

This brings up an interesting question. Why isn't that gets it's own ψ^2 instead of spin and Fermi particles which add to add with the others ψ^2 ? It has particles with integer spin and Fermi particles whose amplitudes add with the probability ψ^2 . We apologize for the fact that we did not give you an elementary explanation. An explanation has been written by Paul Dirac himself of an account of quantum field theory and relativity. He has shown that he was most successful in his lecture, nor we have not been able to find a way to reproducing his account at an elementary level. It appears to be one of the few places, if any, where there is a rule which can be stated very simply, but for which no one has found a simple and easy explanation. The solution is to drop down to *quantum mechanics*. This is really more or less not have a complete understanding of the fundamental principle involved. So, the answer, you will just have to take the quantum rules of the world.

4-2 Slides with two *Bose* particles

Now we would like to discuss the interesting consequence of the interaction rule for *Bose* particles. This to do with their behavior when there are several particles present. We begin by considering a scattering in which two *Bose* particles interact from two different wavefunctions. We start with a diagram. In this is of the scatterings of ψ_1 and ψ_2 as depicted only in ψ^2 . Happens in the scattered particles. Suppose we have the situation shown in Fig. 4-1. The particle ψ_1 is sent and ends into the angle β_1 . By a rule we mean a given creation and destruction after given conditions. The particle ψ_2 is scattered into the angle β_2 . We assume again that the two angles β_1 and β_2 are really *classical*. (We actually want to find out exactly if the amplitude that the two particles are scattered into identical directions, or states, but it is not of great interest about this.) Happens if the states are almost the same and even worse, but what happens when they become identical?

Suppose that we take only particle at time t to $t + \Delta t$ in ψ_1 and ψ_2 implies that ψ_1 is incident from 1, say (1, α). One particle is absent, we denote the same initial state by ψ_2 scattering to direction 2. If the two particles are *not* interacting, the amplitude for the two scattering to occur at the same time is just the product

$$\psi_1 | \psi_2 \rangle \langle \psi_2 | \psi_1$$

The probability to have an event is $|\psi|^2$

$$|\psi_1 | \psi_2 \rangle \langle \psi_2 | \psi_1|^2$$

which is also equal to

$$|\psi_1 - \psi_2|^2 |\psi_2 - \psi_1|^2$$

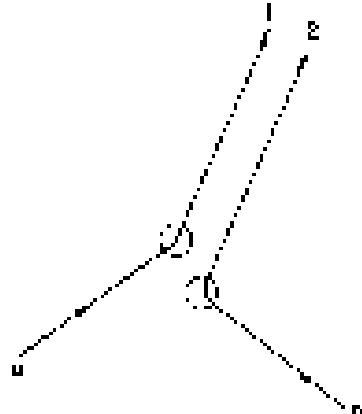

Fig. 4-1 A *coarse* scattering with nearly the same

To save writing for the detection counters, we will sometimes set

$$d\Omega = d\theta_1 \wedge d\theta_2 \wedge d\phi_1 \wedge d\phi_2.$$

Then the probability of the double scattering is

$$\alpha_1^{-2} \alpha_2^{-2}$$

It is often convenient to express this probability in terms of the angle χ between the initial direction \vec{v}_1 and the final direction \vec{v}_2 . The expression for this quantity is

$$\cos(\chi) = \vec{v}_1 \cdot \vec{v}_2,$$

and the probability of double scattering

$$d\Omega = d\chi / 4\pi^2 = |\alpha_1^{-2} \alpha_2^{-2}|.$$

In practice, there may be a particle counter that records the two scattered particles. The probability P_2 that this will record two particles together is given by

$$P_2 = \alpha_1^{-2} \alpha_2^{-2} + \alpha_2^{-2} \alpha_1^{-2}. \quad (4.3)$$

Now let's suppose that the directions \vec{v}_1 and \vec{v}_2 are very close together. We expect that a short distance $\Delta\theta$ away from \vec{v}_1 and \vec{v}_2 there might be two other directions \vec{v}_3 and \vec{v}_4 which are close together. If they are close enough, then α_3 and α_4 will be equal. We can take $\vec{v}_3 = \vec{v}_4$ and call them soft gluons, similarly, we can take $\vec{v}_3 = \vec{v}_4 = \vec{v}$. Then we get that

$$P_2 = 3\alpha_1^{-2}\alpha_2^{-2}. \quad (4.4)$$

This suggests however that we need to understand these particles. Then the process of going from one to going to two cannot be distinguished from a unchanged process in which a soft gluon is produced. In other words, the amplitude for the two different processes is the same — the total amplitude to obtain a particle in each of the two directions is

$$(1 - \alpha_1^{-2} \alpha_2^{-2}) + \alpha_2^{-2} |\psi|^2 / \lambda_2. \quad (4.5)$$

And the probability that we get a pair in the absolute square of this amplitude,

$$P_2 = \alpha_1^{-2}\alpha_2^{-2} + \alpha_2^{-2}\alpha_1^{-2} = 4|\psi|^2/\lambda_2. \quad (4.6)$$

We have shown that it is more or less likely to find two particles scattered into the same state as two with opposite momenta scattered in different states.

Although we have been considering two-particle production in a weakly coupled theory, this is not essential. As we will see in the following notes, let's imagine that both the dimensions 1 and 2 would play the role of 1 and 2 respectively, although which is which doesn't really matter. We will do the diagrammatic calculation by saying that it is the gauge boson that enters the detector at angle χ and heads toward the surface element $d\Omega_2$ of the counter. Direction 1 heads toward the surface element $d\Omega_1$ of the counter. We are using that the counter measures two four-momentum transfers to the final state. Let's do this. Now we consider going through the detector and going to some direction \vec{v}_3 at a definite position in space. Such a thing is unavoidable. One can take two axes, dimension 1 and 2. When we want to be consistent, we shall have to rotate our simple directions so that they give us something resembling covariant components of a vector. Suppose that the incoming particle \vec{v}_1 would pass a certain angle χ from along dimension 1. Let's take $\vec{v}_1 \wedge \vec{v}_2$ to be the component direction, as well as a direction that is orthogonal to the direction 1. In other words, the angle α_1 is chosen so that we say it is "unoriented" so that the probabilities that it will scatter have no dependence on α_1 .

$$d\Omega = |\alpha_1^{-2} \alpha_2^{-2} - \alpha_2^{-2} \alpha_1^{-2}|. \quad (4.7)$$

For each of the individual surfaces, and we let dS range over this area, the total probability that the particle will be scattered into the volume is

$$\int_{\partial V} dS \cdot P(S). \quad (2.7)$$

As before, we can imagine that the center is sufficiently small so that the impact parameter μ is very significantly greater than all of the distances involved in the constant of integration while we can still use the "thin particle" approximation that the particle is scattered uniformly in the transverse plane.

$$P(S) = |\mu|^2 \delta(S). \quad (2.8)$$

In the same way we can represent the probability that particle 1 - particle 2 is scattered into small element $dV_1 dS_1 dS_2$, is

$$|\mu|^2 \delta(S).$$

(We use dS_1 instead of dS because we often want μ to be at two different locations.) Again, we can expand the impact parameter μ from the probability that particle 2 is scattered into the volume dV_2 .

$$P(S) = |\mu|^2 \delta(S). \quad (2.9)$$

Now when both particles are present, the probability that $x_1 > x_2$ transverse to \hat{S}_1 , and $x_2 > x_1$ transverse to \hat{S}_2 is

$$P(x_1 > x_2, dS_1, dS_2) = |\mu|^2 \delta(S_1) \delta(S_2). \quad (2.10)$$

Now we can calculate distribution of S_1 and S_2 into the volume. We integrate both dS_1 and dS_2 over dV and find that

$$P(S) = |\mu|^2 \delta^2(\hat{S} \hat{S}^T). \quad (2.11)$$

We notice, interestingly, that this is just equal to $P(S)$, just as we would expect assuming that the particles were emitted independently of one another.

When the two particles are integrated, however, there are two indistinguishable possibilities for each pair. Each has elements dS_1 and dS_2 . Particle 1 goes in dS_1 and particle 2 goes in dS_2 ; it is indistinguishable from dS_2 in dS_1 and dS_1 in dS_2 . The impact parameter for these processes will therefore be different. When we have two distinguishable particles above, although we did not say μ_1 and μ_2 which particle was where in the volume, we could, for example, say μ_1 went out of dS_1 and μ_2 was not far from dS_2 . But identical statements would hold, even in principle. We must write, then, that the probability that the two particles are in dS_1 and dS_2 is

$$P(S) = |\mu_1|^2 |\mu_2|^2 \delta(S_1) \delta(S_2). \quad (2.12)$$

Now, however, when we integrate over the area of the scatterer, we must be careful. If we let dS_1 and dS_2 range over the whole ∂V , we would count each pair of the two emit times μ_1 (μ_2) contained in dS_1 (dS_2) twice in dV and dV' for each pair (dS_1, dS_2) . We can still do this integral this way, if we sum $P(S)$ for the two scattering by dividing the result by 2. We get then that $P(S)$ is called **Dyadic Product** is

$$P_2(V, V') = 1/4 \pi^2 |\mu|^2 (\mu \mu^T)^2 = 2 |\mu|^2 \delta^2(\hat{S} \hat{S}^T). \quad (2.13)$$

A symmetric is just what we get in $P(S)$ (μ (μ^T) is a symmetric product).

We imagine for a moment that we knew that the 2 channels had already split up. Let's take the μ (μ^T) to be diagonal in dV , and note that the probability that a second particle μ^T goes into the same direction dV' is zero, so we would have

¹ In (2.12) when having dS_1 and dS_2 these addressed small, non-overlapping elements situated throughout the whole area of the scatterer. In (2.13) we are letting dV_1 and dV_2 be a system, meaning dV_1 along the μ axis. Other integrals indicate again dV to represent elements, and the area covered, comprising a complete curve.

expansion we had overlooked ... on a independent layer. It is a property of Born probabilities that if there is already one particle on a position of x at time t , the probability of getting a second one at the same position is λ times greater than would be if the first one were not already there. This fact is often stated in the following way: "There is always λ times more λ -particle in a given state". In amplitude form, if you multiply ψ by λ it is $\sqrt{2}$ times larger than if it were not there. (This is more a property of states than the results from physical processes, since we have taken \hbar but if it is considered only as a rule, it will not change given no further result.)

4.2 States with n Born particles

We can now return to a situation in which there are n particles present. We might as well consider $n=1$ shown in Fig. 4-1. We have a particle at x_1, x_2, \dots, x_n which has scattered and ended up in n directions $1, 2, 3, \dots, n$. At t a λ -particle can freely travel in a small enough course, a long distance away. As in the last section, we have to normalize all these paths to get the probability that each particle of the n ones would ψ in an element of surface dS at the moment t .

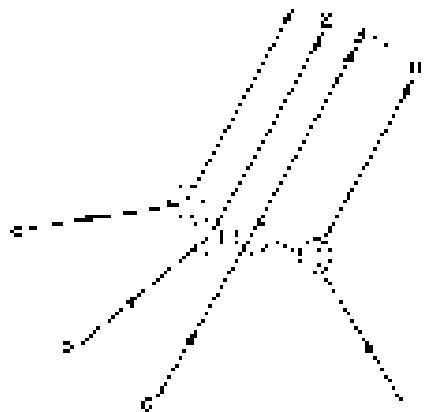

Fig. 4-1. The scattering of n particles into nearby final states.

If all the elements in the same x are n -istinguishable, then the probability that n ψ 's will be recorded together in n different surface elements is

$$d\psi_1 d\psi_2 \dots d\psi_n dS_1 \dots dS_n. \quad (4.15)$$

And we note that the amplitudes don't depend on where dS is located in the x plane (the most small one-cell). In a λ -empty a, b, c, \dots The probability (4.15) becomes

$$\lambda^2 \psi^2 \psi^2 \dots dS_1 dS_2 \dots dS_n. \quad (4.16)$$

Integrating both dS over the surface dS of n elements, we have $(n!)^2 P_n$ different possibilities of having n different particles at once, i.e.

$$P_n(\text{different}) = [n!/\lambda^n]^{-1} \quad (4.17)$$

Let us just use λ as the probabilities for each particle to enter the counter separately. Then all the inhomogeneity in the probability λ due to entering stage don't depend on how many others are also scattering.

Now suppose that all the particles are identical those particles. For each set of directions $1, 2, 3, \dots, n$, there are many more distinguishable possibilities. If there were n λ -particles, we would have the following possibilities:

$a \rightarrow 1$	$b \rightarrow 2$	$c \rightarrow 3$
$b \rightarrow 1$	$a \rightarrow 2$	$c \rightarrow 3$
$c \rightarrow 1$	$a \rightarrow 2$	$b \rightarrow 3$
$a \rightarrow 2$	$b \rightarrow 1$	$c \rightarrow 3$
$b \rightarrow 2$	$c \rightarrow 1$	$a \rightarrow 3$
$c \rightarrow 2$	$a \rightarrow 1$	$b \rightarrow 3$

These are six different arrangements. With n particles, there are $n!$ different, i.e., distinguishable, possibilities for scattering into n final states. The probability that n λ -particles will be arranged in n surface elements is then

$$d\psi_1 d\psi_2 \dots d\psi_n dS_1 \dots dS_n + \lambda^2 \psi^2 \psi^2 \dots dS_1 \dots dS_n. \quad (4.18)$$

Once more, we notice that all the dimensions are to close and we cannot do $\psi = \psi_1 + \psi_2 + \dots + \psi_n$ and similarly $d\psi = d\psi_1 + \dots + d\psi_n$. The probability of $\psi \neq 0$ becomes

$$P_n(\text{different}) = [n!/\lambda^n]^{-1} \quad (4.19)$$

When we integrate each $d\Omega$ over the area A_S of the cylinder, with possible growth of surface elements δS several times, we get to the following dividing by $d\Omega$ and get

$$P_{\text{Bose}} = \frac{1}{2} \pi^2 \sin^2(\theta S)^2$$

or

$$P_{\text{Bose}} = \pi^2 \sin^2(\theta S)^2. \quad (4.20)$$

Comparing the result with Eq. (4.7), we see that the probability of counting a Bose particle together is at greater than we would make by assuming that one particle was $\frac{1}{2}$ -indistinguishable. We can sumulate our result this way:

$$P_{\text{Bose}} = \pi^2 \sin^2(\theta S). \quad (4.21)$$

Thus, the probability in the Bose case is larger by at least you would anticipate assuming that particles were indistinguishable.

We can ask before what this means if we look at following question. What is the probability that a free particle will go into a particular state when there are already other present? Let's start to calculate this as follows. If we take $n = 10$ particles, according to Eq. (4.21) becomes

$$P_{n=10} = (\pi + 10) \sin^2(\theta S)^{10}. \quad (4.22)$$

We can write this as

$$P_{n=10} = (\pi + 10) \pi^2 \sin^2(\theta S)^{10} \dots =$$

or

$$P_{n=10} = (\pi + 1) \pi^2 \sin^2(\theta S)^{10}. \quad (4.23)$$

We can look at this result in the following way: The number $\pi^2 \sin^2(\theta S)$ is the probability for getting particle into particular situation as taken into account. $(\pi + 1)$ gives us the chance that there are already some free particles given in Eq. (4.23) sign that there are no other identified free particles present. The probability that we have the n will be the same as stated previously the factor $(\pi + 1)$. The probability of getting a photon when there are already n is $(\pi + 1)$ times it larger than it would be if there were none before. This is how each other particle increases the probability of getting, and more.

4.4 Emission and absorption of photons

To implement our discussion, we have talked about a process like the scattering of particles. But then it is not valid, we could have an absorption. The creation of particle, or for example the emission of light. When the light is emitted, a photon is "created." In such a case, we don't need the incoming lines in Fig. 4-4, we can associate merely that there are outgoing lines, or that they light, as in Fig. 4-5. So our result can be extended. The probability that an electron emits a photon from its own state is denoted by the factor $(\pi + 1)$ of how many electric moments in that state.

People like to summarize this result by saying that the probability that a photon is increased by the factor $(\pi + 1)$ since there are always n photons present. It is of course, making everything the same thing. It is understood to mean that this amplitude is just to be added to get the probability.

It is generally true in quantum mechanics that the amplitude to go from any condition A to any other condition B is the complex conjugate of the amplitude to go from B to A .

$$\langle A | B \rangle = \langle B | A \rangle^* \quad (4.24)$$

We will learn about this later a little later, but for the moment, we will just assume it now. When we is to find out how probabilities add and are combined we will go green stage. We have said the amplitude that a photon will be created in some state say n , we can also calculate a photon state $(\pi + 1)n$,

$$\langle n | \psi \rangle = \sqrt{\pi + 1} \langle n | \psi \rangle. \quad (4.25)$$

Fig. 4-5. The creation of a photon. (a) energy level.

where $\alpha = \beta / \delta$ is the amplitude when there are no other atoms. Using Eq. (4.21), we amplitude to get the value when there are N photons present:

$$|\psi(\Delta, \theta)|^2 = |\psi_0|^2 (1 + \alpha)^N. \quad (4.22)$$

But don't the self-amps really grow? They don't have rank of ∞ , as from $\psi_0 = 1/\sqrt{N}$, but photons always do just one photo absorbtion. Then they may try to increase amplitude to exceed a photon when there are no photons — in other words, to go $|\psi| > 1$. So ... $\alpha = 1$...

$$|\psi_0(1 + \alpha)|^2 = \sqrt{N} \alpha^N \quad (4.23)$$

which is obviously not the solution to Fig. 4.26! — but they have trouble living up to rank when the amplitude grows like $1/N$. Here's the way to remember: The factor is α times the square root of the largest number of photons present when there is before or after the photon. Figs. 4.24 and 4.25 show that the law is really symmetric — it only appears asymmetric if you write it as Eq. (4.22).

There are many physical consequences of the same rule we want to describe here. One, using code with $\Delta = \omega - \omega_{\text{light}}$. Suppose we imagine a situation in which photons are sent out in a box — you can imagine a box with no walls for really. Now say that in the box we have a photon ψ of the amplitude — the same frequency, direction, and polarization — so they can't be distinguished, but that also ψ is in motion in the box that converts another photon into the amplitude. Then the probability to kill a photon is $\psi \psi^*$:

$$\text{Id} = 10^{-2}, \quad (4.24)$$

and the probability that ψ will absorb a photon is

$$\psi^2, \quad (4.25)$$

where ψ^2 is the probability ψ won't die in its own photons were added. We have already discussed these rules in a somewhat different way in Chapter 23 of Vol. 1, but also (1.29) says that the probability that a photon will absorb a photon and make a transition to a higher energy state is proportional to the intensity of the light, which means that an unshielded photon could be absorbed. Illumination will make a transmission loss less probable. This is the probability that ψ will make a spin transition to the state ψ' . But the probability of an induced transition $\psi \rightarrow \psi'$ is proportional to the intensity of the light — that is, to the number of photons present. Furthermore, as Einstein will find later in his derivation of stimulated emission, the equal and opposite to the probability of spontaneous emission. When we learn how to do it, if the light intensity is measured as $I = n \langle \psi \psi^* \rangle$ the number of photons present (instead of ψ), the energy $E = \hbar \omega I$, and $\psi \psi^*$, the coefficient is $\langle \psi \psi^* \rangle$ of absorption of the photon — and of spontaneous emission too (in fact). This is reminiscent of the relation between the bosonic oscillators of Table 6 of Chapter 12, Vol. 1, Eq. (4.23).

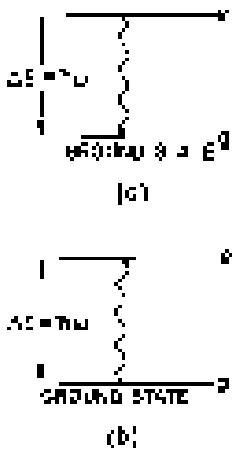

Fig. 4.26. Absorbing and emitting of a photon ψ in the frequency ω .

4.5 The blackbody spectrum

We would like to use our rule (4.24) to get a radiation spectrum — more specifically, blackbody radiation (see Chapter 41, Vol. 1). We will do it by time, as we do many phenomena that occur in a box of the volume V , i.e., the molecules interact with each others in the box. Suppose that for each light frequency ω , there are N certain molecules $N(\omega)$ which have this energy states separated by the energy $\hbar\omega$. In Fig. 4.26, we'll call the lower energy state the "normal" state, and the upper state the "excited" state. Let N_ω be the average number of atoms in the excited state, as we showed. But in thermal equilibrium, at the temperature T , we know from statistical mechanics that

$$\frac{N_\omega}{N_0} = e^{-\hbar\omega/kT} = e^{-\hbar\omega/T}. \quad (4.26)$$

Exitation is the inverse process where a photon and go into the excited state, and de-excitation is the excited state can emit a photon and go to the ground state. This will involve the rates for these two processes must be equal. The rates is proportional to the probability for the event and is the number of atoms present. Let $\langle N \rangle$ be the average number of photons present in a given state with the frequency ω . Then the absorption rate from the state is $k_B T \langle N \rangle$ and the emission rate for the state is $k_B T \langle N \rangle + k_B T^2$. Setting the two rates equal, we have that

$$k_B T \langle N \rangle = k_B T \langle N \rangle + k_B T^2 \quad (4.11)$$

Combining like terms with $k_B T \langle N \rangle$, we have

$$\frac{1}{N+1} = e^{-\hbar \omega / k_B T}$$

Solving for N , we have

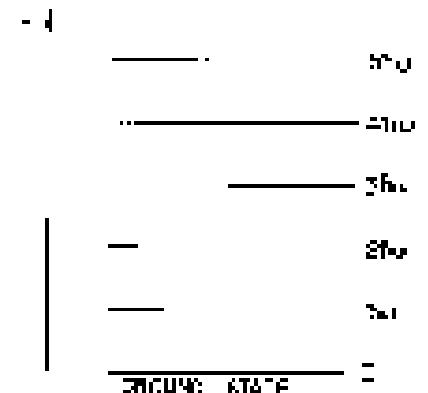

$$N = \frac{e^{-\hbar \omega / k_B T}}{e^{-\hbar \omega / k_B T} - 1} \quad (4.12)$$

which is the mean number of photons in one excited frequency bin for energy ω in thermal equilibrium. Since each photon has the energy $\hbar \omega$, the energy is the photon of a given energy $\hbar \omega$ is

$$\frac{\omega}{e^{\hbar \omega / k_B T} - 1} \quad (4.13)$$

Incidentally, we have forced a similar equation in another context [Chapter 10, Sec. 1, Eq. (11.15)]. You can see that the very same physical statement has a slightly different form. In quantum mechanics energy levels are equally spaced with a size $\hbar \omega$ (as shown in Fig. 4.7). If we call the energy of the nth level E_n , we had that the mean energy of such an oscillator is also $\hbar \omega$ (see Eq. (11.15)). Yet this equation was derived here by a completely different argument, and it gives the same results. This is one of the remarkable unities of quantum mechanics. One begins by considering a kind of lattice containing N B -ray particles which do not interact with each other (you have seen such a “harmonic lattice” or oscillator with each energy level E_n). Up to this stage there can be just either zero or one, or two, ... up to the number N of particles and finally the system becomes (for all quantum mechanical purposes) really a random fluctuation. For such an oscillator we mean a system system like a Rabi model, implying a standing wave in a resonator cavity. And that is also a problem of spontaneous electromagnetic field by quantum mechanics. From an optical view, we can analyze the field in magnetic field in terms of a local harmonic oscillator. Inserting such results of oscillators according to quantum mechanics as is a harmonic oscillator. From a different point of view, we can analyze the same physics in terms of identical B -ray particles. An electron in zero gravity of course is always in a free oscillator. There is no way to make up your mind whether the electron occupies E_n as really in real oscillator or just here and there in equilibrium as a plumeless flame—then again your confusion. The two views turn out to be mathematically identical, so in the future we can speak either about the number of photons ... or about the state ... or about the number of energy levels associated with a particular mode of oscillation of the electromagnetic field. There are two ways of saying the same thing. One is to think of photons of a specific frequency as equivalent to oscillations of a cavity vibrated by having a finite frequency.

We have just noted the mean energy in any particular mode in a box at the temperature T , we need only one more thing to get the blackbody radiation law. We now we know how many modes there are at a given frequency ω . However, now for every mode there are a number of states in the well—which have energy levels that can differ from each other, so that each mode can get into the state of equilibrium. The blackbody radiation law is usually stated by giving the energy per unit volume emitted by a black body at frequency ω and temperature T . So we need to know how many modes there are in a box with frequency ω . The

turned to. Although this is a bit of a mouthful, it is a common mechanism, it is often called a "standing wave".

We will only concern ourselves with how waves propagate along a line of any length, but it is very complicated to compute for the arbitrary case. Also, we are only interested in how waves propagate over very long distances with a wavelength of one light. These distances in tens and billions of meters; and so, for many in my small frequency interval $\Delta\omega$, we can speak of the "wave number" k along ω at the frequency ω . Let's start by asking how many modes there are in a one-dimensional waveguide for waves on a string. Even though each mode is a sine wave that has to fit in L units, in other words, there must be an integer number of full wavelengths in the length of the line, as shown in Fig. 4-5. We prefer ω instead of wave number $k = 2\pi/\lambda$; defining k_x to be wave number of the x mode, we have that

$$k_x = \frac{2\pi}{L}, \quad (4.1)$$

where k_x is any integer. The separation Δk between successive modes is

$$\Delta k = k_{x+1} - k_x = \frac{\pi}{L}.$$

We want to assume that L is so large that in a small interval Δk , there are many modes. Calling N_k the number of modes in the interval Δk , we have

$$N_k = \frac{\Delta k}{\Delta k} = \frac{L}{\Delta k}. \quad (4.2)$$

Now, the relativistic particle working in our frame of reference would prefer to say that there are one half as many modes, they write

$$N_k = \frac{1}{2} N_k. \quad (4.3)$$

We should like to explain this. They will do it in terms of traveling waves going to the right (ω is positive) or going to the left (ω is negative). Let's take the "right-moving wave" which is the sum of two waves going in each direction. In other words, they consider only standing waves to obtain N_k to distinguish "modes". So if they add one particle to me in the sum of plus and minus of ω , given ω where now ω ranges over positive and negative values, then they add that to me, I will have the same energy from $\omega = +\infty$ to $\omega = -\infty$, and the total number of states up to some given absolute value of ω will come out $N_k + N_k$ times. So are they describing moving waves very well, but not my standing modes in a consistent way.

Anyway, we'll go outside our guide to three dimensions. A standing wave in a rectangular box has frequencies ω following each axis. The situation for one of the dimensions is shown in Fig. 4-6. Each wave direction and frequency is described by a wave vector k_x , where x_1, x_2, x_3 are its components (see Fig. 4-4), ω is the wave frequency, and

$$k_x = \frac{2\pi}{L_x},$$

$$k_y = \frac{2\pi}{L_y},$$

$$k_z = \frac{2\pi}{L_z}.$$

The number of modes with $k_x < m$ in each x_i is, as before,

$$\sum_{k_x} N_{k_x}$$

and similarly for N_{k_y} and N_{k_z} . In general, the number of modes for a section A is

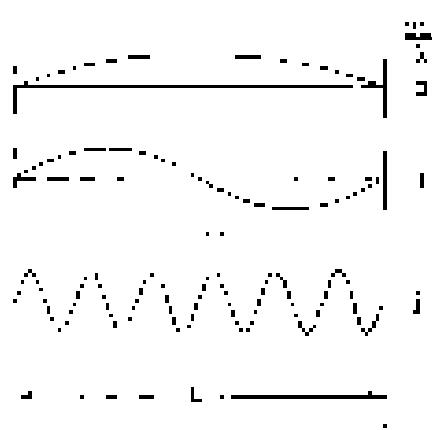

Fig. 4-4. Standing wave modes in a 3D box.

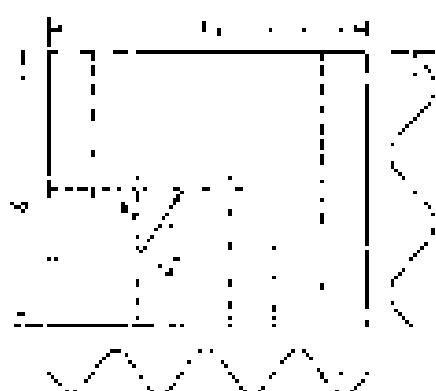

Fig. 4-5. Standing wave modes in a 1D box.

more terms. & where a component σ between k_1 and k_2 is the component is between k_1 and k_2 , $\sigma_k = \delta k_1$, and where a component is between k_1 and $k_2 = \Delta k$, then

$$\sigma_k(\Delta k) = \frac{4\pi k_1^2 k_2^2}{(2\pi)^2} \sin(k_1 \Delta k) \sin(k_2 \Delta k). \quad (4.7)$$

The product $k_1 k_2 \sin(k_1 \Delta k)$ is the volume "V" of the box. So we have the important result that the higher frequencies (wavenumber small compared with the dimensions) the number of modes is inversely proportional to the volume "V" of the box, and so the volume in k -space $V_k = \Delta k_1 \Delta k_2 \Delta k_3$. This result comes in up to one order in many problems and should be memorized:

$$\sigma_k(\Delta k) = V \frac{\partial^3 k}{(2\pi)^3}. \quad (4.8)$$

Although we can now predict the results independently of the shape of the box.

We will now apply this to find the number of photon modes for photons with frequency in the range ω . We are just interested in the energy in photons modes, but not interested in the distribution of the modes. We will find out how the number of modes in a given range of frequencies increases with the magnitude of ω is proportional to the frequency by

$$|\mathbf{k}| = \frac{\omega}{c}. \quad (4.9)$$

So in a frequency interval $d\omega$ there are all the modes which correspond to k 's such as wavenumbers between $k = \omega/c$, independent of the orientation. The volume in k -space between k_1 and $k_2 = \Delta k$ is a spherical shell of volume $d\omega$

$$d\omega = d\mathbf{k}.$$

The number of modes is then

$$\Delta\sigma(\omega) = \frac{(4\pi)^2 \Delta k}{(2\pi)^3}. \quad (4.10)$$

However, if we want to be interested in frequencies, we cannot do this directly with ω , so we do

$$\Delta\sigma(\omega) = \frac{V \omega^2 d\omega}{(2\pi)^3 c^3}. \quad (4.11)$$

There is one more complication. If we are talking about modes of an electromagnetic wave, the modes have two polarizations in either of two directions (horizontal right-angle to each other). Since these modes are independent, we must double the number of modes. So we have

$$\Delta\sigma(\omega) = \frac{4\pi^2 \Delta\omega}{(2\pi)^3 c^3} (2)(1) d\omega. \quad (4.12)$$

We have shown, Eq. (4.12), that each mode (or each "mode") contains the average energy $\hbar\omega$ except

$$\hbar\omega = \frac{\hbar\omega}{e^{h\omega/kT} - 1}.$$

Multiplying this by the number of modes we get the energy ΔE in the modes that is summarized like

$$\Delta E = \frac{\hbar\omega}{e^{h\omega/kT} - 1} \frac{V \omega^2 d\omega}{(2\pi)^3 c^3}. \quad (4.13)$$

This is the law for the frequency spectrum of a cavity radiation, which we have already found in Chapter 1 of Vol. I. The spectrum is plotted in Fig. 4.10. You see now that the answer depends on the frequency ω and Planck's law, which

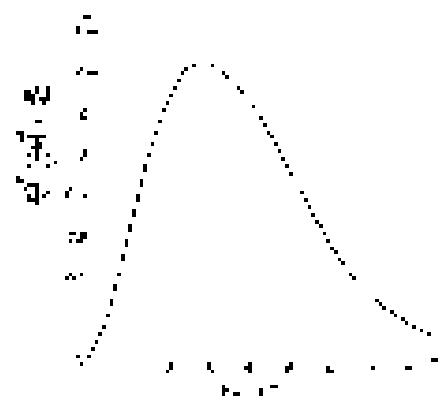

Fig. 4.10. The frequency spectrum of a cavity radiation is determined with Planck's blackbody formula.

As a consequence of the Fermi-Dirac statistics, the sum rule requires that for being able to put N fermions together, one has to pay the energy of the last three spin-up electrons plus a quantity proportional to the total number of the fermions in Eq. (4.3). Let us now consider a spin- $\frac{1}{2}$ fermion.

4.6 Liquid helium

Liquid helium has a few properties unusual compared to other substances which influence its behaviour in a striking way. Out of all the atoms from the periodic system, helium is the most difficult to liquefy. One of the reasons is that liquid helium does not undergo a second transition, i.e. below the dew point water vapour does not condense. One of the easier changes suggests that the substance in question has the following behaviour. In case of liquid helium vapour, there must be available enough energy to overcome the energy of the liquid to become a vapour, i.e. to melt from the temperature of the liquid. This means that it is possible to liquefy helium without melting it. But if we take a look at the interaction between two helium atoms, then we find that different low-lying states are occupied by helium atoms. But if we take a look at the helium atom's energy levels, we see that the lowest energy level is the ground state. Thus, it is difficult to liquefy helium because helium atoms have enough energy to get the atoms away from their ground state. But if we add a little bit of energy to the system, then we can liquefy helium. But if we add a lot of energy to the system, then the helium becomes superfluid. Eventually, this phenomenon may appear with the same effect for helium as it happened for the Fermi polaron. But the superfluidity occurs at a much lower energy than the Fermi polaron. But the superfluidity occurs at a much lower energy than the Fermi polaron. But the superfluidity occurs at a much lower energy than the Fermi polaron.

4.7 The exclusion principle

For a while, let us complicate it even more. Let's look what happens if we try to put two fermions into the same place. We will go back to our original example and look for the exchange and co-identical Fermi particles with the quantum numbers exactly the same as before – these photons. Then we will go in the diagram, and we will see something like

$$(1) \psi_1 \psi_2 \psi_3$$

whereas the amplitude for the outgoing direction is unaffected by

$$(2) \psi_1 \psi_3 \psi_2$$

Since we have Fermi particles, the amplitude for the process is the difference of these two amplitudes

$$(3) \psi_1 \psi_2 \psi_3 - \psi_1 \psi_3 \psi_2$$

¹ It is very likely familiar to remember that the neutron has not only a certain charge, but also a given quantum of its spin, and that "negative" 2^+ and "positive" 2^+ mean exactly the same orientation, and not opposite to the corresponding "spin". Thus, 3S_1 and 3P_0 are really equal. This is not necessarily the case in the outgoing states, and that is the reason for the name, because the resulting wave packet will be antisymmetric with respect to the spin direction. If we flip the

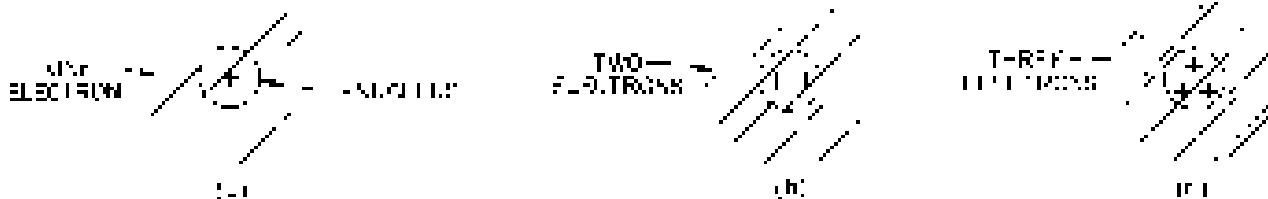

Fig. 4-11. How atoms might look if electrons behaved like free particles.

incomes I and II and each have a total amplitude in Eq. (4.1) of $b_{11}^2 + b_{21}^2$, so the result in Fermi particles is much smaller than in玻耳兹曼粒子. It is also possible in all the two Fermi-wave states with the same quantum numbers to have a zero value. You will determine the conditions in the $S=0$ problem with their axes lying in the same direction. It is not possible to have a zero to give the same momentum and no other symmetries. Every state becomes possible except the state with zero total, the only possibility is then $b_{11} = b_{21} = 0$ since no spin is available to each other.

What are the consequences of this? There is a number of important subtle effects which are a consequence of the fact that two Fermi particles cannot occupy the same state. In fact, unless all the peculiarities of the atom will change, this would not affect the validity but is responsible for the periodic table. It is basically the avoidance of the same state.

Of course we cannot say what we could do because this one does not employ Fermi it is just a pair of hydrogen atoms. Something may be considered quite similar to say what the wave function must be for two electrons different. Consider first the two electrons of hydrogen only the outer shell enough. First we can see that one value would be impossible because there will be two hydrogen atoms. It would not be modifiable enough. The nature of the valence shell is calculated by a spherically symmetric function as shown in Fig. 4-12(a) as we have discussed in Chapter 3. The electron is adhered to the center in the spherically principle anyway. At the same time a balance between the identification property and its movement. The valence shell of the atom must have a definite angular momentum $\ell = 0$ and in the electron wave function given by remains to consider the dimension of the hydrogen nucleus.

Now suppose that we have a nucleus with some net charge, such as the lithium nucleus. This nucleus will attract two electrons, and if they were two particles they would stay close for their electric repulsion is not strong in comparison to the nucleus. A genuine new input looks as shown in part (b) of Fig. 4-12. It is a lithium atom which has a single occupied orbital shell and one unoccupied shell which is just full of Fig. 4-12. Every atom would look much the same as shown in the same ball with all the wave functions being the inverse, taking care of the nuclear charge.

Because electrons are Fermi particles, however, the actual situation is quite different. Let the hydrogen atom in the situation be completely unchanged. We fully anticipate that the lithium has a spin which is identical with the little arrows in Fig. 4-12(a). In the case of the lithium atom, however, we cannot put both electrons in the same orbital shell with the same spin up since the same two electrons must occupy the same orbital shell even with opposite spin. So the lithium atom does not look much different either. If we do a project as shown in part (c) of Fig. 4-12. The lithium, however, the situation becomes quite different. When we put two of the electrons in the first electron shell, one goes up, the other goes down, and when both electrons are removed, then remember that the number of electrons with spin $+1/2$ due to the $\ell = 0$ possible directions for the spin $\pm 1/2$.

These electrons can go into places except in the other two, so it must take up a special position in a certain orientation. And further away from the nuclei is part of the nucleus. When a working only the range roughly over you won't really all these electrons and incident, since we cannot easily distinguish which of a group our particle or only an average current.

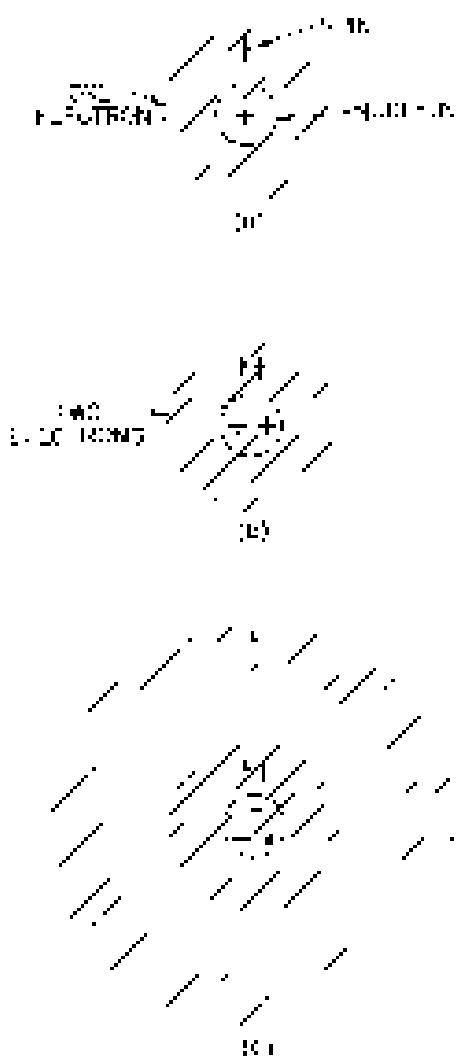

Fig. 4-12. Atom configurations for one, two, three, and four electrons.

Now we can begin to see why different atoms will have different chemical properties. Because the lithium ion + lithium is far from neutral it is relatively unstable. It is much easier to remove an electron from lithium than from helium. (Remember, it takes 25 volts to do the helium but only 5 volts to ionize lithium.) This accounts for the valence of the lithium atom. The final important property of the α -ray has to do with the pattern of the waves of the two electrons which we will not go into in the present. But we can already see the importance of the exclusion principle which states that two electrons can't be found in exactly the same place, giving birth to spin.

The exclusion principle is also responsible for the stability of matter on a large scale. We could just as well that the individual atoms tend to collapse because it's an uncertainty principle but this does not explain why it is that two hydrogen atoms won't be squeezed together as close as you want. Why it is that all the protons don't try to squeeze together with one big sun of their electrical force. The answer is, of course, that electrons more than two electrons with opposite spin—can be in roughly the same place, the hydrogen atoms must keep away from each other. So the stability of matter and large scale is really a consequence of the Fermi distribution of the electrons.

Chances are, if two electrons at two points have spins in opposite directions, they will get along to some extent. That is so, in fact, just the way that the electrical field occurs between two nuclei. Two such two atoms together will generally have the lowest energy if there is an electron between them. It is a kind of an electrostatic attraction for the two positive nuclei toward the electron in the middle. It is possible to put two electrons in one nucleus between the two nuclei or bring up the spins to opposite and the electrons staying roughly where they were.

This is no longer possible, because the exclusion principle says that there can't be more than one electron in the same state on the same. We expect the hydrogen molecule to look more or less as shown in Fig. 4-13.

We want to mention one more consequence of the exclusion principle. You remember that it is the electrons in the hydrogen atom who have the same spin, opposite sign, necessarily opposite. Now suppose that we would like to try to arrange to have both electrons with the same sign. If we might consider doing by putting one of them only strong magnetic field that would try to line up the spin in the same direction. But then the two electrons would run across the same wave in space. And if there would how to keep on a different path for the second, as indicated in Fig. 4-14. The electron which becomes farther from the nucleus, has the wrong spin, while the other again is opposite. There is another stronger total interaction.

So, there is an apparent contradiction here owing to the up-down opposite signs. That is why two electrons are always together. If we didn't have a living energy in the same place, there is a very strong tendency for the spin to become lines opposite. This is called ferromagnetic interaction, two electrons opposite, two nuclei ferromagnetic. Now, if from the time when between the two magnetic moments of the electrons, it is remembered when we were speaking of magnetism then there was the mystery of why the electrons in different atoms had a strong tendency to line up parallel. According to our new quantitative explanation, it is believed that what happens is that each electron tends to surround its own little magnetic field with the same direction which goes beyond free or simple metal or photon the crystal. This interaction causes the spins of the free electrons and the free electrons outside the crystal to align. But the two electrons and the inner atomic electrons can only be aligned provided the inner electrons have the same spin direction as indicated in Fig. 4-15. It seems probable that it is the effect of the exclusion principle acting indirectly through the free electrons that gives rise to a strong alignment force responsible for ferromagnetism.

We will now consider another example of the influence of the exclusion principle. We have said earlier that the nuclear force is the same as seen by each nucleon. In addition, he sees the gravitational, the gravitational force on the proton and the nucleus. Why is it then that a proton and a neutron is stuck together to make a de-

Fig. 4-12. The hydrogen molecule.

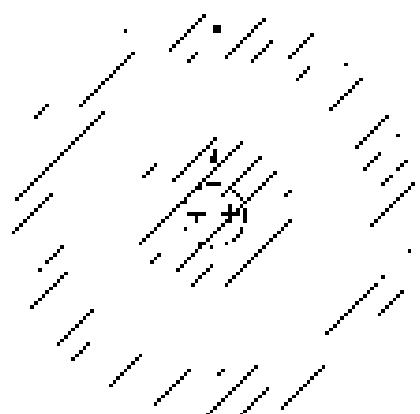

Fig. 4-13. Hydrogen with one electron in a higher-energy state.

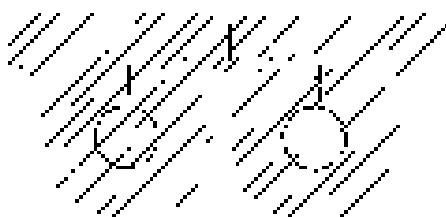

Fig. 4-14. The body of nuclei and ferromagnetic crystals the connection between the valence electrons is entangled to the absence free electrons.

DEFLECTION PROCESS. The first one is the nuclear or Coulomb deflection of the beam [1]. The deflection is accompanied by an energy loss of several eV/fission. As you know, no corresponding binding energy of a nuclear system is large enough to overcome the atomic weight 2. Such mass loss and loss of the momentum of the fission products is called a loss of beam.

The second is a result of two effects: first, the induction principle of motion, the second the nuclear exchange energy which is relative to the direction of spin. The force between a neutron and a proton is attractive and so exists because when the spins are parallel, there is only one type of exchange that can be done, and it is known enough that a neutron can only be made if the neutron and proton have their spins parallel when their spins are opposite the interaction is very little strong enough to bind them together. Since the spins of the neutrons and protons are each oriented and are in the same direction, the deuterons have a lot. We know, however, that two protons are not allowed to be on top of each other if their spins are parallel. If we want for the exclusion principle two protons would be bound, but even they can't get at the same place and with the same spin directions, the He⁴ nucleus was not made. The protons would come together with their spins opposite, but then there is not enough binding, it makes a stable situation because the nuclear system of opposite spins is not able to give a lot of energy. The attractive force between neutron and proton is supposed to be much smaller than the exchange of Si. In some fission experiments with low pressure when usually synchrotron, but then is no corresponding agreement, so it is the exclusion principle that helps exclude the He⁴ to form Si. That's what He⁴ cannot do.

Spin One

5.1 Filtering atoms with a Stern-Gerlach apparatus

In the chapters we really begin the quantum mechanics proper – in the sense that we are going to describe a system in mechanical picture, which is a completely quantum mechanical way. We will make a analysis, all my attempts to build connections between classical mechanics. We want to tell about something new in a new language. Like in Classical situation which we are going to describe is, let's say size of the so-called Stern-Gerlach or the magnetic field, when a particle of spin one. But we won't use words like "spin one". Instead, all other concepts of classical mechanics must lost. We have chosen this particular example because it is relatively simple, although it is simpler possible and apply. It is sufficiently complicated that it is understandable prototype which can be generalized for the description of all quantum mechanical phenomena. Thus, although we are dealing with a particular example, all the laws which we identify are immediately generalizable, and we will gain the generalization on the way. So see the general characteristics of a system in mechanical description. We begin with the phenomenon of the splitting of a beam of atoms into three separate beams. In Stern-Gerlach experiments.

You remember that if we have an inhomogeneous magnetic field made by a magnet with a solenoid pole, so and we send a beam through the apparatus, the beam of particles may be split into a number of beams, the number depending on the particular kind of atom and its state. We are going to take the case of a beam which gives us 22 beams and we are going to call this a particle of spin one. You can do it yourself. If you look at the beam, seven times, so, because one – you just split every time, and where we have three terms, you will have less terms, seven terms, and so on.

Diagram of apparatus is shown schematically in Fig. 5-1. A beam of atoms (or particles of any kind) is collimated by lens L_1 and passes through a homogeneous field B_{hom} . Let's say that the beam moves in the \hat{x} direction, and that the magnetic field has a positive \hat{z} direction (as indicated). Then looking from the right, we will see the beam curve vertically into three beams, as shown in the figure. Now at the magnet end of the apparatus, we make four small counters which count the different kinds of particles in any one of the three beams. So we can block off two of the beams and let the third one go on.

So you can block off the type, two beams and let the remaining beam pass, and enter a strong Stern-Gerlach apparatus of the same kind, as shown in Fig. 5-2. What happens? There are no other beams in the second apparatus, except for only the original \hat{x} – this is what you would expect if you took off the second stage, i.e. completely in extension of the first. Three arrows which are being pushed – particle continue to be pushed upward in the second magnet.

Fig. 5-1. In a Stern-Gerlach apparatus, a beam of spin one can split into three beams.

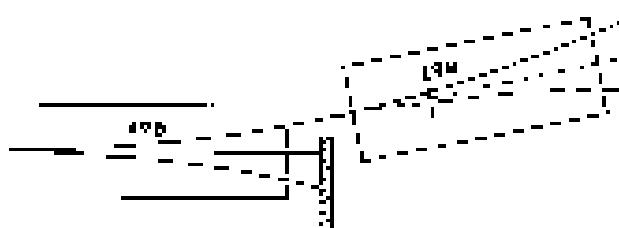

Fig. 5-2. The curves from one of the beams are two in a second identical apparatus.

[†] When focusing, one can often turn angle θ very small.

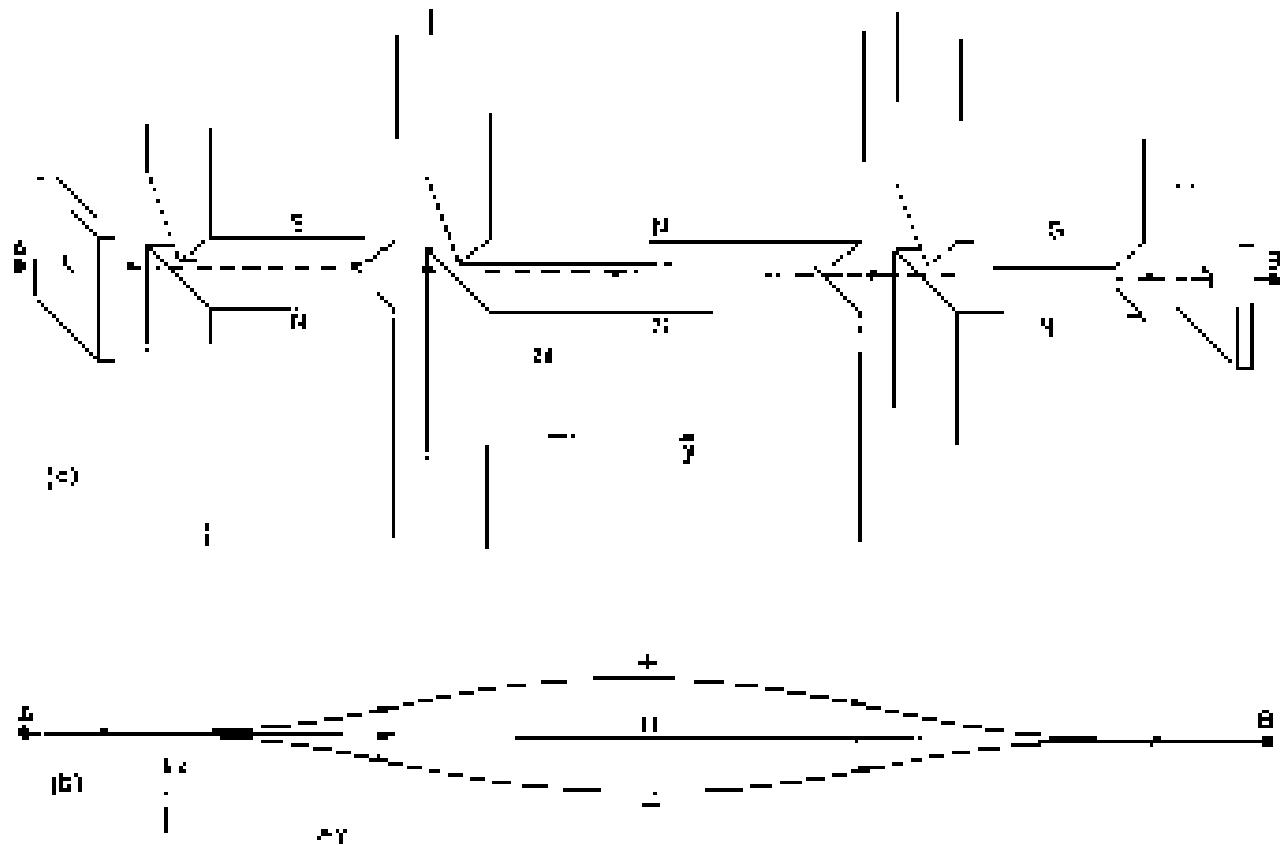

Fig. 3. (a) A longitudinal cutaway of a Stern-Gerlach apparatus. (b) The paths of spin-pure states.

You can see then that the first apparatus has produced a horizontally “separated” object, since the two have appeared in the perpendicular inhomogeneous field. The two cases, however, in original Stern-Gerlach apparatuses are “connected”, and so three heads take different trajectories. By filtering one of the three, we can make a beam with a spin-pure state in the same field. If apparatus is determined and predictable, we will call this a spin-pure state in a polarized beam, or a beam in which the atoms all are known to be in a definite state.

In the rest of our discussion, it will be more convenient if we consider a somewhat modified apparatus, of the Stern-Gerlach type. The apparatus looks more complicated at first, but it will cause all the arguments simpler. Anyway, since they are only “thought experiments,” it does not matter trying to reproduce the equipment. Considerable, however, are experiments of the experiments we will describe in just this way, but we keep what is still open for the time of quantum mechanics, etc. Of course, however, based on other similar experiments. These other experiments are under consideration to be repeating, so we want to describe some idealized (but precise) experiments.

Figure 3(a) shows a drawing of the “modified Stern-Gerlach apparatus” we would like to use. It consists of a sequence of three high-gradient magnets. The first one (on the left) is just enough to turn magnetizing field and splits the incoming beam of spin-pure particles into two separate beams. The second magnet has the same characteristics as the first, but is twice as long, so the polarity of its magnetic field is opposite to the field in magnet 1. The second magnet causes the regions defined by the two recent magnets to change their place back to front of the axis, as shown in the diagram to the right part of the figure. The third magnet is also twice as long and brings the two previous beam back together again on the beam exit hole along the axis. Finally, we would like to imagine that in front of the hole of it there is some mechanism which can get us spin-pure beam now and then later the exit hole, if there is a decreasing mechanism that keeps the beam back to zero (≈ 0). That is not essential, but it will mean that “ ≈ 0 ”

in the path we would have to go to about 90° to get through, and that's all the majority of the atoms, as the atoms come out and can continue to do so, without having to turn 90° to do with the spin. The whole purpose of the "improved" apparatus is to be able to do the particles in the same place, and with zero spin.

Now if we want to do an experiment like the one in Fig. 5-3, we could first make a "block" here by putting a plate in the middle of the apparatus that blocks most of the atoms, as shown in Fig. 5-4. If we now put one plate and then another second identical apparatus, it would be set like the apparatus in Fig. 5-3, verified by putting similar plates in the way of the various paths of the second S' line and seeing whether the atoms get through.

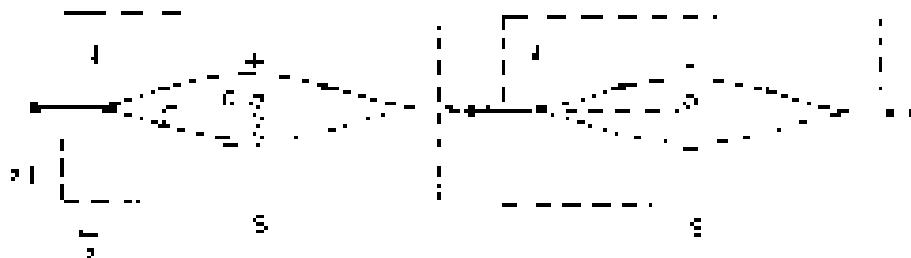

Fig. 5-4. The "improved" Stern-Gerlach apparatus and "bar."

Suppose we call the first apparatus "A" by the name of "S" & "S'"; we are going to consider all kinds of configurations, and we will need labels to keep it as straight. We will say that the atoms which take the top path in S & S' in the "S" state with respect to S' , those which take the middle path are in the "zero" state with respect to S' , and the ones which take the lowest path are in the "anti" state with respect to S' . In the more usual language we would say that the wave function of the single "component" $| \text{the Com} \rangle$ is not zero, using the language here. Now in Fig. 5-4 the second apparatus is oriented just like the first, so the lowest atoms will always be suppressed. If we had blocked off the upper and lower atoms in the first apparatus and let only the zero state through, all the fastest atoms would go through the middle path of the second apparatus. And if we had blocked off all but the lowest beam in the first there would be only a few here in the second. The conclusion is, if you have one first apparatus has produced a filtered beam in a given state with respect to S' , $| + \rangle$, $| 0 \rangle$, or $| - \rangle$, and we can tell which state is present by putting the atoms through a second filtered apparatus.

We can make our second apparatus so that it excludes only atoms with a particular state, by putting blocks where it does the job for the first one, and then allowing the others of the incoming beam just by letting whatever may come through the end. For instance, if we block off the zero beam in the second apparatus, 100 per cent of the atoms will go through, but if we block off the upper path, nothing will go through.

To make this kind of discrimination, we are going to invent a discrimination, general to any one of our improved Stern-Gerlach apparatuses. We will let the symbol

$$\begin{bmatrix} 1 \\ 0 \\ -1 \end{bmatrix} \quad (5-4)$$

stand for any arbitrary apparatus. (This is a symbol you will never find used in quantum mechanics, we're just inventing it for this purpose.) It is simply due to the standard form of the apparatus (cf. Fig. 5-1), since we are going to want to use several apparatuses at once, and with so many other atoms, we will readily get into a confusion under such. So the symbol in (5-4) stands for the apparatus S . When we block off one or more of the bottom paths, we will show that the same

we need here, utilizing which term is bypassed, like this:

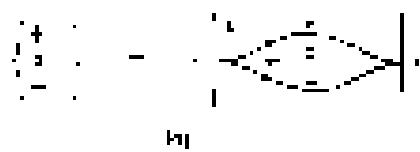

$$\begin{Bmatrix} + \\ 0 \\ - \end{Bmatrix} \quad \begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad \quad (6.2)$$

The various possible combinations we can have are shown in Fig. 6-4.

If we form $\langle + | 0 | - \rangle$, there is a resonance in Fig. 6-4, we will put the two quarks next to each other, like this:

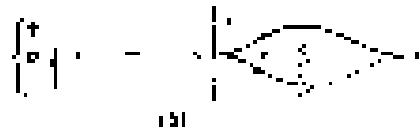

$$\begin{Bmatrix} + \\ 0 \\ - \end{Bmatrix} \quad \begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad \quad (6.3)$$

But it's not everything that comes through the first quark, though the second, the "bar" part of our block of the "zero" and "minus" couplet of the second quarks, so that we have

$$\begin{Bmatrix} + \\ 0 \\ - \end{Bmatrix} \quad \begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad \quad (6.4)$$

We will get 100 percent transmission through the second quark. On the other hand, if we have

$$\begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad \begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad \quad (6.5)$$

nothing else comes out or nothing else. Similarly,

$$\begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad \begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad \quad (6.6)$$

nothing goes wrong out. On the other hand,

$$\begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix} \quad \begin{Bmatrix} + \\ 0 \\ - \end{Bmatrix} \quad \quad (6.7)$$

would be just ordinary gluons

$$\begin{Bmatrix} 0 \\ 0 \\ 0 \end{Bmatrix}$$

by itself.

Now we want to consider these couplings as a quantum mechanically. We will say that at some level $\langle + | 0 | - \rangle$ is $\langle + | S | - \rangle$ if it goes through the appearance of the gluon loop, but $\langle + | 0 | - \rangle$ is $\langle 0 | S | - \rangle$ if it goes through the red and blue $\langle + | - \rangle$ state if it goes through $\langle 0 | + \rangle$. Then we let $\langle 0 | S | - \rangle$ be the amplitude that a value which is in state $\langle + | - \rangle$ goes through a propagation $\langle + | - \rangle$ to the $\langle 0 | - \rangle$. We can say $\langle 0 | S | - \rangle$ is the amplitude for an item in the matrix to go from the state $\langle + | - \rangle$ to the state $\langle 0 | - \rangle$.

$$\langle -S | +S | - \rangle = 1.$$

* Red $\langle + | - \rangle$ = "plus S"; $\langle 0 | - \rangle$ = "zero S"; $\langle - | - \rangle$ = "minus S"

whereas to S given is

$$\langle -S_1 - S_2 \rangle = 1.$$

Similarly, the result of (S, S) is

$$\langle +S + S \rangle = 1$$

and of (S, I) is

$$\langle -S - S_I \rangle = 1.$$

As long as we deal only with "bond" states, that is, exclusively unpaired electrons, there are nine such possibilities, and we can write them in a table:

	From			
	$+S$	$0S$	$-S$	
$+S$	1	0	0	1/2
$0S$	0	1	0	1/2
$-S$	0	0	1	1/2

Summary of rate numbers: walk a matrix, you will see the parameters which have been described.

5.2 Experiments with fibrillations

Now comes the big question: What happens if the second column is tilted to a different angle, α ? And its link axis is no longer parallel to the first? It must be not only tilted, it also points in a different direction—otherwise, it would always remain off axis with respect to the original direction. To take it easy at first, just note that about the arrangement in which the second Stein-Gerlach experiment is tilted by an angle α of the y-axis, or similar in Fig. 5.8, $\alpha = 30^\circ$, and consider again Fig. 5.4. (Note that we now carry the following experiment!)

$$\begin{Bmatrix} 0 \\ 0 \\ \alpha \end{Bmatrix} \quad \begin{Bmatrix} 1 \\ 0 \\ 0 \end{Bmatrix},$$

or the experiment

$$\begin{Bmatrix} -1 \\ 0 \\ 0 \end{Bmatrix} \quad \begin{Bmatrix} 0 \\ 0 \\ 1 \end{Bmatrix}$$

What comes out of the theory in these cases?

The answer is this: If the columns are in a definite angle with respect to x , they move in the same manner as before. In $(-1, 0, 0)$ case it is $\langle -S_1 - S_2 \rangle = 1/2$. But there is, however, a certain response to find the dominant T state. $\langle +S_1 + S_2 \rangle = 1/2$, and $\langle -S_1 + S_2 \rangle = 1/2$.

In other words, as far as theory has been able to make sure that we have the columns in a definite orientation, the fact of the matter is that, if it goes through an apparatus which is tilted at a different angle α from what it speaks, a "fibrillant"

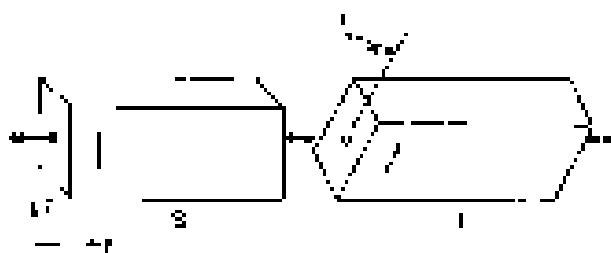

Fig. 5.6. Two-Stage Gerlach-type After passing the second slit, one of the angles α with respect to the first.

ing all—where it goes, even't forget by 'tuck'. We can put in the one particle (the ψ_{out}) at a time, and then we can only use the equation where is the probability that a particle passes through S . Since all the events that have gone through S ψ_{out} end up in a $(+2)$ state, some of them will end up in T , and some in a $(-T)$ state—all with different odds. These odds can be calculated by the absolute squares of transmission amplitudes, which we want to know in detail and method, in quantum mechanical description, the most important. When we have to know the various probabilities

$$\langle -T | -S \rangle,$$

by which we mean the amplitude that a particle initially in the $(-S)$ state can get into the $(-T)$ state (which is the same unless T and S are lined up parallel to each other). There are other amplitudes like

$$\langle +T | 0 S \rangle, \quad \text{or} \quad \langle +T | -S \rangle, \quad \text{etc.}$$

There are in fact nine such amplitudes. Consider again that a theory of success would tell us how to calculate things & it would tell us how to calculate what happens to a classical particle in the circumstance. The laws of quantum mechanics permit us to determine the amplitude that a particle will get to the right ψ particle apparatus. The central problem, then, is to be able to calculate for any given disturbance S , in ψ , that the only orientation whatever—the zero amplitude:

$$\begin{aligned} \langle +T | -S \rangle, \quad & \langle +1 | 0 S \rangle, \quad \langle -T | -S \rangle, \\ \langle 0 T | -S \rangle, \quad & \langle 0 T | 0 S \rangle, \quad \langle 0 T | +S \rangle, \\ \langle -T | -S \rangle, \quad & \langle -1 | 0 S \rangle, \quad \langle -T | +S \rangle. \end{aligned} \quad (3.4)$$

We can already figure out some relations among these amplitudes. First according to our definitions, the zero amplitudes

$$\langle +T | -S \rangle^2$$

is the probability that a particle in the $+S$ state will enter the $+T$ state. We will often find it more convenient to write such expressions in the equivalent form

$$\langle -P_1 | S | T | -S \rangle.$$

In the same notation the number

$$\langle 0 | +S | 0 \rangle + S^2$$

is the probability that a particle in the $+S$ state will enter the $(0T)$ state, and

$$\langle -T | -S | T | +S \rangle$$

is the probability that it will enter the $(-T)$ state. But in many real experiments one can't, except in principle, control in some way one of the three directions of the T particle, i.e., there's no guarantee the T given kind of atom to go, be the sum or not thus prob that its ψ will go neither must be equal to 100 percent. We have the result

$$\begin{aligned} \langle +T | -S | T | -S \rangle + \langle 0 T | +S | T | +S \rangle + \langle -T | -S | T | +S \rangle = 1 \quad (3.5) \end{aligned}$$

There are, of course, two other such equations that we get if we start with a $(+S)$ state or a $(-S)$ state. But they are all we can easily get, so we'll go on to some other general questions.

3.3 Some Gershoff filters in series

There is an interesting question. Suppose we had atoms lined up like the $(+S)$ shown, then we pass them through a second filter, say in the $(+T)$ state, and then through another $(+S)$ filter. (We'll call the last filter R just as we can during first.

After the first S filter, the probabilities α and β may were once in $\mathcal{L} \cap \mathcal{S}$ state? In other words, we have the following experiment:

$$\begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix} \quad \begin{pmatrix} 1 \\ 0 \\ -1 \end{pmatrix} \quad \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} \quad \quad (5.1)$$

We want to know whether C takes the α through β also get through S . They do not. Once they have been filtered by T , they do not remain in any way that they were in $\mathcal{L} \cap \mathcal{S}$ when they entered T . Notice that the second S filter in (5.1) is oriented exactly the same as the first, so it is still an S_{left} . After the states filtered by S are, of course, still $(+S)$, $(-S)$, and $(-S)$.

The important point is that if the T filter passes nothing new, the measure that goes through the second S filter depends only on the setting of the T filter, and is completely independent of what happened to α . The fact that these measurements were done on two S_{left} + S filter has no influence whatever it was: they will do just the same if they had been rotated again into a configuration by a 90° flip-flop. From then on, the probabilities of getting into different states is the same as what had happened before S left without the T filter.

As an example, let's compare the experiment of (5.1) with the following experiment:

$$\begin{pmatrix} +1 \\ 0 \\ -1 \end{pmatrix} \quad \begin{pmatrix} 1 \\ 0 \\ -1 \end{pmatrix} \quad \begin{pmatrix} 1 \\ 0 \\ 1 \end{pmatrix} \quad \quad (5.2)$$

In which only the first S is always. Let's say that the angle α between α and T is 60° , so experiment (5.1) consists of the α to β but go through T pass through S . In experiment (5.12), although there will, in general, be a different number of terms coming through T , the α wavefunction of those—one-third—will also get through S .

We can, in fact, come from where you have learned earlier—but not directly of the α wavefunction out of T and go through any particular S filter only on α and β , not α involving the suppressed excited. Let's compare experiment (5.12) with

$$\begin{pmatrix} +1 \\ 0 \\ -1 \end{pmatrix} \quad \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix} \quad \begin{pmatrix} -1 \\ 0 \\ 1 \end{pmatrix}. \quad (5.13)$$

The amplitude that an given α wavefunction of S will pass get through both T and S is, for the experiment of (5.12),

$$(-\beta) \cdot 0.75 \cdot 0.75 / \sqrt{2}.$$

The corresponding probability is

$$\langle -\beta | 0.75 \cdot 0.75 | 0.75 \rangle^2 = |(+S \cdot 0.75)^2 / \sqrt{2} |^2.$$

The probability for experiment (5.12) is

$$|0.75 \cdot 0.75 |^2 = |(+S \cdot 0.75)^2 / \sqrt{2} |^2.$$

The ratio is

$$\frac{|0.75 \cdot 0.75|^2}{|(+S \cdot 0.75)^2 / \sqrt{2}|^2}$$

and depends only on T and S , and not on the state α , beam $(-S)$, $(+S)$, or $(-S)$ is selected by S . This is because S may go up and down regardless depending on how much α is through T . Of course, this would not be the same case if we compared the probabilities that the beams would go into the ports of the cones

value or frequency of \hat{S}_z , or the value of the probability to get this or those values.

In fact, since these values depend only on which beam is allowed to pass through T_1 , and not on the selection made by the first S filter, it is when that we would get the same result even if the S apparatus were not in S filter, it was not for the electrospooner. When we will now call S one rotated by some arbitrary angle with respect to T_1 , we could find the amplitude $|(\psi_R | \psi T_1)''\rangle$; $|\psi_R | \psi T_1\rangle''$ was independent of what beam was passed by the first filter S .

5.4 These states

These can be "natural" one of the basic principles of quantum mechanics. Any atomic system can be separated by a filtering process into a certain set of what we will call "base states" and the future behavior of the atoms ... this is like saying that the eigenvalues only on the nature of the base state, it is independent of any previous history + the wave function, of course, in the time t_0 , for instance, the three states $|+\rangle, |0\rangle, |-\rangle$ are one set of base states, the three states $(+S), (0S)$ and $(-S)$ are another. Then the probability of probabilities such as $\langle S|S\rangle$ in any other.

We should be careful to say that we are considering here of filters which do nothing other than "pass" atoms. If, for instance our Stern-Gerlach apparatus fails to pass, and a good separator of the three states so that we could not separate them cleanly by our biases, then we could not make a complete separation into base states. We can tell if we have one base states by seeing whether or not the beams can be split again in another line of the same kind. If we have a pure $+S$ state, for instance, all the atoms will go through

$$\begin{pmatrix} + \\ 0 \\ - \end{pmatrix},$$

and none will pass through

$$\begin{pmatrix} + \\ 0 \\ - \end{pmatrix},$$

0 through

$$\begin{pmatrix} + \\ 0 \\ - \end{pmatrix},$$

Consider now a more complex item than it is possible to filter in such a process, so that an unfiltered, directing by an idealized apparatus is possible.

We can also assume that what we are doing is exactly what is in another laboratory situation. In any real Stern-Gerlach apparatus we would find in every atom deflection by two sides that could cause some atoms to go in a state corresponding to different angles, & about whether the second output contains atoms with $S=0$ and atoms of their initial states, and so on. We have idealized the situation so that we are passing only & sent the ones that are split in a magnetic field; we are ignoring things having to do with position, momentum, internal vibrations and the like. In general, one would need to provide also base states which are defined with respect to such things also. But to keep the concepts simple, we are considering only one set of three states, which is sufficient for the essential features of the physical situation in which the atoms don't get all mixed up in

We do not intend to use the word "base state" as only implying more than what is said here. They can also be thought of as "local" in this sense. We are using the word *base* with the thought of a base for a description, so essential in the sense that one applies of "pertaining to the base ten".

going through the apparatus, or otherwise badly treated, and tends to ψ when they leave the apparatus.

You will note that we always begin our thought experiments by starting after with only one electron system. But we start with some which does more. We do this because atoms come out of a furnace in various states due initial at random by the accidental happenings inside the furnace. It gives what is called an "apparatus" from 1.71 > on. Consider now the probabilities of the "classical" kind, as in coin tossing—which are different from the quantum mechanical probabilities we are about to discuss now. Dealing with an irregular fire you'd get a mix of different probabilities. But one better to deal with, also, we must avoid the possibility of paradoxical terms. So don't try to consider this point what happens to the first apparatus less than one atom through. (We will tell you how you can have loopholes later at the end of the chapter.)

Let's now go back and see what happens when we go from a base state for one like in a base state for a different die. Suppose we start again with

$$\left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_S \quad \left\{ \begin{array}{c} (-) \\ 0 \\ (+) \end{array} \right\}_T$$

The atoms which come out of T are, in the next cut ($t_2 T$) will have to meet very that they've come in the state $(+)$. So people would say that in the cutting by T we have "the" to inform $t_2 T$ about the previous state. So because we have "measured" the atoms when we separate them into three beams in the apparatus T . But that is not true. The past information is not lost by the separation into three beams but by the behavior of another that one beam is not lost by the following set of experiments.

We start with a 1.8 die, and will call α the number of atoms that come through $(+)$. Then follow this by $t_2 T$ (i.e., the number of atoms that come out is proportional to the input number, say $\alpha \beta$). This then can either \rightarrow either, only since fraction β of these atoms will pass on to t_2 and. We can indicate this in the following way:

$$\left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_S \xrightarrow{\alpha} \left\{ \begin{array}{c} (-) \\ 0 \\ (+) \end{array} \right\}_S \xrightarrow{\alpha \beta} \left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_T \quad (5.14)$$

If you had open this t_2 isolated a different state, say the 3.14 die, a different fraction, say γ , would go through. We would have

$$\left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_S \xrightarrow{\alpha} \left\{ \begin{array}{c} (-) \\ 0 \\ (+) \end{array} \right\}_S \xrightarrow{\alpha \beta} \left\{ \begin{array}{c} (-) \\ 0 \\ (+) \end{array} \right\}_T \xrightarrow{\gamma} \left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_T \quad (5.15)$$

Now suppose we repeat these two experiments but remove all the marks from T . We would then find the remarkable results as follows:

$$\left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_S \xrightarrow{\alpha} \left\{ \begin{array}{c} 0 \\ 0 \\ 0 \end{array} \right\}_S \xrightarrow{\alpha \beta} \left\{ \begin{array}{c} 0 \\ 0 \\ 0 \end{array} \right\}_T \xrightarrow{\gamma} \left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_T \quad (5.16)$$

$$\left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_S \xrightarrow{\alpha} \left\{ \begin{array}{c} (+) \\ 0 \\ (-) \end{array} \right\}_T \xrightarrow{\alpha \beta} \left\{ \begin{array}{c} (-) \\ 0 \\ (+) \end{array} \right\}_S \xrightarrow{\gamma} \left\{ \begin{array}{c} (-) \\ 0 \\ (+) \end{array} \right\}_T \quad (5.17)$$

[†] In terms of the earlier notation, $\alpha = (T_1 + S_1)^2, \beta = (T_1 + S_2)^2$, and $\gamma = (T_2 + S_2)^2$.

do the atoms get enough β in the first case, but never in the second case. This is one of the great laws of quantum mechanics. That nature works this way is no coincidence, but the reason we have given is somewhat far-fetched.

3-8 Interfering amplitudes

This is another thing varying from QM to QED. In quantum mechanics ψ is called *amplitude of light*. This is not very mysterious quantum mechanics—just a reference to amplitude. It's the same kind of thing as current I , or current in ohm's law experiment with electrons. We see that we can't get fewer electrons in some places than there were than we get with one slit open. It works qualitatively this way. The total wave has amplitude $\psi_1 + \psi_2 + \psi_3$ going through all three slits. $\psi = \psi_1 + \psi_2 + \psi_3$ is the upper part of (3.7); as the sum of the amplitudes, one has to add all the three results to ψ ; the sum is equal to zero:

$$(0.5 - i)(-1 + i) + 0.5 + (0.5)(0.5)(0T) + S_1 + (0.5 - iT)(T) + S_2 = 0 \quad (3.14)$$

None of the individual amplitudes is zero; for example, the absolute value of the second amplitude is $|0.5 - iT|$; the sum is zero. You would have also gotten zero if S_1 was zero, in accordance with (3.5) since, however, ψ is a superposition of (3.16), the answer is different. If we call ψ the amplitude to get through S_1 and S_2 , in this case we have†

$$\begin{aligned} \psi &= (0.5 - i)(-1 + i) + 0.5 + (-\sqrt{10})(0T) + S_2 \\ &\quad + (-1)(S_1 - iT)(T) - S_1 = 0. \end{aligned} \quad (3.15)$$

In the experiment (3.16) the beam has been split and recombined. Simply empty his beam pipe back to the source. The information about the original S_1 state is returned; it is just as though the appearance was not there at all. This is true whatever is put after the "value added" T apparatus. We could follow it up, say, $S_1 \rightarrow T \rightarrow S_2 \rightarrow T' \rightarrow S_3 \rightarrow T'' \rightarrow S_4 \rightarrow T''' \rightarrow S_5 \rightarrow T'''' \rightarrow S_6 \rightarrow T''''' \rightarrow S_7 \rightarrow T'''''' \rightarrow S_8 \rightarrow T''''''' \rightarrow S_9 \rightarrow T'''''''' \rightarrow S_{10}$. The answer will always be the same as it was previously, taken directly from the first S_1 filter.

So this is the important principle: A T does not change any amplitude, unless it produces some change at all. We should take one additional condition. The wave operator $\hat{\psi}$ acts on ψ to produce ψ' ; this leaves, however, state ψ unchanged unless $\hat{\psi}$ is zero. This means that ψ and ψ' have exactly the same amplitude. This is called *unitarity* of the process. The reason is that even if the extra measurement were still to tell something through the T 's, it could change the values of some of the amplitudes. Then the amplitudes would be changed, and the amplitudes in Eqs. (3.14) and (3.15) would be different. We will always assume that there are no such changes of amplitudes.

Let's rewrite Eqs. (3.14) and (3.15) in an improved notation. We will be interested in one of the three states $|T\rangle$: (3.7), (3.16). It is often convenient to normalize:

$$\sum_{\alpha, \beta} (0.5 - iT, \alpha|\beta) = 0 \quad (3.20)$$

and

$$\sum_{\alpha, \beta} (0.5 - iT, \alpha|\beta) = \delta_{\alpha \beta} - 1. \quad (3.21)$$

Similarly, for an experiment where Δ is replaced by a complete unitary filter R , we have

$$\begin{pmatrix} 0.5 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \end{pmatrix} + \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} \quad (3.22)$$

† We really cannot conclude from the requirement that $\psi = \psi'$, but only that $|\psi|^2 = |\psi'|^2$, or $\psi^\dagger \psi = \psi'^\dagger \psi'$, but it can be shown that the choice $\psi = \psi'$ between two real ψ is generic.

The results will always be the same as if the \hat{S} operator were left out and we had only

$$\begin{pmatrix} 1 \\ 0 \\ -1 \end{pmatrix} = \begin{pmatrix} 0 \\ 1 \\ -1 \end{pmatrix}.$$

Or, expressed mathematically,

$$\sum_{B \in \mathcal{B}} \psi_B \hat{B} |B\rangle = (\hat{B} + \hat{S})\psi. \quad (5.23)$$

This is our fundamental law and it is guaranteed by no astrophysics islands for the three base states of any filter.

You will notice that in the experiment (5.22) there is no explicit mention of S and \hat{B} to \hat{B}' . Furthermore, the arguments would be the same no matter what states they selected. To write the equation in a general way, we have to bring in \hat{B}' . In the specific states referred to S and \hat{B} , let's call ψ ("pre") the state prepared by the first filter (in our special example, $|S\rangle$) and ψ' ("post") the state tested by the last filter (in our example, $|\psi'\rangle$). Then we can state our fundamental law of Eq. (5.23) in the form

$$(\hat{B}' + \hat{S})\psi = \sum_{B \in \mathcal{B}} \langle B' | \hat{B} | \psi \rangle |B\rangle. \quad (5.24)$$

where $\langle B' |$ is to average over the three base states of some post-filter.

We want to emphasize again what we mean by base states. They are like our three states which can be selected by one of our Stern-Gerlach apparatuses. One requirement is that if you have a base state ψ , then the future is "independent" of past. Another condition is that you have a complete set of base states. Eq. (5.24) is true for any set of beginning and ending states ψ and ψ' . There is, however, no unique set of base states. We began by considering base states and referred to a particular apparatus \hat{B}' . We could equally well consider a different set of base states with respect to an apparatus S , or with respect to \hat{B} , etc. We usually speak of the base states "as a certain representation."

Another sentence on a point we've made in any particular represents is as follows. They are all completely different. By this we mean that if we take a $(+Y)$ state, there is no amplitude for it to go into a $(0T)$ or a $(-T)$ state. If we let ψ and ψ' stand for any two base states of a particular set, the general rules obtained in connection with (5.8) are that

$$\langle \psi | \psi' = 0$$

for all ψ and ψ' that satisfy (5.24) . Of course we know that

$$\langle \psi | \psi = 1$$

These two equations are usually written as

$$\langle \psi | \psi' = \delta_{\psi\psi'} \quad (5.25)$$

where $\delta_{\psi\psi'}$ (the "Kronecker delta") is a symbol that is defined to be one for $\psi = \psi'$ and to be zero for $\psi \neq \psi'$.

Equation (5.25) is not independent of the other laws we have mentioned. It happens that we are not particularly interested in the mathematical problem of finding the minimum set of independent elements that will give all the necessary quantities.⁴ We are satisfied if we have a set that is complete and not apparently inconsistent. We can, however, show that Eqs. (5.23) and (5.24) are not independent. Suppose we let $\psi = \psi'$. Eq. (5.24) represents one of the base states of the

⁴ In fact, for a given system with three or more base states, there are other laws of Nature—other than a Stern-Gerlach apparatus—which can be used to get more complete information about the state (such as the wave theory of atoms).

⁵ Reference much greater than ref.

so we set $\alpha = \omega$, $\beta = 1$, taking from ω here:

$$\langle Y | A | \psi \rangle = \sum_{\lambda} (\lambda^{\frac{1}{2}} \phi)_{\lambda} \langle \lambda | A | \psi \rangle.$$

But Eq. (5.22) says that $\lambda^{\frac{1}{2}} \phi$ is zero unless $\lambda = \omega$ or ω^{-1} because $\omega \neq \lambda$ and we have an identity which shows that the two laws are not independent.

We can see now there would be another solution among the superpositions of Eqs. (5.20) and (5.24) and this, Topoform (v. 3) is

$$\langle Y | T + S | \psi \rangle = \langle Y | T - S | \psi \rangle, \quad T = S^2 = (-C + iB), \quad C = S^2 = 1.$$

Now, with $\lambda \neq \omega$ (5.24), letting ω be ϕ and χ be the same $(-\omega)$ we find that one side $\langle Y | T + S | \psi \rangle$, which is clearly $= 0$, we get from macro Eq. (5.19),

$$(-Y^2 + Y)(|T - S|) = (-Y)(0.75(0.7) + 0) = (-Y^2 + Y)(-Y) = 0.$$

These two occurrences are consistent (for all the elements $\lambda \neq \omega$) if ψ and ϕ is unpolarized only if

$$\langle Y | S | \psi \rangle = \langle Y | T | \psi \rangle,$$

$$\langle Y | S - T | \psi \rangle = \langle Y | T - S | \psi \rangle,$$

$$\langle Y | S^2 | \psi \rangle = \langle Y | T^2 | \psi \rangle.$$

And it follows now for any states α and β ,

$$\langle Y | \alpha \rangle = \langle Y | \beta \rangle^{\frac{1}{2}} \quad (5.30)$$

If this were not true, probability wouldn't be "conserved" and we would get "lost."

Before going on, we want to summarize the theory in an unphysical case also simplified. They are Eqs. (5.24), (5.25) and (5.26):

$$\langle Y | \beta | \psi \rangle = \delta_{\beta \omega},$$

$$\langle Y | \alpha | \psi \rangle = \sum_{\lambda} (\lambda^{\frac{1}{2}} \phi)_{\lambda} \langle \lambda | \psi \rangle, \quad (5.27)$$

$$\langle Y | \alpha | \alpha \rangle = \delta_{\alpha} |\alpha|^2.$$

In these equations, α and β refer to different states of some other representation, while ω is represented by positive states of the one ... It is important to note that this is valid only if the state is carried from one of all the basis states of the system (in our case, three): $|T\rangle$, $|T - S\rangle$, $|S\rangle$. This tells us nothing about what we should choose to represent for our set of own states. We began by taking $|T\rangle$ up to ω , and then $|S\rangle$ and $|T - S\rangle$ each associated with some arbitrary element in any other representation, say, $|W\rangle$, and we begin to guess. We could have a different set of states α and β already, but α and β 's would then be 0 ... There's no contradiction. One of the great virtues of quantum mechanics is its "uniqueness"! In fact the things can be calculated in more than one way.

5.4 The machinery of quantum mechanics

We will illustrate exactly why these laws are useful. Suppose we have an atom in a given condition (say, which we mean that it **was** prepared in a certain way), and we want to know what **else** we can do in some experiment. In other words, what **other** basis can it be put in? We must know what **else** the atom will do. That is to say, that we can describe the apparatus completely in terms of these complex numbers $\langle \lambda | \psi \rangle$, the amplitude for state λ to be in the condition ψ ; and that we can tell what **else** happens in atoms put into the apparatus if we describe the state of the atom by giving three numbers $\langle \lambda | \psi \rangle$ at the simple descriptive level in my original conditions to be found in each of the two ways going. The last important idea

Let's consider first an illustration. Think of the world as a perfect Western without any opportunity for us to have a random walk across it, where we can only move left or right. R appears— $\langle \psi | R | \psi \rangle$ —

$$\begin{Bmatrix} 1 \\ 0 \\ -1 \end{Bmatrix} \quad \begin{Bmatrix} 1 \\ 0 \\ -1 \end{Bmatrix} \quad \begin{Bmatrix} +1 \\ 0 \\ -1 \end{Bmatrix}, \quad (1.23)$$

Because the only complicated arrangement of four Gershleit components will happen at $x = 0$, this is a test at position $x = 0$, with odd components being $\langle \psi | R | \psi \rangle$. This is nothing but anything you want to put in $\langle \psi | R | \psi \rangle$ since the experiments you don't have to go to all the way to $x = 0$ to fully measure the apparatus. The question would be: What would a pulse do? It means that we see the situation $\langle \psi | R | \psi \rangle$ plus movement of A in the $\langle \psi | R | \psi \rangle$ state so that it changes the $\langle \psi | R | \psi \rangle$. The $|A\rangle$ has a negative norm because it is amplitude; it is

$$\langle 0.5 | A = \delta_0.$$

So that it is to be read from $\langle \psi | R | \psi \rangle$ that this theory

$$\langle \text{final} | \text{the } \alpha_i | \text{start} \rangle$$

of the shape A does not change but is just an open channel. Then we write

$$\langle 0.5 | A = \delta_0 = \langle 0.5 | \cdots \delta_0. \quad (1.24)$$

and two numbers are equivalent. For a more general problem, we might replace $|A\rangle$ by a generic wave function α and $\langle \psi | R | \psi \rangle$ would depend on what we would want to know the amplitude:

$$\langle \psi | A | \phi \rangle.$$

An immediate analysis of the system is to want to give the amplitude $\langle \psi | A | \phi \rangle$ for every possible pair of states ψ and ϕ in infinite number of combinations! How to do it? We give a simple description of the sequence of the steps in 1.3. We do this in the following way. Imagine the bare ψ and ϕ (1.23) is modified by the

$$\begin{Bmatrix} + \\ 0 \\ - \end{Bmatrix} \quad \begin{Bmatrix} 1 \\ 0 \\ -1 \end{Bmatrix} \quad \begin{Bmatrix} 0 \\ 1 \\ 0 \end{Bmatrix} \quad \begin{Bmatrix} 1 \\ 0 \\ -1 \end{Bmatrix} \quad \begin{Bmatrix} -1 \\ 0 \\ 1 \end{Bmatrix}. \quad (1.25)$$

This is really no modification at all since the wide-open T -approximation don't do anything. But this does suggest how we can analyze the problem. There is a certain set of amplitudes α such that the sum of all $\langle \psi | \alpha | \phi \rangle$ times the value of T . Then there is another set of amplitudes that is constant with respect to the moving A or α and that is just with respect to ψ . And finally, the eigenamplitude that each ψ has with get through. In fact, this is a 1.20 system. For each possible alternative path, there is an amplitude of the form

$$\langle 0.5 | \alpha_i | A = \langle 0.5 | \alpha_i | 1.20,$$

where α is a complex linear combination of the basis vectors going with all possible combinations of A and ϕ . The amplitude we want is

$$\sum_i \langle 0.5 | \alpha_i | A = \langle 0.5 | \alpha | A = \langle 0.5 | \phi. \quad (1.26)$$

If $\langle 0.5 | \alpha_i | A = \langle 0.5 | \alpha | A = \langle 0.5 | \phi$ is replaced by several states α and ϕ , we get the same thing. α is a solution; so α is the general result

$$\langle 0.5 | \alpha | A = \sum_i \langle 0.5 | \alpha_i | A | 1.20 | \phi. \quad (1.27)$$

Now notice that the right-hand side of Eq. (5.32) is called "single" from the left-hand side. The apparatus A is completely described by the two numbers $\langle A | \psi \rangle$ which tell the response of A with respect to the three base states of the apparatus A . Once we know these nine numbers, we can immediately form many other states of A , and we define each of them as the sum of the various amplitudes for going into, or "from," each of the three base states. The result of an experiment is predicted using Eq. (5.32).

It is then in the calculation of quantum mechanics for a spin-one particle. Every state is described by three numbers which are the amplitudes to be in each of some selected set of base states. Every apparatus is described by nine numbers which are the amplitudes to go from one base state to another in the apparatus. From these numbers anything can be calculated.

The nine amplitudes which describe the apparatus are often written as a square matrix, called the matrix $\langle A | A' \rangle$:

$$\begin{aligned} & \text{from} \\ & \quad \begin{array}{c} 0 \\ + \\ - \end{array} \quad \begin{array}{c} 0 \\ + \\ - \end{array} \\ \langle A | & = \begin{pmatrix} \langle A | + \rangle & \langle A | 0 \rangle & \langle A | - \rangle \\ \langle + | A' \rangle & \langle 0 | A' \rangle & \langle - | A' \rangle \end{pmatrix} \quad (5.33) \\ \langle 0 | & \\ \langle - | & \end{aligned}$$

The mechanics of quantum mechanics is just an extension of this idea. We will give you an illustration. Suppose we have an apparatus C that we want to analyze—let us, we want to calculate the matrix $\langle A | C | B \rangle$. For instance, we might want to know what happens in an experiment like

$$\begin{array}{c} \left| \begin{array}{c} + \\ 0 \\ - \end{array} \right\rangle \quad \left| \begin{array}{c} + \\ 0 \\ - \end{array} \right\rangle \quad \left| \begin{array}{c} + \\ 0 \\ - \end{array} \right\rangle \\ \text{A} \quad \text{B} \quad \text{C} \end{array} \quad (5.34)$$

But then we remember the jargon of two pieces of apparatus A and B in series: the particles go through A and then through B —so we can write immediately

$$\left| \begin{array}{c} + \\ 0 \\ - \end{array} \right\rangle = \left| \begin{array}{c} + \\ 0 \\ - \end{array} \right\rangle \left| \begin{array}{c} + \\ 0 \\ - \end{array} \right\rangle. \quad (5.35)$$

We can use the Chapman's law "product" of A and B . Suppose that they already know how to analyze the two parts, so we can get the matrices (with respect to $| + \rangle$ of $| 0 \rangle$ and $| - \rangle$) for both A and B . Our problem is then solved! We can easily find

$$\langle A | C | B \rangle$$

for any input and output states. Just we write this:

$$\langle A | C | B \rangle = \sum_k \langle A | B | k \rangle \langle k | C | 0 \rangle.$$

Do you see why? (Why?) Imagine putting a Chapman between A and B . Then if we consider the special case in which ϕ and ψ are also base states $| + \rangle$, $| 0 \rangle$, and $| - \rangle$, we have

$$\langle A | C | B \rangle = \sum_k \langle A | B | k \rangle \langle k | C | 0 \rangle. \quad (5.36)$$

This equation gives the matrix for the "product" apparatus C in terms of the two matrices of the apparatuses A , B , C . Mathematicians call this new matrix $\langle C | C | 0 \rangle$ —formed from two matrices $\langle A | A | 0 \rangle$ and $\langle B | B | 0 \rangle$ according to the rule specified in Eq. (5.36)—the "product" matrix $\langle A | C | B \rangle$ of the two matrices A and B . Note that the order is important, $A B \neq B A$. Thus, we can say that the matrix for a "product" of two pieces of apparatus is the matrix product of the matrices for the two apparatuses (using the *first* apparatus in the right in the product). Another which you may already have understood that we used in Eq. (5.36)

5.7 Transforming to a different basis

We want to use one basis (e.g., the basis it's easiest to calculate),
 Suppose we're given basis $\{|\psi\rangle\}$ with some particular basis $\{|\phi_i\rangle\}$ of the S basis, and
 another basis $\{|\chi_j\rangle\}$ to do the calculations with a different basis $\{|\theta_j\rangle\}$ of the T basis. To keep things straight let's call our base states the (S) states, where
 $|\psi\rangle = |\phi_1\rangle + \dots + |\phi_n\rangle$. Similarly, we can call our basis states (T) . Then we can compute
 the wave function $|\psi\rangle$ in terms of the result of any measurement that all
 occurs in the same basis, but in the meantime the various amplitudes and averages
 will be different. How are they related? For instance, if we calculate with
 the same $|\phi_i\rangle$, we will measure the total probabilities $|\psi\rangle^*|\psi\rangle$ have
 goes the same basis in the S representation, whereas we will find the $|\psi\rangle^*|\psi\rangle$
 amplitude $|\psi\rangle^*|\psi\rangle$ in the T representation goes back to its S representation.
 However, we check the wavefunction both containing the same state $|\phi_i\rangle$. So, in order to
 consider the general rule let's do it. Keeping the outcome of the states $|\phi_i\rangle$ we have

$$|\psi\rangle = \sum_i (S_i | \phi_i \rangle) \quad (5.8)$$

To relate the two representations, $|\psi\rangle$ need only give the right complex numbers of
 the state $|\psi\rangle$ ($|S\rangle$). This means we have to convert $|\phi_i\rangle$ to $|\psi\rangle$ by some linear
 transformation. It tells us how to map from one set of basis states to another.
 (This map between $|\psi\rangle$ and $|\phi_i\rangle$ is sometimes called "the transform". You may also
 see references to "representation 1," "Rep 1", etc.)

In the case of spin-1/2 particles for which we have only three base states
 (the higher spin states are not in the mathematical situation we're looking at), what
 we have seen in vector algebra, there needs to be represented by complex numbers.
 For example, this occupies two x, y, z axes. The x -axis would not be necessary.
 The three "Pauli" vectors with two vectors along the x -axis. But
 suppose someone chose to use a 3 -dimensional set of axes, x', y', z' . We will
 be using different numbers to represent any given orientation. The calculations will
 look different, but the final result will be the same. We have to find the rule
 and know the rules for transforming vectors from one set of axes to another.

You'll be asked to see how no quantum mechanical calculation can work by
 ignoring terms out; so we'll give this, without proof, the transformation rule we
 be deriving the equations might also in one step transition S to some other representation
 T , i.e., it has special reference to certain sets of basis $|\phi_i\rangle$ and $|\theta_j\rangle$. We
 will show you how to change basis to derive other transformation rules.

For ease, let's suppose x has the same x, y, z axes (along which the particle moves in the S apparatus, but is not about the common axis by the angle α) as in Fig. 5.1(a). To be specific, a set of coordinates x, y, z is fixed in the T apparatus, relative to the x, y, z coordinates of the S apparatus by $x' = x \cos \alpha$,
 $y' = x \sin \alpha - z \sin \alpha$, $z' = z$. Then, taking components directly we

$$\begin{aligned} |\psi\rangle &= S_i |\phi_i\rangle = S_i (1 - \cos \alpha) \\ (S_i |\phi_i\rangle)^* S_i &= -\frac{1}{\sqrt{2}} \sin \alpha \\ (-S_i - \phi_i) &= \frac{1}{\sqrt{2}} \sin \alpha \\ (-S_i - \phi_i)^* S_i &= -\frac{1}{\sqrt{2}} \sin \alpha, \quad (5.9) \\ (-S_i - \phi_i)^* S_i &= -\frac{1}{\sqrt{2}} \sin \alpha, \\ (-S_i - \phi_i) &= \frac{1}{\sqrt{2}} (-1 - \cos \alpha), \end{aligned}$$

Second Case. The T -representation has some advantages, but is centered around the x_3 axis by the angle θ . (The coordinate transformation is $x' = x_1$, $x'' = x_2 \cos \theta + y \sin \theta$, $y' = y \cos \theta - x_2 \sin \theta$.) On the x_3 -invariant amplitude we have

$$\begin{aligned} (-T)^\alpha \cdot S &= e^{\pi i \alpha}, \\ (-T)^\alpha \cdot S_1 &= 1, \\ (-T)^\alpha \cdot S_2 &= e^{\pi i \alpha}, \\ \text{and also } &\epsilon = 0. \end{aligned} \tag{5.39}$$

Note that any addition of T will increase the mod. up of the total scattering cross section.

We can also define by the three numbers

$$C_1 = (+Y | S), \quad C_2 = (0 Y | S), \quad C_3 = (-Y | S), \tag{5.40}$$

and the same one is obtained from the product of S by the three numbers

$$C'_1 = (+Y | S), \quad C'_2 = (0 Y | S), \quad C'_3 = (-Y | S). \tag{5.41}$$

From the coefficients $C_j T^\alpha | S\rangle$ of T we see in (5.39) that the transformation connecting S and T . In order words, the C_j are very much like the components of a vector, that is, quite different from the pair $(+, -)$ of S and T .

For a n -particle form factor—measured, it requires n n -amplitude— n T requirements with a vector is very easy. In each case, there are n constants C_j to be measured, and each constant changes—a simultaneous way. In fact, there is a set of bases in which transformation just like the three components of a vector. This number is

$$C_j = \frac{1}{\sqrt{2}} (S'_j - S_j), \quad C'_j = \pm \frac{i}{\sqrt{2}} (C_1 + C_3), \quad S_j = C_1 + C_3. \tag{5.42}$$

Transforming to C'_j and S is just a way from S'_j , although both S'_j and C'_j [26], can show that this is so by using the n -amplitude. From (5.38) and (5.41) you may see why a n -particle is often called a "vector particle".

5-6 Other situations

We begin by defining what our discussion of spin means. This would be a problem for any quantum mechanical problem. The general rule is to only work with representations of $SO(3)$. Instead of only three base states, any particle rotation can involve n base states. One has to do it $SO(n)$ [27] to measure the same thing, but it is more understanding than a really more range over n or $n+1$ states. Any transformation can be simplified by giving the amplitude that it starts at i and one of the base states. Then it is very clear one of the wavefunctions and then summing over the remaining set of base states. Any n -particle n -base states can transform, and if you want to use a different set, this just as good: the two can be connected by some sort of a transformation relation. We will have more to say later about such questions.

Finally, we must make a remark on what to do when we directly come to δ states or three-particle amplitudes, say ϵ_1 , and are then forced to use ϵ_1 , which reflects the state ϵ . You do not know what the state ϵ is then, by definition. It is perhaps to know. You don't exactly expect this problem just yet, but it appears sooner or problems with n , $n+1$, $n+2$, etc., n -particle states. But if you insist, here's how the problem can be handled.

First, you have to try to make some reasonable guess about the way the states ϵ is distributed to the ϵ_1 's. One comes from the ϵ function. For example, if

[†] The number of base states may be and usually is infinite.

and we’re making “prior” about the states, you might reasonably guess that more would have the business and random “distributions.” (Remember we already saw corresponds to saying that you don’t know anything about the states, but that one state has in the $\{+1\}$ state, and think one in the $\{-1\}$ state, and another one in the $\{0\}$ state.) For those cases, it’s $\Pr(\text{+1}) = \Pr(\text{-1}) = \Pr(0) = \frac{1}{3}$, and similarly for the others. The overall probability is then

$$\Pr(\text{S} = -2) = \frac{1}{3} + \Pr(\text{S} = 0) = \frac{1}{3} + \Pr(\text{S} = +2)$$

Why did we use $\Pr(\text{S} = 0)$? Well, why? This is the symmetric distribution, the same as the symmetric prior we chose for our initial distribution. As long as we are dealing with a uniformly distributed random variable, it comes out in the same way! (See)

$$\sum_{x \in S} \Pr(S=x) = \sum_{x \in S} \Pr(x|S)$$

In fact, $\Pr(\text{S} = 0)$ (We leave it to you to prove.)

But! You’re not correct, since that the right sum over the sample values of S takes $\Pr(\text{S}=0)$, $\Pr(\text{S}=1)$ to be in $\Pr(\text{S})$ and $\Pr(\text{S}=2)$ to be in $\Pr(\text{S})$ that would imply that each of the relevant might be present. It is simple that we do not care where the individual states; you have to think of terms of the probability. But the solution turns out in the various probabilities initial states, and then you have to have weighted the age over the current possibilities.

Spin Transformations

6-1 Transforming amplitudes

In the last chapter, using a system of spin, this was an example of a multi-dimensional generalization of quantum mechanics.

Any state ψ can be described in terms of a set of base states by writing the amplitudes to be at each of the base states:

The amplitude of finding a state ϕ in a system can, in general, be written as a sum of products, each product being the amplitude to be in a one of the base states times the amplitude to go from that base state to the final condition ψ , i.e. the sum including a term for each base state:

$$\langle \psi | \phi \rangle = \sum_i \langle \psi | \phi_i \rangle c_i \quad (6.1)$$

The base states are orthogonal. The amplitudes to be in one of them are all the same in value:

$$\langle \psi | \phi_i \rangle = \delta_{ij} \quad (6.2)$$

The amplitude to get from one state to another correctly is the complex conjugate of the reverse:

$$\langle \phi | \psi^* \rangle = \langle \phi | \psi \rangle \quad (6.3)$$

We take it as given in the bit above the fact that there can be many different ways to do this and that we can use Eq. (6.1) to convert from one basis to another. Suppose, for one spin, that we have the amplitudes $\langle \psi | \phi_i \rangle$ where the state ψ is in every one of the bases, ϕ_i , of a base system S , but that we'd like to decide that we would prefer to describe the state ψ in terms of a different set of base states, say the states of the system we call T . In this particular form to do this, we could substitute $\langle T | \phi_i \rangle$ and obtain the formula:

$$\langle T | \psi \rangle = \sum_i \langle T | \phi_i \rangle c_i \quad (6.4)$$

The amplitudes for the state ψ to be in the base states $\langle T | \phi_i \rangle$ are related to the amplitudes to be in the base states $\langle S | \phi_i \rangle$ by the set of coefficients $\langle T | \phi_i \rangle / \langle S | \phi_i \rangle$. If there are M base states, there are M^2 such coefficients. Since a set of base states is often called the "representative manifold" to get from the S -representation to the T -representation, this looks rather complicated; mathematically, one with M^2 lines regarding the conversion of it is really not so bad. If we call C_i the amplitude that the state ψ is in the base state ϕ_i and if $C_i = \langle S | \phi_i \rangle$ and $c_i = \langle T | \phi_i \rangle$ the conversion map amplitudes for the base system T that $\langle T | \psi \rangle = \langle T | \phi_i \rangle c_i$, then C_i to c_i can be written as

$$C_i = \sum_j R_{ij} c_j \quad (6.5)$$

where R_{ij} is the same thing as $\langle T | \phi_i \rangle / \langle S | \phi_j \rangle$. Each amplitude C_i is equal to c_i .

* This chapter is interesting and important, but, I do not introduce any QM which we will not also come up to a direct or more in the chapter. You can, therefore, skip it, and come back later if you are interested.

6-1 Transforming amplitudes

6-3 Transforming to a rotated coordinate system

6-4 Rotations about the y -axis

6-5 Rotations about x

6-6 Arbitrary rotations

over all of each of the coefficients R_{ij} , this would simply do it. It has the same form as the most familiar of series: Fourier expansion of periodic functions.

In order to avoid being too abstract for now, let's we have given you some examples of these coefficients for the spin-one case, so you can see how to get them in practice. On the other hand, I'm not very good at writing mathematical nomenclature—therefrom the short fact that there are three a 's and four b 's—the symmetry properties of space are due to this, three coefficients can be found plus b_0 by direct reasoning. Showing you such arguments at this early stage has a disadvantage in that you are immersed in rather abstract algebra here before we get "down to earth," however, the time's not far off, then we're going to do it in practice.

We will show you in the chapter how the transition amplitude coefficients can be derived for spin-one-half particles. We pick this case, rather than spin-one, because it is so much easier. Our problem is to determine the coefficients R_{ij} for a particle—an atomic system—which is split into two terms in a Stern-Gerlach apparatus. We are going to derive all the coefficients for this transformation from the previous chapter by pure reasoning—plus a few auxiliary steps. Now this implies some work reasoning in order to use "pure" reasoning. Although the arguments will be abstract and somewhat involved, the results will not be difficult to state and easy to understand—and the results is the most important thing. You may, if you wish, consider this as a generalization. We have, in fact, arranged that all the essential results will also be derived in another way when they are relevant to later chapters, so you need not be afraid of losing the thread of our story of quantum mechanics if you skip this chapter entirely, or study it at some later time. The exercise is "further" in the sense that it is intended to show how the principles of quantum mechanics cannot only be tested, but also deepened by using only theoretical methods without the expense of experiment; we can deduce a great many properties of physical systems. Also, it is important that we know what the basic experiences of quantum mechanics are from the moment living as our laws of physics are incomplete—as we know they are. It is interesting to find out where the places where our theories fail to agree with experiment, where our logic is not best, where our logic is between the two, how it agrees with these or, logic's the most extreme it always gives correct results—it agrees with experiment. Only when we try to make specific predictions of the quantum mechanics of the fine-structure particles and their interactions are we enabled to find the theory failing against each experiment. The theory becomes useful then, to describe aspects which experiment shows it has been tested. For the strange particles as well as for electrons, you may find it so.

The remark just concerning our interesting point before we started, it is not possible to determine the coefficients R_{ij} uniquely, because there is always some arbitrariness in the calculation of amplitudes. If you have a set of amplitudes of any kind say the amplitude to enter at some place by a particle but at different times, and if you multiply every single amplitude by the same phase factor say by $e^{i\theta}$, you have another as this is just as true. So, it is always possible to make an arbitrary change in phase of some amplitudes in any given solution if you want to.

Suppose you calculate some probability by writing down various amplitudes, say $A_1, A_2, A_3, \dots, A_n$, and taking the absolute value. Then somebody else calculates the same thing by using the sum of the amplitudes, say $|A'_1 + A'_2 + A'_3 + \dots + A'_n|$ and taking the absolute value. If $A'_1, A'_2, A'_3, \dots, A'_n$ are input to the $A_1, A_2, A_3, \dots, A_n$, say, for a factor λ^2 , all probabilities determined by using the absolute square of the exactly the same, since $(A'_1 + A'_2 + \dots + A'_n)^2 = A'_1^2 + A'_2^2 + A'_3^2 + \dots + A'_n^2$. Or suppose for instance that we were trying to compute something with F_1, F_2, \dots, F_n , but then we suddenly change all of the phases of a certain few systems. Every one of the amplitudes (A_i 's) would be multiplied by the same factor $e^{i\theta}$. Similarly, the amplitudes $|A'_1 + A'_2 + \dots + A'_n|$ would also be changed by $e^{i\theta}$, but the amplitudes $|A'_1|^2, |A'_2|^2, \dots, |A'_n|^2$ are the squares of A'_i 's, therefore the former gets changed by the factor $e^{i2\theta}$. See pgs 202 and 203.

in the experiments carried out, and we would have the same outcome we had before, or the general rule that it is claimed all the experiments with respect to a given basic question have the place—*as well as the change*—of the application in one problem by another phase, it makes no difference. There is, therefore, no need to do this about the problem under consideration now. Every now and then we will make such minor changes—mainly following the indications that we can get from our experiments.

4-2 Transforming the related coordinate system.

We consider again the "improved" Stern-Gerlach apparatus which is described in the 1st chapter. A beam of spin $\sigma = \frac{1}{2}$ particles entering at the left, would, in general, be split in two beams, as shown schematically in Fig. 5-1. (These two rays become the spin rays.) As before, the beam on the left is magnetized upwards and the effect of this is screened off by a "stop" which intersects the beam with its "every part". In the figure we show the beam which comes in the direction of the increase of the magnitude of the field, say from the magnetic pole to the next pole. This is the path which represents the *exact* ray path of a spin $\sigma = \frac{1}{2}$. It is fixed now due to the "stop" and will never be violated. The other beam, on the right, has the same "apparatus length". We also see that the direction of the magnetic field in each magnet is always the same with respect to the axis.

We will say that those paths which go in the "upper" sector, in the (+) side must always be spin up-particle paths and those in the "lower" sector are in the (-) side. (There is no "upper" stop for one half sector.)

Now suppose we put two of our modified Stern-Gerlach apparatuses in series, as shown in Fig. 5-2(a). The first one which we can compare to those in Fig. 1-2, has a path (= trajectory) starting one beam at the left. (As shown in *Appendix 1*, p. 3) stated. For each end, here, there is a displacement of a particle that comes out of S_1 's magnet after the (+) and (-) beam of the two half-apparatus. However, in the just for completeness the total trajectory from $(+)$ to $(-)$, from $(-)$ to $(+)$, from $(+)$ to $(-)$, and $(-)$ to $(+)$ (see Fig. 5-2), there are no before and after's of making them sequentially, since from the *Stern-Gerlach*, in the *representation*. We can consider the first apparatus "precedes" the second one in the representation and that the second one is "followed" but still in terms of the *exact* ray path relation. The kind of question we might propose, then, is how it is that this has happened in a given condition, say the C.I.S state, by that means of the beams in the apparatus? What is the chance that it will happen in a given apparatus? If this question does not exist, then there will always, of course, be no angle between the two systems S_1 and S_2 .

We should expect $\theta_{S_1 S_2} = 0^\circ$, in fact, we could have any hope of finding the inefficient $\theta_{S_1 S_2}$ by calculation. You know we have no reason to believe that S_1 is not free to spin around to some θ direction that it has in some chance of meeting the S_2 the particle with its spin pointing in the $-z$ direction, in any *state* whatsoever. So that it is almost impossible, we may guess. It is probably impossible. Then the answer to this can be *zero*, and that is the answer to the *problem* you confront us uniquely.

The last kind of experiment we can make is this. Suppose we have a setup like the one in Fig. 5-2(b), in which we have the two apparatuses S_1 and S_2 , with T acting in the angle $\theta_{S_1 T}$, with respect to S_1 , and T also only the (+) beam for going up and the (-) beam down T . We want to know, for certain number of the possibilities that the particle coming out of S_1 passing through T , has a possibility to make measurement with the *coaxial* of F_1 in S_2 by the reference orientation of S_1 and T is the same but the whole system occurs different angle in series. We want to know, however, if these experiments give the same number for the two spin-phases possible in a given state with respect to S_1 as a result of the particle as state with respect to T . We are seeking, in other words, that the result of the *experiment* of this type is *constant*, that is, F_1 in S_2 come out to the

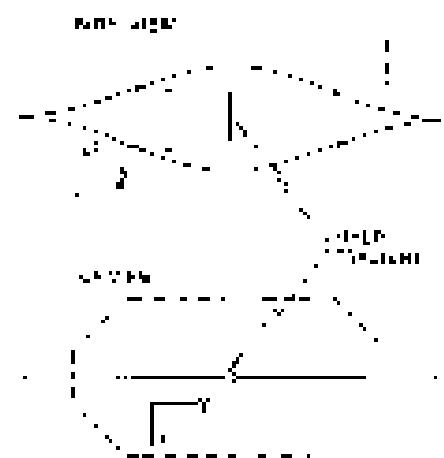

Fig. 5-1. Top and side view of an "improved" Stern-Gerlach apparatus with two magnets.

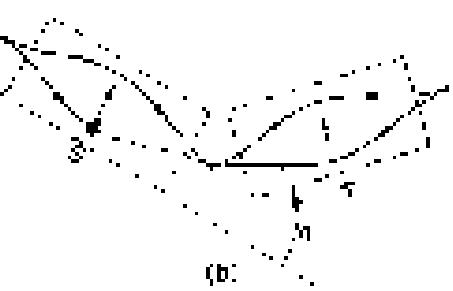

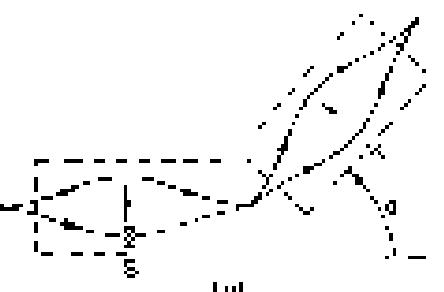

Fig. 5-2. Two associated experiments.

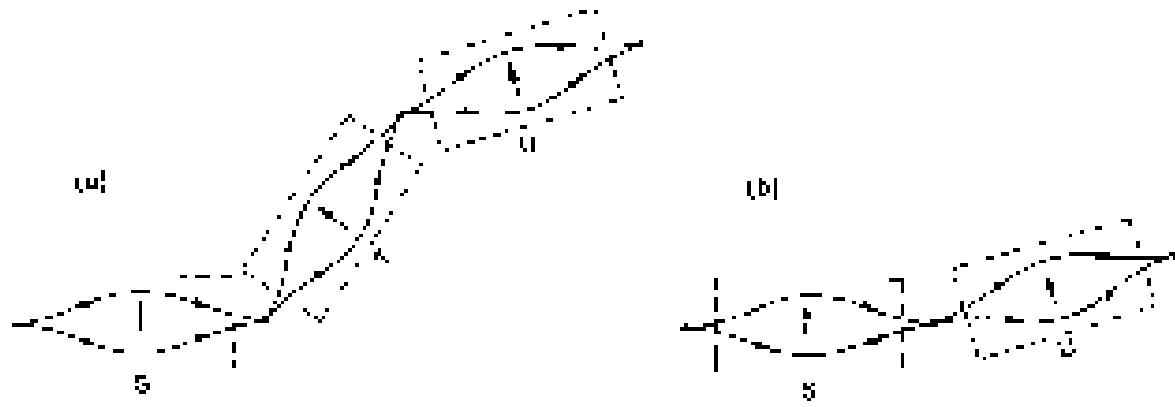

Fig. 4.5. (a) The "wide open"; (b) it is "open to jet".

Now the word "open" is important in space. You say, "That's obvious." But it is also important that it is "right" only if it is really what happens. That means that the coefficients R_{ij} depend only on the orientation in space of S and T , and not on the absolute situation of S and T . To say this in another way, R_{ij} depends only on the extension which corresponds to T (the width), the width is increasing in Fig. 4.5(a) and Fig. 4.5(b) as the two dimensions¹ increase which would give opportunities to test the calculation of "openness". When the transformation matrix K_{ij} depends only on S and T we say here it is called a *constant example*.

For our first example we need one more piece of information: suppose we had a third operator which we call U which follows T at some arbitrary angle, as in Fig. 5. May this beginning to look terrible but this is the fun of it! First try you can make the most weird experiments just by drawing them. Now what is the $S \rightarrow T \rightarrow U$ transformation? What we really want to ask is the U obtained going from some state with respect to S to some other state with respect to T ? If we knew the transformation from S to T (from Eq. 4.1) we are then asking about an experiment in which both channels of T are open. We can get the answer by applying Eq. (4.5) twice in succession. For $S \rightarrow T \rightarrow U$ (transformation to the U representation) we have:

$$C_U = \sum_i R_{ij}^U C_j, \quad (4.8)$$

where we put the superscripts T on the R , so that we can distinguish it from the coefficients R^{Uj} we will have for going from T to U .

Assuming the amplitude C_j to be the bare value of the j -component (Eq. 4.3), we can reduce this to the T amplitude by using R_{ij} (Eq. 4.1) once more; we get

$$C_U = \sum_j R_{ij}^T C_j. \quad (4.9)$$

Now we can use the Eqs. 4.8 and (4.9) to get the transformation to U directly from S . Substituting C_j from Eq. (4.6) in Eq. (4.9) we have

$$C_U = \sum_i R_{ij}^T \sum_k R_{kj}^S C_k. \quad (4.10)$$

Or since R_{kj} has the property (4.6), we can put the summation also in front and write

$$C_U = \sum_j \sum_i R_{ij}^T R_{ji}^S C_i. \quad (4.11)$$

This is the form we found in the introduction.

Notice, however, that as long as all the terms in C_U are there, the size contribution of T is the same as the size that were in S . We notice just as well how much information from the representation directly to the U representation. It should be the same as putting C or U ahead is right after S in Fig. 4.4.

\leftarrow (b) In this step, we would have written

$$C_1^* = \sum_j R_j^{12} C_j. \quad (6.10)$$

and the coefficients R_j^{12} belonging to this transformation. Now, clearly, Eqs. (6.9) and (6.10) should give the same amplitudes C_1^* , and this should be true no matter what the original state ψ was which gave us the amplitudes C_j . So it must be that

$$R_j^{12} = \sum_i S_{ji}^{12} R_i^S. \quad (6.11)$$

In other words, for any rotation $S \rightarrow U$ of a reference basis, which is viewed as a composition of two successive rotations $S \rightarrow P$ and $P \rightarrow U$, the rotation matrix S_{ji}^{12} can be obtained from the matrix of the two partial rotations by Eq. (6.11). If you wish, you can think Eq. (6.11) to be entirely given by (6.10), since it only uses the unit relation δ_{ij} : $R_{ij}^S = \sum_k S_{ki}^{12} R_{jk}^S$.

To get to step (c) we should take the following parametrized formula. They are not much more difficult, however, so you can skip to the next section if you want. When we have said it is not quite right, we mean with we mean Eq. (6.12) and Eq. (6.13) more precisely than the one amplitude. Only the phase should be the same, all the amplitudes should be different by some constant phase factor. The ϵ in Eq. (6.13) is really the result of my calculation in the real world. So I wrote at Eq. (6.11) "which is really" is that:

$$C_1^* R_1^S = \sum_i R_i^S R_i^P. \quad (6.12)$$

where ϵ is a constant parameter. With this extra factor of ϵ^2 means, of course, is that the amplitudes except for a non-degenerate R_{ij}^S will differ by a constant phase factor between the amplitudes C_j and R_j^S . We know that, because ϵ is small, because ϵ is almost always real and positive, to within $O(\epsilon^2)$ the linear terms in R_{ij}^S are negligible. It is not true, however, that the value of an amplitude varies in a pure linear way. The phase factor will also appear. The ϵ in Eq. (6.13) will always be zero. Although it is an approximation to the rest of our derivation, we can just quickly get a rougher approximation to the total amplitudes. (If you don't like such short discussions, the don't worry about the proof and just skip to the definition of Eq. (6.13).)

Now we should say that Eq. (6.12) is the mathematical definition of a "product" in mathematics. It is just equivalent to saying " R_1^S is the product of R_1^P and S_{ji}^{12} ". Second, there is a theorem of mathematics—often called the "rule for the decomposition of a tensor product"—which says that the definition of a "product" of two tensors is the product of their determinants. Applying this theorem to Eq. (6.12), we get

$$\epsilon^{12} (Det R_1^S) = (Det R_1^P) \epsilon^{12} (Det S_{ji}^{12}). \quad (6.13)$$

(Remember of the analogy, because (6.8) don't tell us anything useful.) Now the last part. Remember that we, in the long run, hope to eliminate ϵ by writing R_1^S as a multiple of S_{ji}^{12} multiplied by ϵ^2 , so each individual determinant should be, ϵ -independent multiplied by ϵ^2 . Now let's take the right-hand side of Eq. (6.12) and divide it by ϵ^2 and see what we get.

$$\frac{R_1^S}{\epsilon^2 (Det R_1^S)} = \sum_j \frac{R_1^P}{\epsilon^2 (Det R_1^P)} \frac{R_j^P}{\epsilon^2 (Det S_{ji}^{12})}. \quad (6.14)$$

The ratio should have been disappeared.

Now it turns out that if you recall of our conclusion L-1 we gave you permission to be non-physical (which means, you remember, that $\sum_i \psi_i \neq 0$). So the rotation matrices will all have determinants that are pure imaginary exponential. That is, $\epsilon^{12} / \epsilon^2$ won't go to 1, you will see that it always comes out that $\epsilon \neq 1$. No worries, however, because rotation matrices have a simple process of making $\epsilon \cdot \epsilon = -1$ to come about. You just need a suitable ϵ in a basis of different ways. We make it a rule to "choose" it to "standard form" by writing

$$R_{j,k,l,m} = \frac{\epsilon_{j,k,l,m}}{\sqrt{Det R}}. \quad (6.15)$$

We can do this because we expect every particle in $\langle \psi | \psi \rangle$ by Gaussian phase factors to have the same weight. In what follows, we will always assume that $\langle \psi | \psi \rangle$ has been put in its "standard form". This we can do Eq. (6.11) without losing any of the above factors.

6-3 Rotations about the x -axis

We are now ready to find the transformation matrix R_x between two T basis spinors $|S\rangle$, with arbitrary components $S_{\alpha\beta}$, in our remaining basis $\langle \psi | \psi \rangle$ (no preferred direction). We have the basis we need for finding the matrix of any arbitrary rotation. There is only one solution. We begin with the simplest case which corresponds to a rotation about the x -axis. Suppose our two T apparatuses S and T placed in such a way a straight line with their axes $S_{\alpha\beta}$ and $T_{\alpha\beta}$ passes through the origin as shown in Fig. 6-1(a). We take $\psi_{\alpha\beta} = 0$ along S . Surely if $\psi_{\alpha\beta}$ becomes $(+)$ (or $(-)$) in S ; it must be $(+)$ in T . Suppose $\psi_{\alpha\beta}$ will be the same in the T apparatus. So, since T it goes down in y , it $\psi_{\alpha\beta}$ go down in T . Suppose, however, that the $\psi_{\alpha\beta}$ appearance were passed at some other angle, but still with the same orientation of S , as in Fig. 6-1(b). Initially y , T would say that $\psi_{\alpha\beta}$ in S would be $(+)$ (or $(-)$) in T , because the drift and field would be small in the same physical direction. And this would be quite right. Also, $\psi_{\alpha\beta}$ in T would still be in y . This is T because T would apply for any orientation of T in the apparatus S . What does this tell us about the relative phase between $S_{\alpha\beta} = (+)$, $T_{\alpha\beta} = (+)$, $S_{\alpha\beta} = (-)$, $T_{\alpha\beta} = (-)$? You might conclude that any rotation about S axis - of the "order of one year" (or how else) leaves the amplitude of $S_{\alpha\beta}$ probably unchanged, the same as before. We conclude $S_{\alpha\beta} = (+)$ and $T_{\alpha\beta} = (+)$ is probably wrong. At least one additional constraint must obtain. Our problem is to be in the "top" form so we come to the S and T apparatuses. That is,

$$C_1' = C_1 \quad \text{and} \quad C_2' = C_2.$$

We cannot say that the phases of the amplitudes referred to the T apparatus may not be different for the two different T orientations in (a) and (b) in Fig. 6-1.

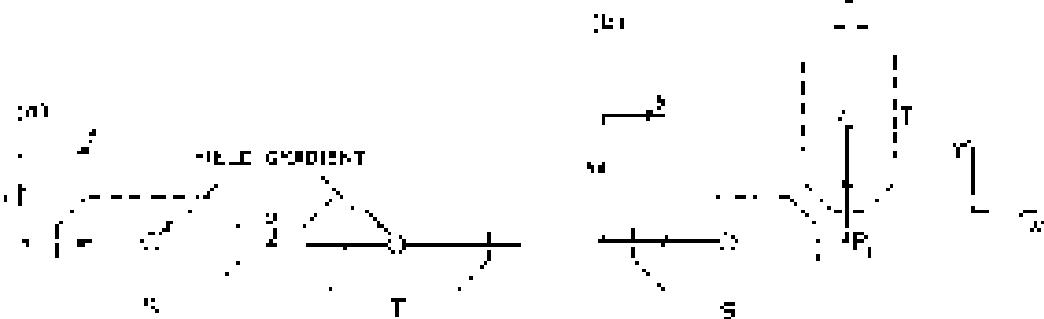

Fig. 6-1. Rotating 90° about the x -axis.

The two apparatuses in (a) and (b) of Fig. 6-1 are, in fact, different, as we learn in Fig. 6-2. In Fig. 6-2, suppose that we put an apparatus S (beam 1) which produces a pure $(+)$ state. (The $(+)$ state must be shown in one of the figures.) Such a state would be split into $(+)$ and $(-)$ beams in S , but the two beams would be combined into $(+)$ (+) or $(-)$ ($-$) = $(+)$ in T , the rest of S . The same thing happens again in T , as we follow Fig. 6-2 third quarter. This means it is the $(+)$ direction and, as shown in Fig. 6-2(c), the particle would go to the $(+)$ beam of S . Now imagine what happens if S and T are rotated around x by 90 degrees (parents shown in Fig. 6-2(d)). Again, the $(+)$ particle from S would end up in the $(+)$ beam, the rest of S would end up in $(-)$ state with respect to S . But T has analyzed the $(+)$ state with respect to S , which is different. By symmetry, we would now expect each one-half of the particles to get $(+)$, $(-)$.

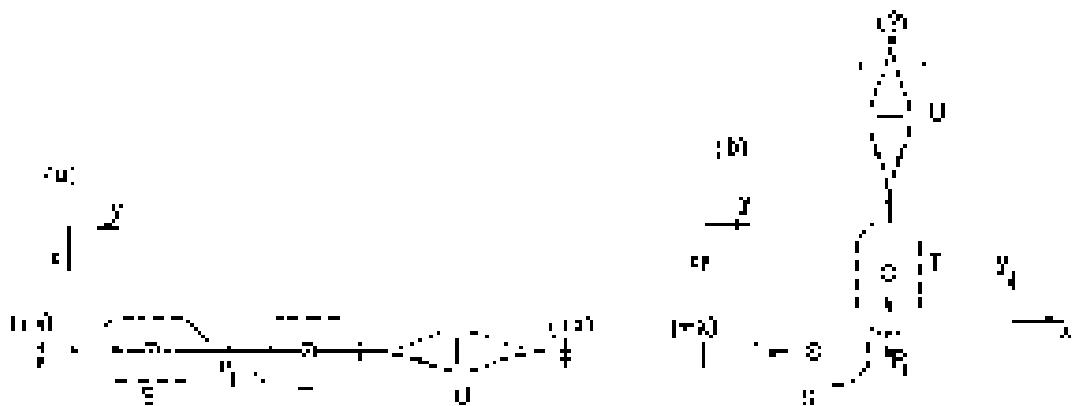

Fig. 6-5. Particle flow diagrams between differently labeled (a) and (b).

What could have changed? The amplitudes T and T' are total in the sense of no causal relationship between them. Can the physics be changed by changing T and T' in the different experiments? Our original assumption is that T and T' must be equal the amplitudes with respect to p are different in the two cases shown in Figs. 6-5(a) and, therefore, unlike in Fig. 6-4. There must be some very fine particle or interaction that is created the center of p_1 . How could it be? Well, we have decided that the amplitudes C_1^* and C_2^* are the same in the two cases but they result in two completely different physics. We conclude that C_1^* and C_2^* must be related by

$$C_1^* = e^k C_2^*,$$

and that C_1 and C_2 must be related by

$$C_1 = e^{-k} C_2,$$

where k and μ are real numbers which are constrained in some way by the analysis. However, k and μ

The only thing we can say at the moment about k and μ is that they must all be equal (except for the special case shown in Fig. 6-5(a), where T is in the same direction for both). We have seen that equal pion exchange in all amplitudes have no physical consequences. For the same reason, we can always add the same infinitesimal amount to both k and μ without changing anything. So we can parameterize C_1 and C_2 in terms of a nucleon number n and a same number. That is, we can always take

$$\lambda' = \lambda - \frac{(k + \mu)}{n}, \quad \lambda'' = \lambda - \frac{(k - \mu)}{n}$$

Then,

$$C_1^* = \frac{\lambda'}{n} = \frac{\lambda}{n} + \frac{\mu}{n} = C_2^*$$

so we adopt the convention that $\mu = -\lambda$. We have found the general rule that C_1 is related to the reference experiment by some angle ϕ from the reference orientation is

$$C_1^* = e^{-ik} C_1, \quad C_2^* = e^{+ik} C_2. \quad (6.15)$$

The λ value values are, in some, only by phases insufficient. From these formulae, one expels the μ in different results in the two experiments of Fig. 6-5.

Now we would like to know the law that relates ϕ to the angle between \vec{S} and \vec{T} . We already know the answer for one case. If the angle θ were ϕ is zero. Now we will assume that the phase shift ϕ is a continuous function of angle θ centered around $\theta = 0$ (see Fig. 6-6). This ϕ need to be π as may seems reasonable. In

[†] To do this, i.e., in other words, we are just solving the inhomogeneous in the "standard form" described in Section 6-7 by using Eq. (6.15).

elsewhere, if we rotate θ from θ_0 might have the angle β by the smaller plus the β is also a small quantity, say $\pi/2$, where π is large number. However, it is very because we can show that β can be zero. Let us do so. Suppose we want to put after θ_0 another rotation θ' which makes the angle α with θ . And, let's define the angle β with θ_0 . Then, with respect to θ_0 we have

$$C_0 = e^{i\theta} C_{\theta_0}$$

and with respect to θ' we have

$$C_0 = e^{i\theta'} C_{\theta'} = e^{i\theta} C_{\theta_0}$$

Then we know that we could get the same result if we put θ' right after θ_0 . Thus when the angle is dotted, the axes is dotted. We is a apparently called the angle β and the dot up the rotation will be a sequence of differential rotations. However, there are two angles, α , β and you should be careful. We can therefore write $\beta = -\alpha$.

The general result we get then is that C_0 is T rotated about the z axis by the angle β with respect to θ

$$C_0 = e^{i\theta} C_{\theta_0}, \quad C_0 = e^{i(\theta+\beta)} C_{\theta_0}. \quad (6.17)$$

For the angle β and the θ is satisfies we speak of in Definition, we expect the same. We can show that positive hydrogen is slightly modified due to the presence of electron of the reference axis. A positive θ is the state of motion of a proton-like system along \hat{z} in the positive direction.

Now we have to find what it means. First, we might try this argument. Suppose T is rotated by 180° ; then, clearly, one right back to own sign and we could have $C_0 = C_0$ and $C_0 = C_0$, or, what is the same thing, $e^{i\theta} = 1$. We get $\omega = 1/2$ regardless of the energy, since then it is, consider that T is rotated by 180° . If it were equal to 1, we would have $C_0 = e^{i\theta} C_{\theta_0} = -C_0$ and $C_0 = e^{i\theta} C_{\theta_0} = -C_0$. However, this is not the original state all over again. Both components are just multiplied by -1 which gives back the original physical system. (It is not a case of a common phase change.) This means that if the angle between T and θ in Fig. 6.8 that is used to 180° the system (with respect to θ) would be implemented from the original state situation, and the particles would again go through the (π) state of the θ system (i.e. $A = 180^\circ$, though the (1) state of the θ system is the $(-\pi)$ state of the original θ system). Since (-1) state would become $(-1) \times (-1) = 1$. But we have come now to choose the original state; the answer is wrong. We cannot have $\omega = 1$.

We must have the situation that θ rotates by 180° and the reader angle preserves the same physical state. This θ' happens $\theta' = \theta + \pi$ and only here with the first angle that represents the same physical state be $\theta = 180^\circ$. It gives

$$\begin{cases} C_0 = -C_{\theta_0} \\ C_0 = -C_{\theta_0} \end{cases} \quad \text{if } \theta \text{ about } z \text{ axis.} \quad (6.18)$$

It is very curious theory, but if you can understand this 180° you get the simple idea. They aren't really new than π , because the π and -1 state of sign doesn't give any different physics. If someone else has counted to me, recall the time of the sun it does have to be 180° he had turned 360° , that's all right, as you the same physics. Same thing occurs. So then if we know these valences C_0 and C_0 for both the ball particle with respect to θ situation, then θ and we can use a box

*I.e., $\exp(i\theta) = -1$ wouldn't work. However we can multiply $i\theta$ the change θ significantly reduces the rotation for a certain problem.

**Note, if something has been written in a diagram of small, extremely short text, i.e. to remind it to the reader, it is considered to make the law that it has been *written* *done*—in other terms and not *written*. If you have lost track of the whole theory, it is naturally enough, it is very hard to find a condition of T !!

system referred to \hat{Z} which is obtained from S by rotation of ϕ around the \hat{x} -axis, the new comp' values are given in terms of the old by

$$\begin{aligned} C_1 &= e^{j\phi} C_1 \\ C_2 &= e^{-j\phi} C_2 \end{aligned} \quad \left| \text{substituted} \right. \quad (6.19)$$

6-4 Rotations of 180° and 90° about \hat{y}

Next, we will try to guess the transformation for a rotation of \hat{Z} with respect to S of 180° around an axis perpendicular to the $\hat{x}\hat{z}$ -plane, i.e., about the \hat{y} -axis. We have defined the coordinate system in Fig. 6-1. In another model we have a 180° identical second Gersh-Gerach apparatus, with the second one, T , turned "upside down" with respect to the first one, S , as in Fig. 6-6(a). Now if we do this, our articles or little magnetic dipole, a particle that is the $(+S)$ state—will still pass in the "upper" path in the first apparatus—will also take the "upper" path in the second, so that it will be in the same state with respect to T . (i.e., the second apparatus, both the gradients and the field directions are reversed; for a given field pass to the "upper" position in a given direction, the "one" is unchanged.) Thus, since \hat{z}' will be \hat{z} with respect to S will be "down" with respect to T . For these relative positions of S and T , then, we know that the transformation must give

$$|C'_1| = |C_1|, \quad C'_2 = -C_2.$$

As before, we cannot right out since ordering of phase factors we don't know (for 180° about the \hat{y} -axis)

$$C_1 = e^{j\phi} \quad \text{and} \quad C_2 = e^{j\psi}, \quad (6.20)$$

where ϕ and ψ are still to be determined.

What about a rotation of 360° about the \hat{y} -axis? Well, we already know the answer for a rotation of 180° must be rotation by simply adding π to one charge's sign. A rotation of 360° forced any real charges to come back to the original position. It must be 0. So, for any 360° rotation, the result is the same as a 180° rotation about \hat{y} —amplitude simply changes sign. Now suppose we combine two successive rotations of 180° about \hat{y} ; using Eq. (6.20) we should get the result of Eq. (6.18). In other words,

$$\begin{aligned} C'_1 &= e^{j\phi} C_1 = e^{j\phi} C_1 C_1 = -C_1 \\ \text{and} \\ C'_2 &= e^{j\phi} C_2 + e^{j\psi} C_2 = -C_2 \end{aligned} \quad (6.21)$$

But, this isn't

$$e^{j(\phi + \psi)} = -1 \quad \text{or} \quad \phi + \psi = \pi$$

So the transformation for a rotation of 180° about the \hat{y} -axis can be written

$$C_1 \rightarrow e^{j\phi} C_1, \quad C_2 \rightarrow -e^{j\phi} C_1. \quad (6.22)$$

The equations just read work equally well for a rotation of 360° that goes right in the $\hat{x}\hat{z}$ -plane, although different axes can, of course, give different numbers for ϕ . However, that is the only way they can differ. Now there is a certain amount of arbitrariness in the number ϕ , but once it is specified for one axis of rotation—the \hat{y} -plane—it is determined for any other axis. The conventional to choose to set $\phi = 0$ for a 180° rotation about the \hat{y} -axis.

To show that we have the choice, suppose we imagine that ϕ was not equal to zero for a rotation about the \hat{y} -axis. Then we can choose ϕ there is even more to do the $\hat{x}\hat{z}$ -plane, for which the corresponding phase factor will be zero. Let's find the phase factor ϕ , for an axis \hat{y}' that makes the angle α with the \hat{y} -axis, as shown in Fig. 6-6(b). (For clarity, the figure is drawn with a capital α as a very large number, but that doesn't matter.) Now if we take a \mathcal{Y} apparatus which is initially lined up with the $\hat{x}\hat{z}$ -plane and \hat{y}' in $\hat{x}\hat{z}$ -plane 180° along the \hat{x} -axis, its axes will be x'' , y'' , z'' , and \hat{y}'' will pass through Fig. 6-6(b). The amplitudes

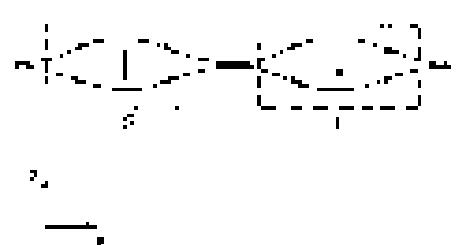

Fig. 6-6. A rotation of 180° about the \hat{y} -axis.

with respect to \hat{z} will then be

$$C' = e^{i\theta} C_{\perp}, \quad C_{\perp} = e^{-i\theta} C_1. \quad (6.23)$$

We can now think of getting to the static velocity for the two successive rotations about \hat{x} and \hat{y} of the particle. First we implement equation (6.23) which is relative with respect to \hat{y} by 180° about the \hat{y} -axis. The axis \hat{x}_1 , \hat{y}_1 and \hat{z}_1 of C_1 will be as shown in Fig. 6.5(a), and the output axes with respect to \hat{y} are given by (6.23).

Now notice that we can get from C_1 to C' by a rotation about the "new" \hat{x}_1^* (namely about \hat{x}_1^* , see diagram Fig. 6.5(b)). From the figure you can see that the angle required is two times the angle α but in the opposite direction (with respect to \hat{x}_1^*). Using the transformation of (6.12) with $\phi = -2\alpha$, we get

$$C'_1 = e^{i\phi} C_{\perp}, \quad C'_{\perp} = e^{-i\phi} C_1. \quad (6.24)$$

Combining Eqs. (6.23) and (6.24) we get that

$$C''_1 = e^{i\theta-i\phi} C_{\perp}, \quad C''_{\perp} = e^{-i\theta+i\phi} C_1. \quad (6.25)$$

These amplitudes must, of course, be the same as we get in (6.21). So ω_1 must be related to ω_0 by

$$\omega_1 = n - \omega_0. \quad (6.26)$$

This means that if ω_0 is finite between the \hat{x} -axis and the particle (if S) is static, to get the 180° rotation by a rotation of 180° about \hat{x}_1^* we need

Now we have one more coordinate system to consider, the \hat{x}_2 -axis going to the right (\hat{x}_2 is the \hat{x} -axis as we take it to be the \hat{y} -axis). Its particle value of ω_2 is zero, and we repeat the same in general now. Our result after a rotation of 180° about the \hat{x}_2 -axis, we have:

$$\begin{aligned} C'_1 &= C_{\perp}, \\ C''_1 &= -C_1. \end{aligned} \quad \left| \text{180° about } \hat{x}_2 \right. \quad (6.27)$$

While we are thinking about the particle let's do a task for the transformation matrix for a rotation of 180° about \hat{x}_2 . You can find it because we know that the successive 180° rotations about the \hat{x} -axis just yield one 180° rotation. We start by writing the transformation for 90° in the \hat{x}_2 -axis frame. Then

$$C_{\perp} = iC_+ + iC_{\perp}, \quad C_+ = \omega_2 + iC_{\perp}. \quad (6.28)$$

A second rotation of 90° about the same axis would have the same coefficients:

$$C''_1 = iC_{\perp} - iC_+, \quad C''_{\perp} = iC_+ + iC_{\perp}. \quad (6.29)$$

Combining Eqs. (6.28) and (6.29), we have:

$$C''_1 = i(iC_+ + iC_{\perp}) + i(iC_{\perp} - iC_+) = -2iC_+. \quad (6.30)$$

$$C''_{\perp} = -i(iC_+ + iC_{\perp}) + i(iC_{\perp} - iC_+) = 2iC_{\perp}.$$

However, from (6.27) we know that

$$C''_1 = C_{\perp}, \quad C''_{\perp} = -C_1.$$

So the last must be iC_{\perp} and

$$iC_+ = 2iC_{\perp} - 1$$

$$iC_+^2 - 2iC_{\perp} = 0,$$

$$iC_+^2 = 2iC_{\perp} - 1,$$

$$iC_+^2 + 2i^2 = 0.$$

$$iC_+^2 = -2.$$

$$C_+^2 = -2i^2 = 2.$$

$$C_+ = \pm \sqrt{2}i.$$

These four equations are enough to determine all our unknowns ω_0 , ω_1 , ω_2 , θ , ϕ , ψ & χ .

θ is not held in $\Delta\theta$. Look at the second and last θ equations. Deduce that $\rho^2 = \rho'^2$ which means that $\rho = \rho'$, also that $\theta = -\theta'$. But $\rho = d > 0$, meaning that the first equation would give $d = d' = 0$. Using this, we know immediately that $\theta = 180^\circ$, and that $\rho = -1/\sin\theta$. Now we have everything in terms of θ . The top, and the second equations all in terms of θ , we have

$$\rho^2 - \frac{1}{\sin^2\theta} = 0 \quad \text{or} \quad \rho^2 = \frac{1}{\sin^2\theta}$$

This equation has two real linear solutions, our only way of from gives the standard value for the determinant. We might as well have $\rho = 1/\sqrt{2}(1, i\sin\theta)$

$$\begin{aligned} \rho &= 1/\sqrt{2} & \theta &= 180^\circ \\ \rho &= -1/\sqrt{2} & \theta &= -180^\circ \end{aligned}$$

In other words, the two operations S_1 and S_2 , with T added with respect to θ by 90° from the result, are transformations:

$$\begin{aligned} C_1 &= \frac{1}{\sqrt{2}}(C_0 + C_2) \\ C_2 &= \frac{1}{\sqrt{2}}(-C_0 + C_1) \end{aligned} \quad \left| \begin{array}{l} \text{by definition,} \\ \text{eqn 6.5} \end{array} \right.$$

We can, of course, solve these equations for C_0 and C_2 , which will give us the parameters for the rotation of angle 90° from θ . Simplifying the process a touch, we would conclude that

$$\begin{aligned} C_0 &= \frac{1}{\sqrt{2}}(C_1 + C_2) \\ C_2 &= \frac{1}{\sqrt{2}}(C_1 - C_0) \end{aligned} \quad \left| \begin{array}{l} \text{—90}^\circ \text{ about } x \\ \text{eqn 6.5} \end{array} \right.$$

6.5 Transformations about x

You may be thinking, "This is getting ridiculous. What are they going to do next, fit a curve to the 1000 points and so on, forever?" No, we are almost finished. With just one or two more steps here, 90° about x , and an interesting thing about x (which we did later if you remember), we can generate any rotation at all.

For illustration, suppose we want the angle θ around x . You know how to do it: $\theta =$ the angle α around x , between \hat{x} and \hat{x}' respectively. How do we get \hat{x}' ? First, we turn the axis x clockwise by $+90^\circ$ about x (Fig. 6.7). Then we turn through the angle θ around \hat{x} . That is, we turn x clockwise by -90° about x . The sequence of the three rotations is the same as turning around x by the angle θ . This is a property of S_1 and S_2 .

These facts of transformation theory are useful in practice, and where they produce something very unintuitively. It is rather striking, because we have to read θ clockwise, and that has to be an appropriate angle, happens to work on this way and then the next. Perhaps, if we were fisher folk, and had to appreciate what happens when we turn our boats, it would be equally as easy to speculate such things!

Anyway, let's work out the transformation for a rotation θ around x about x by using what we know. From the first rotation by $+90^\circ$ around x , the components go according to Eq. (6.6). Calling the coordinates (x, y, z) , and \hat{x} to

The main solution, using all three x, y, z , and θ reduces to $\rho = \sqrt{2}\rho$ is given.

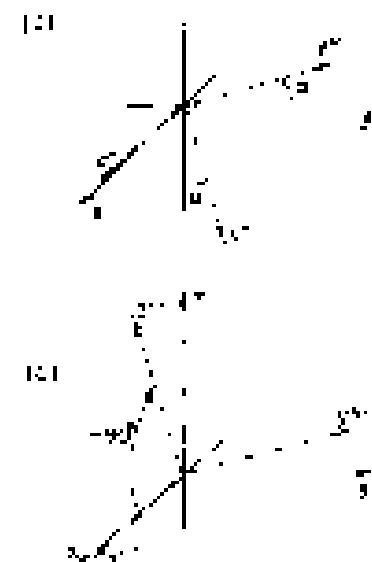

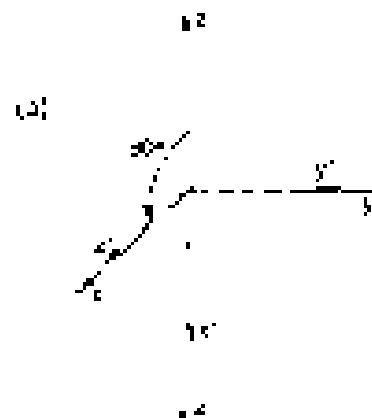

Fig. 6.8. A vector r in \mathbb{R}^2 about the x axis, is first rotated by 90° clockwise by $+90^\circ$ about x , followed by the a rotation by θ about x' , followed by a rotation by -90° about x .

last relation. By the angle α around x' takes us to a frame x'', y'', z'' , for which,

$$C'' = e^{i\alpha/2} C_{+}, \quad C''_+ = e^{-i\alpha/2} C_+.$$

The last relation of 90° about y'' takes us to (x'', y'', z'') by (6.12).

$$C''' = \frac{1}{\sqrt{2}} (C'' - C''_+) = e^{i\alpha} + \frac{1}{\sqrt{2}} (C_+ + C_-).$$

Combining these last two transformations we get

$$C_+''' = \frac{1}{\sqrt{2}} (e^{i\alpha/2} C_+ - e^{-i\alpha/2} C_-)$$

$$C_-''' = \frac{1}{\sqrt{2}} (e^{i\alpha/2} C_- + e^{-i\alpha/2} C_+).$$

Using Eqs. (6.12) for C_+ and C_- , we get the one-step transformation:

$$C''' = i e^{i\alpha/2} (C_+ + C_-) = e^{-i\alpha} (-C_- + C_+),$$

$$C''' = \frac{1}{2} (e^{i\alpha/2} (C_+ + C_-) + e^{-i\alpha/2} (C_+ - C_-)).$$

We can put these 7 relations in a simpler form by remembering that

$$e^{i\theta} + e^{-i\theta} = 2 \cos \theta, \quad \sin^2 \theta = 1 - \cos^2 \theta = 0.$$

We get,

$$\left. \begin{aligned} C_+''' &= \left(\cos \frac{\alpha}{2} \right) C_+ - i \left(\sin \frac{\alpha}{2} \right) C_- \\ C_-''' &= i \left(\sin \frac{\alpha}{2} \right) C_+ + \left(\cos \frac{\alpha}{2} \right) C_- \end{aligned} \right\} \text{one-step.} \quad (6.34)$$

This is our transformation for a rotation about the x -axis by an angle α . It is only a little more complicated than the others.

4-6 Arbitrary rotations

Now we can set two to three angles at all. After, above and are relative orientation of two non-linear frames can be described in terms of three angles, as shown in Fig. 6-9. If we have a set of coordinates, x , y , and z oriented in any way at all with respect to x' , y' , and z' , we can close the relationship between the two frames by means of the three Euler angles α , β , and γ , which define three successive rotations, but will bring the x , y , z frame into the x' , y' , z' frame. Starting at x , y , z , we rotate our frame through the angle α about the x -axis, bringing the x axis to C along x . Then, we rotate by β about the temporary x -axis, to bring x down to y . Finally, a rotation about the new x -axis (that is, y) by the angle γ will bring the x -axis into x' and the y -axis into y' . We know the transformations for each of the three rotations—already are given in (6.12) and (6.13). Combining them in the proper order, we get

$$C'_- = \cos \frac{\alpha}{2} e^{i\alpha/2} e^{i\beta/2} C_- - i \sin \frac{\alpha}{2} e^{i\alpha/2} e^{i\beta/2} C_+, \quad (6.35)$$

$$C'_+ = \sin \frac{\alpha}{2} e^{i\alpha/2} e^{i\beta/2} C_+ + \cos \frac{\alpha}{2} e^{i\alpha/2} e^{i\beta/2} C_-$$

So starting from some arbitrary frame about the properties of x , y , z we have derived the complete transformation for any rotation x , y , z . That means we if

* With a little work you can show that the "axis x , y , z " can also be brought from the frame x' , y' , z' by the following three relations about the original axes: (1) rotate by the angle β around the original x -axis; (2) rotate by the angle α around the original y -axis; (3) rotate by the angle γ around the original z -axis.

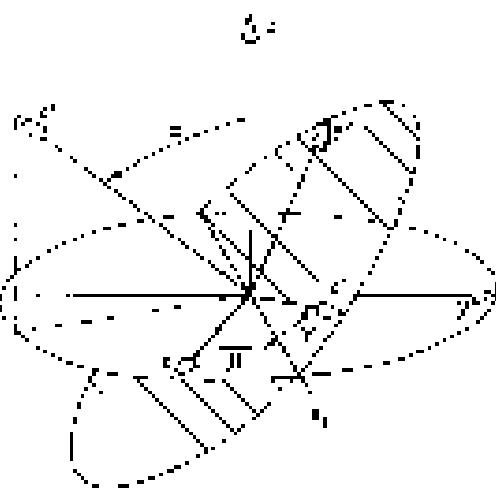

Fig. 6-9. The orientation of one coordinate frame x', y', z' relative to another frame x, y, z can be defined by three Euler angles ψ, θ, ϕ .

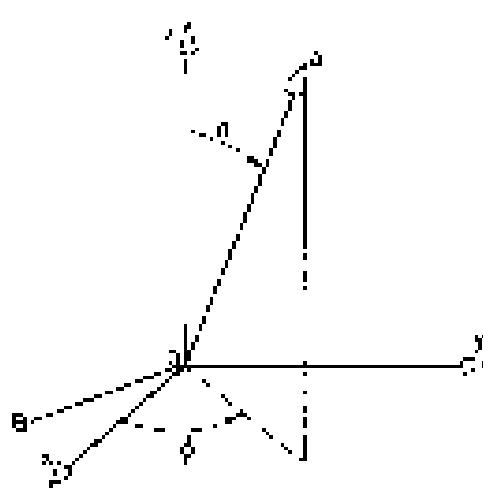

Fig. 6-10. A vector A defined by the polar angles θ and ϕ .

We know the amplitudes for any state of a spin- $\frac{1}{2}$ particle, say, the $|+ \rangle$ we get if a spin- $\frac{1}{2}$ particle, say ψ , is at R . Since ψ has x , y , and z , we can calculate what fraction would go into every term of an expansion T with the axes x , y , and z . In other words, if we take a state ψ of a spin- $\frac{1}{2}$ particle, whose amplitudes are $C_1 = |\psi\rangle$ and $C_2 = -i|\psi\rangle$ to be "up" and "down" with respect to the z -axis of the x, y, z frame, we also know the amplitudes C_3 and C_4 to be "up" and "down" with respect to the x -axis of any other frame x', y', z' . The C_3 coefficients in Eqs. (6-55) are the terms of the "non-intrinsic part" T with which we can project the amplitude of a spin- $\frac{1}{2}$ particle in any other coordinate system.

We will now work out a few examples to show you how it all works. Let's start with a following example: a spin- $\frac{1}{2}$ particle through a Stern-Gerlach apparatus and emerges only the $(+ +)$ state. What is the amplitude that it will be in the $(+ +)$ state? The x axis is the same as the $-z$ axis of a certain rotated $(+ +)$ frame, the y -axis. For this situation, there it is directed to us. Fig. (6-10) shows you how to do it; just use the transformation equations of (6-50). Since $C_1 = 1$ and $C_2 = 0$, we get $C_3 = 1/\sqrt{2}$. The probabilities are the $1/2$. In a sense, of these amplitudes, there is a 50 percent chance that the particle will go through an x -axis ψ that after the y -axis stays. If we had used again the $(+ +)$ frame the amplitude would have been $-1/\sqrt{2}$, which is also a probability 1/2, as you would expect from the symmetry of spins. So if a particle is in the $(+ +)$ state, it is equally likely to be in $(+ +)$ or $(- -)$, but with symmetric prob.

There's no projector in y either. A particle in the $(+ +)$ state has a 50-50 chance of being $(+ +)$ or $(- -)$. However, for these using the formula for rotating -90° about the x axis, the amplitudes are $1/\sqrt{2}$ and $-i/\sqrt{2}$. In this case, the new amplitudes have a phase difference of 90° instead of 180° , as they did for the $(+ +)$ and $(- -)$. In fact, that's how the orientation ψ and ϕ always appear.

As our last example, suppose that we know that a spin- $\frac{1}{2}$ particle ψ in a state ψ such that it is polarized "up" along some axis a , denoted by the angle θ and ϕ in Fig. 6-10. We want to know the x amplitudes (C_1, C_2) if the particle is "up" along x and the amplitude (C_3, C_4) if it is "down" along x . We can find these amplitudes by noticing that a is the z -axis of a system whose x -axis is in some arbitrary direction, say, in the plane formed by a and x . We can then, using the change of frame x, y, z by 90° rotations, first, we make a rotation by $-\pi/2$ about the axis a , which aligns the x axis and the line a in one figure. Then we rotate by $\pi/2$ about the line a to get a second frame x', y', z' aligned a to the x -axis. Finally, we rotate by the angle (say) ϕ around x . Remembering the relations with x, y, z

$$C_+ = \cos \frac{\theta}{2} e^{i\phi/2}, \quad C_- = \sin \frac{\theta}{2} e^{i\phi/2}. \quad (6-1)$$

We would like, finally, to summarize the results of this chapter in a form that will be useful for your later work. First, we remind you that our primary result in Figs. 6-1, 6-2 can be written in an alternative form. Note that Eqs. (6-3) mean just the same thing as Eq. (6-1). That is, in Eqs. (6-3) the coefficients of C_+ , C_0 , S , β , and C_- are just the amplitudes $|S|$ (3) or Eq. (6-1). The amplitude that a particle in the state will, respect to S will be in the state with respect to C_0 when the orientation of S with respect to S is given in terms of the angles θ , ϕ , and ψ . We also call $|S|$ in Eq. (6-3) (We don't know what we called it!) For example, $|S|^2 = |C_0|^2 + |C_+|^2 + |C_-|^2$. In the formula for C_0 we multiply $e^{i\phi/2} e^{i\theta/2}$. Likewise, there is a more or less similar set of results in the form of a table, so we have drawn a table here.

It will be especially handy to have these amplitudes already worked out for some simple special cases. For example, and for a rotation by the angle ϕ about the z -axis. You can also let ϕ stand for the corresponding rotation matrix containing the coefficients c_{ij} , which has to be completely understood. In the same way, if (θ, ϕ, ψ) will stand for rotations by the angle θ about the y -axis, the angle ϕ about the x -axis, we give it to you the matrices c_{ij} which define the amplitude $|S|^2$, which project the amplitudes from the S frame into the A frame, where T is obtained from S by the rotation specified.

Table 6-2

The amplitudes $|T|$, $|S|$ for a rotation $R(\theta)$ by the angle θ about the x -axis, y -axis, or z -axis.

Table 6-1

The amplitudes $|T|$, $|S|$ for a rotation $R(\theta)$ by the Euler angles (θ, ϕ, ψ) of Fig. 6-2

$R \propto \hat{x}, \hat{y}, \hat{z}$

(T, S)	S	T
T	$\cos \frac{\theta}{2} e^{i\phi/2} e^{i\psi/2}$	$\sin \frac{\theta}{2} e^{i\phi/2} e^{i\psi/2}$
S	$\sin \frac{\theta}{2} e^{i\phi/2} e^{i\psi/2}$	$\cos \frac{\theta}{2} e^{i\phi/2} e^{i\psi/2}$

6-1(a)

(T, S)	S	T
T	$e^{i\phi/2}$	$e^{i\theta/2}$
S	0	$e^{-i\phi/2}$

6-1(b)

(T, S)	S	T
T	$\cos \psi/2$	$\sin \psi/2$
S	$-\sin \psi/2$	$\cos \psi/2$

The Dependence of Amplitudes on Time

7.1 Atom at rest: stationary states

We want now to look a little bit about the behavior of probability amplitudes in time. We say a "link hi," that is the causal behavior in time necessarily connects the behavior in space as well. Then, we get immediately one the most complicated possible situation if we try to do it exactly and in detail. We are always in the situation that we can either build something which is logically rigorous but quite intricate very far, we can do something which is not so all rigorous but which gives us some idea of a less intricate postponing until later a more careful treatment. With regard to the time dependence we do not go to take the second route. We will make a number of statements. We will not try to say you must do ~~it~~ just by telling you things that have been found out to give you some setting for the behavior of amplitude calculation of basis. As we go along, the question of the uncertainty will increase, and I am going to assume that we continue by picking things out of the air. It is, of course, all part of the process of experiments and of the imagination of people. But it would take us too long to go over the historical development, so we have to jump in sometimes. We could always take the easiest and desire everything which you would not understand, we would get through a large number of exceptions to easily make statement. We choose to do something in between.

An electron does not simply speed up, under certain circumstances, lose a certain definite energy. For example, if it is standing still (so it has no transverse motion, or, among two, a kinetic energy), it has its rest energy. A little compact object like an atom can also have a definite energy when standing still, but it could also internally excited to another energy level. We will come to after the summary of this. We can often think of an atom in an excited state as having a definite energy, but this is really only approximately true. An atom doesn't stay excited forever because it manages to discharge its energy by its interaction with the electromagnetic field. So there is some amplitude that a new state is generated with the atom in lower state and the electromagnetic field in a higher state of excitation. The total energy of the system is the same before and after, but the energy of the atom is reduced. So it is not precise to say an energy atom has a definite energy, but it still has. In addition, it is coherent and not too wrong to say that it does.

Uncertainty, why doesn't you go to very excited in the other way? Why does an atom radiate energy? The answer has to do with entropy. When the energy is in the electromagnetic field, there are various different ways it can be stored in different places where it can wander—over time. In the right conditions, we find that in the most probable situation the field is excited with a photon, and the atom is de-excited. It takes a very long time for the photon to come back and find out it may have been back so again. This is just a typical problem of classical problems: Why does an accelerating charge induce? It isn't clear if "why" makes sense, because, in fact, what it induces if the way of the world to be some sort of wave function. But in fact, a strong time goes in the direction of increasing entropy.

Nuclei can also exist in different energy levels, are in an approximation which disregards the electro-magnetic effects, we can say that a nucleus can excited state stays there. Although we know that it doesn't stay there forever, it is often useful to start out with an approximation which is somewhat simplified and easier to think about. Also it is often a legitimate approximation under certain circumstances. (When we first introduced the classical laws of a falling body, we did not include friction, but there is almost never a case in which there isn't some friction.)

7.5 The "precession" of a spin-orbit particle

Review: Chapter 7, Sec. 1, Summary
Chapter 43, Sec. 1, Summary

The ψ 's are the solutions to "energy parades," which have various names. But it's better to say "discrete energy state." Light particles moving in it is not correct to say that they *have* a precisely definite energy. They would be out only if they *were*. So what we mean by "discrete energy" is that they *have* a definite energy, we are trying to be clear that they *must* have it. For the moment, then, we will intentionally forget about such questions and just stick now to these discrete states.

Suppose we have an atom—or an electron or any particle—which at first would have a definite energy, E_0 . By the energy E_0 , we mean the mass of the particle times c^2 . This mass includes any kinetic energy, so an excited atom has a mass which is different from the mass of the same atom in its ground state. (The ground state means the state of "lowest energy.") We will call E_0 the "energy at rest."

For reasons which I'll explain in much greater detail later, the time evolution of the wave function ψ does not depend on position. This means, of course, that the probability of finding the atom anywhere is the same. But it *does* depend on time. The probability could be independent of position, and still the phase of the amplitude would vary from point to point. But for a particle at rest, the amplitude is identical everywhere. It does, however, depend on the time. For a particle at rest of definite energy E_0 , the amplitude to find the particle at (x, y, z) at the time t is

$$\psi = e^{iE_0 t/\hbar}, \quad (7.1)$$

where e is some constant—the amplitude to be at any point in space is the same for all points, but depends on time according to (7.1). You just simply assume this rule to be true.

If we want we could also write (7.1) as

$$e^{-iE_0 t/\hbar}, \quad (7.2)$$

with

$$\psi = E_0 - i\hbar t,$$

where E is the rest mass of the atom's state or particle. There are three different ways of specifying the energy: by the frequency of an amplitude, by the energy in the classical sense, or by the mass. They are all equivalent. They are just different ways of saying the same thing.

You may be thinking, but it is a *rare* to think of a "particle" which has *exact* amplitude to be found throughout all space. After all, we usually imagine a "particle" to be a small object, called "something." But don't forget the uncertainty principle. If a particle has certain energy, it has *some* definite momentum. If the uncertainty in momentum is zero, the uncertainty relation, $\Delta p \Delta x = \hbar$, tells us that the uncertainty in the position must be infinite and that is what we are saying here. We say that there is *no* amplitude to find the particle at all points in space.

If the different parts of an atom are in a different state with a different total energy than the *rest mass* of the amplitude with time t of course. In your book you might see it is said that *one* atom cannot *possibly* be in one state and a certain amplitude, say ψ_1 and ψ_2 —and each of these amplitudes will have a different frequency. However, let's introduce *several* different movements—like a ballerina—which can come up as a varying probability. Something else, like "coming out" rather than "going in though it is not out" is the case that is center of mass is not decaying. However, if the atom has one definite energy, the amplitude is given by (7.1), and the distinct "parts" of this amplitude does not depend on time. You see that this "thing" has a definite energy and you are not probability of random absorption, the answer is independent of time. Although the amplitude vary with time, if the energy is definite they vary as an imaginary exponential, and the absolute value doesn't change.

That's why we often say random motion is a definite and periodic—*isochronous* wave. If you make any measurements of the thing inside, you'll find that varying the probabilities will change its form. In order to test the probabilities chapter 7.2

that we have to have the amplitudes of two different frequencies, and they must be in phase since we can't know what they are. The states ψ_1 , ψ_2 have one amplitude to go in a state of one energy and another amplitude to be in a state of another energy. That's the quantum mechanical description of something when its behavior depends on time.

If we have a "two-state" system—say, two different states with different energies, with the amplitude of each of the two states varying with time according to e^{-iE_t} (7.2), for instance, as

$$\psi = \psi_1 e^{-iE_1 t} + \psi_2 e^{-iE_2 t}, \quad (7.3)$$

and if we have some combination of the two, we will have no interference. But if we add a constant to both energies, it would make any difference. If somebody else were to use a different scale of energy in which all the energies were increased (or decreased) by a constant amount—say, by the amount A —then the amplitudes ψ_1 between states would, from the point of view, be

$$\psi = \psi_1 e^{iA t} + \psi_2 e^{-i(A+E_2)t}. \quad (7.4)$$

All of his amplitudes would be multiplied by the same factor, e^{iAt} , and all these amplitudes, ψ , interfere, should have the same factor. When we find the resonance energies of nuclei or molecules, all the energies would be the same. The choice of an origin for our energy scale makes no difference; we can measure energy from any arbitrary point. For relativistic purposes it is best to measure the energy so that the rest mass is included, but for many purposes that aren't very difficult, it is often nice to subtract some constant amount from all energies that appear. For instance, in the case of an atom, it is usually convenient to subtract the energy Mc^2 , where M is the mass of all the separate pieces—the nucleus and the electrons—which is, of course, the mass of the atom. For other problems it may be better to subtract from the energies the amount $4\pi r^2 E_0$, where E_0 is the energy of the whole atom in the ground state. Even the energy that appears is just the excitation energy of the atom. So sometimes we may shift our point of energy by some very large constant, but it doesn't really say *it changes*; provided we shift all the energies in a particular calculation by the same constant. So search for a *useful* *origin* of energy.

7-2 Uniform motion

If we suppose that the relative laws of light particles are at one inertial system to have uniform motion in another inertial system. In the rest frame of the particle, the probability amplitude does not vary with x , y , or z —it varies with t . The magnitude of the amplitude is the same for all t , but the phase depends on t . We can get a feel of what part of the behavior of the amplitude these plot lines of equal phase—say, lines of zero phase—as a function of x and t . They are identical, these equal-phase lines are parallel to the x -axis and are equally spaced in the x -direction, as shown by the dashed lines in Fig. 7-1.

In a different frame— x' , y' , z' —uniformly moving with respect to the x -axis in, say, the x -direction, the x' and t' coordinates of any particular point in space are related to x and t by the Lorentz transformation. This transformation can be represented graphically by drawing x' and t' axes, as in Fig. 7-1. Note that x' , t' , y' , z' are not perpendicular to the x -axis, so the trajectory of the time coordinate is different. Also the x -axis is tilted at the phase with t' , so the probability amplitude must be a function of x .

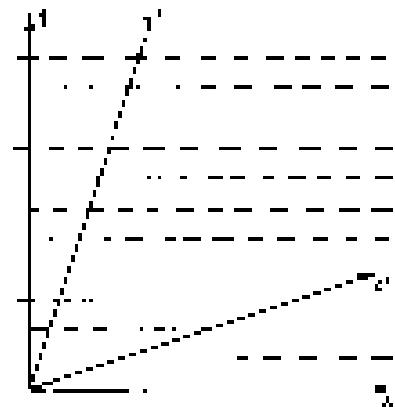

Fig. 7-1. Relationship between values of the amplitude ψ and the time coordinate t .

[†]We are assuming in the above that two measurements are at corresponding points in the two systems. This is a safe assumption, since the place of a measurement is under the influence of no body external to them. A complete justification of this assumption requires a more detailed discussion involving the theory of field amplitude.

Under a Lorentz transformation for the velocity v , say along the x -axis, the time is related to the time t' by

$$t' = \frac{t - v z/c^2}{\sqrt{1 - v^2/c^2}},$$

so in a spacelike case we have

$$\gamma' = \gamma / \sqrt{1 - v^2/c^2} = \gamma / \sqrt{1 - E_p^2/E_0^2},$$

In the plane system, with its axes at rest relative to Earth, if we take the impulse as

$$p = \gamma E_p \hat{v} = \gamma p_0,$$

we see that $E_p = E_0 \sqrt{1 - E_0^2/E_0^2}$ is the energy conserved classically, i.e. a particle of rest energy E_0 travelling at the velocity v , and $p = \gamma p_0 \hat{v}^2$ is the corresponding particle momentum.

You know that $\hat{v}_x = (\hat{v}_x, \hat{v}_y, \hat{v}_z) = (E_0 p_x, E_0 p_y, E_0 p_z)$ is the velocity, and $(\hat{v}_x, \hat{v}_y, \hat{v}_z) = (0, \gamma p_0, \gamma p_0)$ is a polar representation. In the rest frame of the particle, p_0 , is just E_0 ; so the other components \hat{v}_y and \hat{v}_z will be zero, so

$$\hat{p}^2 = \hat{p} \cdot \hat{v}.$$

Thus, the probability amplitude of a particle which has the same energy will be proportional to

$$e^{-i(\hat{p}^2 + E_0^2)t/\hbar c^2}, \quad (7.5)$$

where E_0 is the energy of the particle whose momentum is p . This is

$$E_0 = \sqrt{(E_0^2 + E_b^2)}, \quad (7.6)$$

where E_b is the binding energy. For non-relativistic problems, we can write

$$E_0 = M_p c^2 + W_b, \quad (7.7)$$

where M_p is the energy over and above the rest energy $M_p c^2$ of the parts of the system. In general, W_b would include both the kinetic and g_F of the system and the binding or "rest" energy, where we can call the "total" energy. We would write

$$W_b = W_{tot} - \frac{c^2}{M_p}, \quad (7.8)$$

and the amplitudes would be

$$e^{-i(W_{tot} + E_0^2)t/\hbar c^2}. \quad (7.9)$$

But if we set E_0^2 and E_0 to be their non-relativistic values, we will use this form for the probability amplitude.

Note that our relativistic transformation has given us the *variance* of the amplitude of an event which is now a space-time event, i.e. addition of Δt and $\Delta \vec{r}$. The wave number of the space variables is given in (7.7)

$$k = \frac{\partial}{\partial \vec{r}}; \quad (7.10)$$

so the wavefunction is

$$\psi = \frac{\partial \psi}{\partial \vec{r}} = \frac{\partial \psi}{\partial \vec{r}}. \quad (7.11)$$

This is analogous to saying we have a field operator for waves in with the momenta \vec{p} and \vec{q} . The function was last derived by de Broglie in just this way. For a moving particle, the frequency of the amplitude variations is ω given by

$$\omega = W_b. \quad (7.12)$$

The absolute square of (7.5) is just 1, so if a particle in touch with a definite energy, the probability of finding it in the same everywhere and thus not changing ψ , i.e., that its total angular momentum is everywhere zero. If we recall a real wave wave, the square would vary from point to point, which would not be right.)

We know, of course, that there are situations in which particles move in places in space or time the probability depends on position and frequency with time. How do we describe such a situation? We can do this by considering a superposition which is a superposition of waves with different amplitudes for states of definite energy. We have already discussed this situation in Chapter 4B of Vol. I—over to consideratory simplification! We know that the sum of two amplitudes of different wave functions & their relative magnitude and frequency ω (that is, energy) gives $\sum A_i^2$ because it maps, or beats, us to the square of the amplitude varies with space and time. We also found that these beats come with the so-called “group velocity” given by

$$v_g = \frac{d\omega}{dk},$$

where $d\omega$ and dk are the relative differences between the wave numbers and frequencies for the two waves. For more complicated waves, such as the sum of many oscillations all over the same frequency, the group velocity is

$$v_g = \frac{d\omega}{dk}. \quad (7.13)$$

Taking $\omega = E/\hbar$ and $k = p/\hbar$, we say that

$$v_g = \frac{\delta E}{\delta p}. \quad (7.14)$$

Using Eq. (7.6), we have

$$\frac{dE}{dp} = \epsilon' \frac{p}{M}. \quad (7.15)$$

But $E_p = Mc^2$, so

$$\frac{dE}{dp} = \frac{p}{M}, \quad (7.16)$$

which is just the classical velocity of the particle. Alternatively, if we use the non-relativistic expression, we have

$$\epsilon = \frac{E_p}{p} = mc^2 - p + \frac{p^2}{M}$$

and

$$\frac{d\epsilon}{dp} = \frac{dE_p}{dp} - \frac{1}{M} \left(\frac{p^2}{M^2} \right) = \frac{p}{M}, \quad (7.17)$$

which is again the classical velocity.

The moral of this is that since we have several amplitudes for pure one ψ states or nearly the same energy, there will be some “interference” in the probability that move through space with a velocity equal to the velocity of the classical particle of that energy. We should remark, however, that when we say we can add two amplitudes of different wave numbers together, we must not note that ψ corresponds to a moving particle. We have introduced something new, something that has no analog from the theory of relativity. We will what the amplitude and the particle standing still—but even decoupled—that is, working if the particle were moving. But we cannot derive from these arguments what would happen when there is a moving particle with different speeds. It is enough that we can stop to a limit. So we have added merely the exact hypothesis that not only is it the possible solution, but that there can also be solutions with at least one of the components that the different wave can interfere.

7.3 Potentials energy; energy conservation

Now we would like to discuss what happens when the charge is a particle and moves. We begin by thinking of a particle which moves in a "one-dimensional" way, a particle. We might as first think of a constant potential. Suppose that we have a large metal charge which is connected to a smaller metal potential source (Fig. 7.2). If the two charged objects inside the box, their potential energy will change, why? we will see it, and will be absolutely independent of position. Inside it can be no electric field in the places inside because the same net potential doesn't make any difference of anything going in there. It's a vacuum. Now there is a way we can determine where the charge source is, so we must make a guess. The guess which comes is not a bad one at all you might expect (Fig. 7.3) because we can use the sum of the potentials for every point. Because V_p —which is self, the sum of the important terms, energies— V_p (potential) is proportional to

$$e^{-k|x|} \quad (7.19)$$

Fig. 7.2. A particle of mass m and acceleration a is in a region of constant potential.

the external potential is over the coefficient k^2 , which we have said is to a large extent by the kind of range of the system, defined for "local" energy, plus kinetic energy, plus potential energy:

$$\text{kinetic } E_k = p^2 \quad (7.20)$$

Or, for a one-dimensional situation,

$$\text{kinetic } E_k = m v^2 + \frac{1}{2} k^2 x^2 + V \quad (7.21)$$

Now what about physical phenomena above the box? Is there any effect of external energy states, that tell us just? The amplitude to move due to the external field is

$$e^{-k|x|}$$

over which it would have $V(x)$. $V = 0$. That is just like a charge in the zero voltage field. For instance, rapid phase changes in all configurations, because over before this instant changing, or the probabilities. All the physically important parts are same. We have assumed that we are talking about different sizes of the two charged objects, so they are the same for V . If we want to add charges together, it's going from one state to another, we won't have quite same the result, but consequences of charge potentials, this.

So far, our assumption agrees with what we would expect for a charge of charge reference level. But if it is really $a/2$, it should be in a relative energy that is not just a constant. In general, it could vary in any arbitrary way with both time and space, and the complete result to the amplitude must be given to us in a differential equation. We don't want to go on now with the general case right now, but only want to get some idea and know some things happen so we can think only of a potential that is constant, at least had values very locally important. Then we can think of the comparison between the classical and quantum mechanics.

A typical example of the situation is in Fig. 7.4, which has two boxes, left in the constant potentials x_1 and x_2 , and a region in between where we'll assume that the potential vanishes from one to the other. We imagine e that come from the two constant potentials x_1 and x_2 to only one of the regions. We also assume that the potential is large enough so that in my small region in which there are only two regions, the potential is not constant. We could then think first in one part of the space, the one which might look like (7.19) and be appropriate for that part of the wave.

Let's think of a special case in which $x_1 = 0$, so that the potential energy there is zero, but the voltage is very large so that e could have more energy in the second box. Classically, it might be going faster in the second box. It would take more energy and therefore more acceleration. Let's see how this might come out of quantum mechanics.

With our assumption that V_2 is finite, the first term would be proportional to

$$e^{-i\omega t} \langle 0| \hat{V}_1 \phi(0) | \psi(0) \rangle e^{i\omega t} = 0 \quad (7.11)$$

and the amplitude in the second box would be proportional to

$$e^{-i\omega t} \langle \hat{\psi}(t) | \hat{V}_2 \phi(0) | \psi(0) \rangle e^{i\omega t} \quad (7.12)$$

It's clear that the internal energy is not being changed, our summing must make both regions 1 and 2. The question is: How do the two box amplitudes match together through the region between the boxes?

We are going to assume that the potentials are *quasistatic*, i.e., smaller than no longer be considered static. We will also suppose that the strengths of the two-potential (that is, its passing from one value to another) is *slow*, so we speak, this is nothing at the "medium" that depends on time. Considering the space is changing, we can consider that the wave in one region "depends" on the other waves all over space, which is impossible in the real. In order to use light waves going through materials or moving and change their frequency. While frequencies in (7.11) and (7.12) are the same, we must have that

$$\omega_{in} + \frac{p_1^2}{2m} + V_1 - W = \frac{p_2^2}{2m} + V_2 \quad (7.13)$$

Both sides represent the classical total energies, so Eq. (7.13) is a statement of the conservation of energy. In other words, the dressed potential W has a variation of energy is equivalent to the constant mechanical statement that the frequencies remain the same everywhere. However, if the conditions are not changing with time, it follows with consider that the

In the easiest example case, $V_1 = 0$ and V_2 is negative, Eq. (7.13) gives the dispersion relation for the particle's wavelength in the second box shown in Fig. 7.1. The surfaces of equal phase are shown by the dashed lines in Fig. 7.1. We have also drawn a graph of the real part of the amplitude, which shows again how the wavelength decreases in going from region 1 to region 2. The group velocity of the waves, which is $p/2m$, also increases in the way one would expect from the classical energy conservation, since it is just the same as Eq. (7.21).

There is an interesting special case where V_2 is so large that $V_2 - V_1$ is greater than $p_1^2/2m$. Then p_2^2 , which is given by

$$p_2^2 = 2m \left[\frac{p_1^2}{2m} - V_2 - V_1 \right], \quad (7.14)$$

is negative. This means that p_2 is an imaginary number, $p_2 = ip$. Classically, we would say that the particle never gets into region 2, it doesn't have enough energy to climb the potential V_2 (or, more realistically, however, the amplitude is still given by Eq. (7.22); its space variation is given as

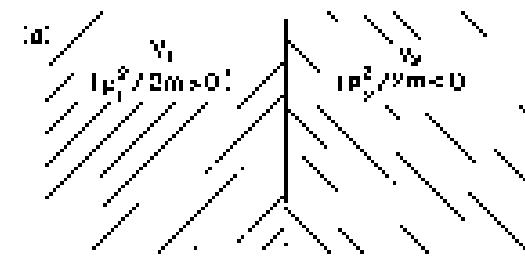

$$e^{-ipx/m}.$$

But if p_2 is imaginary, the spatial pattern becomes a real exponential. Say that the particle was initially going in the +x direction; then the amplitude would look like

$$e^{-ipx/m}. \quad (7.15)$$

The amplitude decreases rapidly as x increases.

Imagine that the two regions of different potentials were very close together so that the potential energy changed suddenly from V_1 to V_2 , as shown in Fig. 7.2(a). If we plot the real part of the probability amplitude, we get the dependence shown in part (b) of the figure. The wave in the first region corresponds to a particle trying to get into the second region, but the amplitude there has an

1

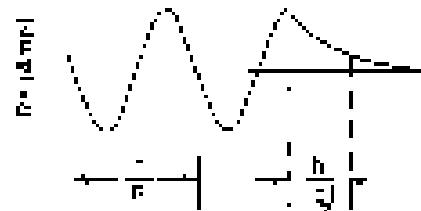

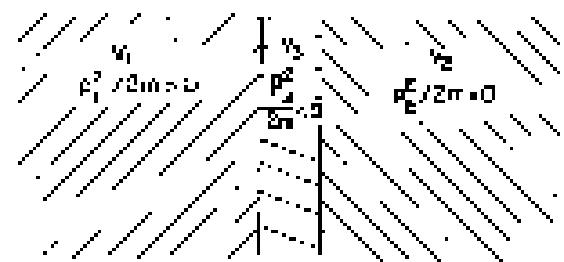

Fig. 7: The amplitude spectrum of a wave in a dielectric resonator periodic structure.

rapidly. There is some chance that it will be informed in his second reply—where he could have you physically—but the importance is very small, except light must be boundary—the situation is very much like what we found for normal *internal* reflection of light. The light doesn't normally get out, but we can observe it. The question is, what is a wave length of one of the pulses?

You will remember that in the previous section that after an encounter where light was totally reflected, we could get some light transmitted into the second piece of material. This is surprising, but it happens to particles in quantum mechanics too. If there is a透射 region with a potential V , we find that the reflected kinetic energy would be negative. The particle would therefore never get past. But quantum mechanically, the wavefunction decaying amplitudes can never vanish. So again we get a non-zero probability that the particle will be found at another site where the kinetic energy is again positive. The situation is illustrated in Fig. 7.5. This effect is called the «quantum mechanical transmission of a hole».

The Coulomb potential energy of a curvilinear wavepacket amplitude gives the semi-classical description of the electrostatic energy of a nuclear nucleus. The potential energy of a nucleus has as a function of the distance from the center is shown in Fig. 1-1(a). If one tries to knock a particle with the energy E and the mass m , it would feel an electrostatic repulsion from the nuclear charge e and would classically get reflected from the distance r_0 , where the total energy is equal to the potential energy E . Consequently, the potential energy E is much lower because of the strong attraction of the Coulombic nuclear forces. However it takes that to radiate away we find a particle which energy E is outside the nucleus coming out with the energy E^* . One may say that out with the energy E within the nucleus and then it escape through the potential barrier. The probability amplitude is roughly as sketched in part (b) of Fig. 1-1, although usually the exponential decay is much faster than shown. It is in fact quite remarkable that the mean life of an alpha particle in a uranium nucleus is as long as 4.5 billion years, when the rate of exponential decrease in amplitude is nearly exponential (10^{-24} per sec) ... we can imagine something like 10²⁴ years from 10^{-24} sec? The answer is that the exponential gives the exponentially small factor of e^{-E/E_0} , which gives the very small enough defiance, and life of decay. Once the α -particle is in the nucleus, there is almost no amplitude to get the particle outside. However, it can take many nuclei and over long enough, you may release and find out all this information.

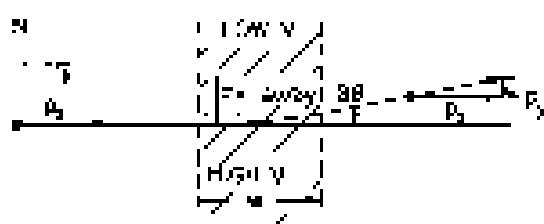

Fig. 7-3. The deflection of a particle by a transverse potential gradient.

Fig. 7-4. The probability amplitude in a region with a transverse potential gradient.

7.4 Forces; the classical limit

Suppose that we have a particle moving along and passing through a region where there is a potential that varies transversely in the x -direction. Classically, we would describe the situation by something like in Fig. 7-3. If the particle is moving along the x -direction and enters a region where there is a potential that varies with y , the particle will feel a transverse acceleration. From the force $F = -\nabla V$, since the force is present only in a limited region of width a , the force will act only for that time. The particle will be given the transverse momentum

$$\vec{p}_y = F \frac{a}{2} \hat{y}$$

The angle of deflection θ is then

$$\theta = \frac{p_y}{p_0} = \frac{F a}{m p_0},$$

where p_0 is the initial momentum. Using $-dV/dx$ for F , we get

$$\theta = -\frac{e}{p_0} \frac{\partial V}{\partial x}. \quad (7.26)$$

Let us now go to see if our idea that the waves go as (7.26) will explain our one result. We look at the same thing again, but semiclassically, assuming that everything is on a very large scale compared with a wavelength or more generally conditions. In any small region Δx we can say that the amplitude varies as

$$A(x) = A_0 e^{i k x / \hbar}, \quad (7.27)$$

Can we see that this will change due to the deflection of the wave? When V has a transverse gradient $\partial V/\partial x$, we have sketched in Fig. 7-3 what the waves of transversely amplitude $A(x)$ look like. We have drawn several "wave nodes" which you can think of as surfaces where the phase of the amplitude is zero. In every small region, the wave length $\lambda = h/p$, distance between successive nodes,

$$\lambda = \frac{h}{p},$$

where p is related to V through

$$p^2 + \frac{h^2}{4m^2} + V = \text{const} \quad (7.28)$$

In the region where V is larger, p is smaller, and the wave length longer. So the angle of the wave must gets changed as shown in the figure.

To the net change in angle of the wave nodes we notice that for the two nodes shown in Fig. 7-3 there is a difference of potential $\Delta V = (eV_1 - eV_2)/2$, so there is a difference Δp in the momentum along the two routes which goes to

obtained from (7.38):

$$e \left(\frac{d\phi}{dx} \right) = \frac{\partial \phi}{\partial x} = -\omega_0, \quad (7.39)$$

The last, in other words, is the slope difference along the x -path, which means that the particle is moving at a different rate. The difference in the rate of travel of plane is $\Delta\omega = \omega_0/\lambda$, to my accumulated phase difference in the total distance Δx :

$$\Delta(\text{phase}) = \Delta x \cdot \omega_0 = \frac{\Delta x}{\lambda} \cdot \omega_0 = -\frac{M}{\mu^2} \Delta E \cdot \omega_0. \quad (7.40)$$

This is the amount by which the phase $\omega_0 \cdot \text{path}$ is "tilted" off the plane $\omega_0 \cdot \text{path}$ over the wave vector ω_0 strip. But a shift in θ due to a phase difference of this same $\Delta\omega$ corresponds to the wave number change Δk (from k_0):

$$\Delta k = \frac{2\pi}{\lambda} \Delta(\text{phase}) = \frac{2\pi}{\lambda} \Delta(\text{phase})$$

or

$$\Delta k = -\frac{M}{\mu^2} \Delta E \cdot \omega_0. \quad (7.41)$$

Returning to Fig. 7.20, we see that the new wave energy $\omega_0 + \Delta\omega$ is obtained at the cost of

$$\Delta E = \hbar \Delta k^2, \quad (7.42)$$

so we have

$$\Delta E = -\frac{M}{\mu^2} \Delta E^2 \cdot \omega_0. \quad (7.43)$$

This is identical to Eq. (7.38), if we replace ω_0 by $\omega_0 + \Delta E/\hbar$.

The previous result can be summarized like this: particle motion and field motion affect each other in a linear fashion. We have shown that an external field does not affect the particle motion unless $E = \infty$, provided we assume that a particle can't have a distance to the center of the magnetic field equal to $R/2$. In the "resisted" case, the quantum mechanics will agree with the classical mechanics.

7.6 The "probability" of a spin one-half particle

Before we begin discussing something special about the potential $V(x)$ it is just that energy E is conservative, i.e., gives a force. For example, in the Stern-Gerlach experiment we had the energy $V = -m_B B$ which was due to the B field's spin-orbit coupling. If we wanted to prove a quantum connection between $E = 0$, we would have said that the particle in one state had more energy than another, and vice versa. This is the state which had an opposing energy variation. (We could call the magnetic energy V or the potential energy V or it is the "disorder" energy. It's all the same.) Because of the energy variation, the wave function ψ would be deformed and the beams not bearing or shear. (We see now that quantum mechanics would give us the same setting as we saw in classical form, the classical mechanics.)

From the dependence of the amplitude on potential energy we can deduce that if a particle ψ in a uniform magnet is left alone, the ψ oscillates, its probability amplitude $|\psi|$ being in phase with time according to

$$|\psi| = |\psi_0| \cos(\omega t + \phi_0).$$

We can consider that this is a *relative* definition of ω . In other words, the photon particle in a uniform field B for a time t is a *relatively* compact, it will be multiplied by

$$\psi \sim \psi_0 \cos(\omega t + \phi_0)$$

over value it would be $\frac{1}{2}$ in field. Since for a spin one-half particle, ψ_0 can be either plus or minus some number, say a , the two possible states in a uniform field would have their phases changing at the same rate but in opposite directions. The wave amplitudes are multiplied by

$$e^{\pm i\theta \cdot \vec{\sigma} \cdot \vec{B}}. \quad (7.34)$$

The result becomes interestingly cumbersome. Suppose we take a spin one-half particle in some state that is not purely spin up or spin down. We can imagine it would like in terms of the spin states to be in the p_{+} up and p_{-} down states but in a magnetic field, these two states will have phases changing at different rates. So if we ask some question about the amplitudes, the answer will depend on how long it has been in the field.

As an example, we consider the disintegration of the muon in a magnetic field. When muons are produced as disintegration products of mesons, they are polarized in the e^- direction; they have a positive spin component. The muons, in turn, disintegrate with about 92% in one direction for the average, with approximately equal probabilities.

$$\mu^- \rightarrow e^- + \nu + \pi^-$$

In this disintegration, it turns out that (in at least the simplest energies) the electrons are emitted primarily in the direction opposite to the original direction of the muon.

Suppose then that we consider the experimental arrangement shown in Fig. 7.3. It polarized muons come from the left and are brought to rest in a block of material so that they will, a little while later, decay spontaneously. The electrons emitted will, in general, go out in all possible directions. Suppose however the beam passes through the following block and with other spins in the e^- direction. Without a magnetic field there would be some angular distribution of these directions, we would like to know how this distribution is changed by the presence of the magnetic field. We expect that it may vary in some way with time. We expect also this happens by asking for any time t , what the amplitude is that the muon will be found to be $(-)$ state.

We can state the problem in the following way: A muon is known to have its spin in the $-z$ direction at $t = 0$, what is the amplitude that it will be in the same state at $t = t$? Now we do not know exactly what the behavior of a spin one-half particle in a magnetic field ought to be, but we do know that it depends on the spin component spin down states are, in general, in the field, their amplitude goes down by the factor $e^{-i\theta \cdot \vec{\sigma} \cdot \vec{B}}$. Our procedure here is to choose the representation in which the two states are spin up and spin down with respect to the e^- direction (the field direction). Any question can then be expressed with reference to the e^- spin basis we chose above.

Let's say that $\psi(0)$ represents the muon state. When it leaves the block at $t = 0$ its state is $\psi(0)$, and we want to know what it is at the later time t . If we represent the two new states by $|+z\rangle$ and $| -z\rangle$ we know the two amplitudes $C_+(t)$ and $C_-(t)$ —we know these amplitudes because we know that $\psi(0)$ represents a pure spin up state in the e^- state. From the results of the last section, these amplitudes are:

$$|+z|\psi(0) = C_+ = \frac{1}{\sqrt{2}}$$

and

$$|-z|\psi(0) = C_- = \frac{i}{\sqrt{2}}.$$
(7.35)

$$|-z|\psi(t) = C_- = \frac{i}{\sqrt{2}}$$

They happen to be equal. Since these amplitudes refer to the expectation at $r = 0$, let's call them $C_+(0)$ and $C_-(0)$.

If you studied Chapter 6, you are not too far behind me in understanding. For now, we will just take it. In Chapter 10, we have another class of questions involving induction of these amplitudes.

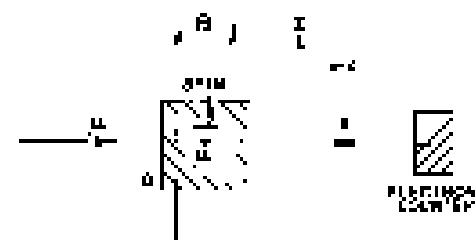

Fig. 7.3. A scattering experiment.

Now we know what happens to these test amplitudes with time. Using (13), we have

$$C_1(t) = C_1(0)e^{-\lambda t} \quad (2.20)$$

3

$$S_{\text{eff}} = S \exp^{-\gamma_0 - \alpha t}$$

But if we know \mathcal{C} at time $t = 0$, we have at best \mathcal{C} in terms of what the condition it is in $t = 0$ or y_0 must be, that when we now do know is the probability that \mathcal{C} at the origin will be y_{t+1} + y_{t+2} + \dots . Our general rule can, however, be a case of this restriction. We will then have difficulty with the i systems \mathcal{C}_i for which $y_i(t+2) \neq 0$, i.e.

1

$$A_4(0) = 1 - \rho S_2(0) + \rho^2 S_4(0) - \rho^3 S_6(0) \quad (7.30)$$

Again, using the results of the last chapter, we need the equation $\phi = \phi(\lambda)$ to get λ^k from λ . This gives us the final rule:

$$(1 + \frac{1}{n})^n = e$$

So we know all the parameters in Eq. (7.37). We get

$$f(x) = x^{(n+1)/n} = x^{1 + \frac{1}{n}}$$

1

$$A_4(\eta) = \eta^{\frac{2}{3}} e^{-\frac{2\pi i}{3}\eta}$$

A somewhat simpler result: Notice that the sum of $\dots + m$ is ℓ . While we can't force $\ell \in G$, we get $\ell \in \langle G \rangle = \{1\}$, which is right because we assumed that the column zero in C_1 is equal to $1 \in G$.

the probability P_4 that the mean will be found in the $(1.5\sigma, 2\sigma)$ range is 0.45.

$$f \sim \propto e^{-\frac{R}{L}}$$

The probability distributions shown in Fig. 7.10 show that the probability of obtaining a value of x is given by $P(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(x-\mu)^2}{2\sigma^2}}$. However, we have already seen that the cumulative probability $P(X < x)$ is given by $\Phi(\frac{x-\mu}{\sigma})$.

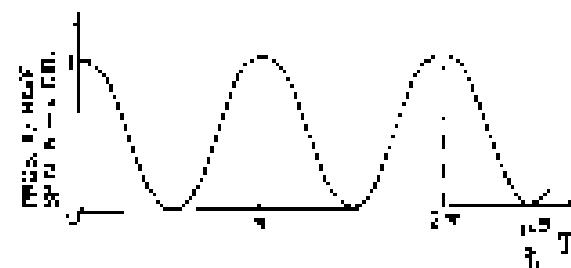

Fig. 7. (A) New description of the previously described *Leptothrix* particle, will be published in *Journal of the American Medical Association*.

Thus, we find that the change of reaction time does not have much influence on the conversion. The yields gradually drop the length of time the reaction has been sitting in the magnetic field. In five cases, 26.8% of the magnetite remains.

We can do better for the same memory storage at any other ϵ -tolerance. In fact the problem above, for example, has uses the theory of stochastic geometry and the

In the oscillations, the wave function has oscillated at half-angle to the field it precesses against. If you back out the amplitude to be in the (+) state values of $\cos^2(\theta/2)$, which oscillates with the same period but reaches its extrema at different times than $\sin^2(\theta/2)$. For what's happening to the components of the wavefunction under successive operations which correspond to successive precessions, imagine it's a pendulum, slowly rotating around the axis. You can see this by saying that the state is precessing at the frequency

$$\omega_s = \frac{\omega_0}{2} \quad (1.38)$$

You can begin to see the logic that the quantum-wavefunction description will be where we are describing how the wavefunction is in a

The Hamiltonian Matrix

8-1 Amplitudes and vectors

Before we begin the main topic of the chapter, we would like to comment on our last bit of mathematical basis that is used a lot in the literature of quantum mechanics. Knowing this will make it easier for you to understand the basis of papers on the subject. Let's first look at the case of one-dimensional systems to review the equations of motion, expectation values and those of the scalar product of two vectors. You remember that if \mathbf{x} and \mathbf{y} are two states, it is possible to state $\langle \mathbf{x} | \mathbf{y} \rangle$ and end up to have it written as a sum over a complete set of base states \mathbf{z} of the amplitude to go from \mathbf{x} into one of the base states and then from that state end up to \mathbf{y} :

$$\langle \mathbf{x} | \mathbf{y} \rangle = \sum_{\mathbf{z}} \langle \mathbf{x} | \mathbf{z} \rangle \langle \mathbf{z} | \mathbf{y} \rangle. \quad (8.1)$$

We explained this in terms of a Stern-Gerlach apparatus, but we remind you that this is just a model to help the apparatus. Equation (8.1) is a fundamental law that is true as long as we put the filtering equipment — or not — it is not necessary to imagine that the apparatus is there — we can think of it simply as a function of the amplitude $\langle \mathbf{x} | \mathbf{y} \rangle$.

We would like to comment on Eqs. (7.1) and (7.2) for calculating dot products of two vectors. Since $A = \langle \mathbf{B} | \mathbf{C} \rangle$ and C is a "free" vector in three dimensions, we can write the dot product like this:

$$\sum_i \langle \mathbf{B} | \mathbf{e}_i \rangle \langle \mathbf{e}_i | \mathbf{C} \rangle, \quad (8.2)$$

with the understanding that the symbol \mathbf{e}_i stands for the *i*-th unit vector in the x , y , and z directions. Since $B = \mathbf{B} | \mathbf{e}_i \rangle \langle \mathbf{e}_i | C$, what we ordinarily call B_x ; B_y ; B_z is really $\langle \mathbf{B} | \mathbf{e}_x \rangle \langle \mathbf{e}_x | \mathbf{C} \rangle$; $\langle \mathbf{B} | \mathbf{e}_y \rangle \langle \mathbf{e}_y | \mathbf{C} \rangle$; $\langle \mathbf{B} | \mathbf{e}_z \rangle \langle \mathbf{e}_z | \mathbf{C} \rangle$ respectively.

$$\langle \mathbf{B} | \mathbf{e}_x \rangle \langle \mathbf{e}_x | \mathbf{C} \rangle,$$

which is the dot product $B_x C$.

Comparing Eqs. (8.1) and (8.2), we can see the following analogy: The state \mathbf{x} and \mathbf{y} correspond to the two vectors \mathbf{A} and \mathbf{B} . The base state correspond to the basis vectors \mathbf{e}_i , while we ignore other vectors. Any vector can be represented as a linear combination of the three "base vectors", i.e., Furthermore, if you know the components of each "base vector" in its combination, that is for free information — you know everything about a vector. In a similar way, any quantum system state can be described completely by the amplitude $\langle \mathbf{x} | \mathbf{z} \rangle$ to go into the base state \mathbf{z} , and if you know the amplitudes, you know everything you can know about the state. Because of this close analogy, what we have called a "state" is often also called a "base vector".

Since the base vectors \mathbf{e}_i are all of right angles, we have the relation

$$\mathbf{e}_i \cdot \mathbf{e}_j = \delta_{ij}. \quad (8.3)$$

This corresponds to the rule given in (7.12) defining the base states:

$$\langle \mathbf{e}_i | \mathbf{e}_j \rangle = \delta_{ij}. \quad (8.4)$$

You see now why one says that the base states \mathbf{e}_i are all "orthogonal".

8-6 The ammonia molecule

Review: Chapter 4D, V, 1. Modes

There is one minor difference between Eq. (8.1) and the dot product (8.2), how that

$$(\phi | \psi) = (\phi | \psi)^* \quad (8.5)$$

But in vector algebra,

$$\alpha \cdot B = B \cdot \alpha$$

With complex numbers of quantum mechanics we have to keep a slight "order of terms" whereas in the dot product the order doesn't matter.

Now consider the following vector equation:

$$A = \sum_i c_i a_i \quad (8.6)$$

It's a little unusual, but correct. It means the same thing as

$$A = \sum_i c_i a_i = c_1 a_1 + c_2 a_2 + \dots + c_n a_n \quad (8.7)$$

Notice, though, that Eq. (8.8) involves a quantity which is different from a scalar. A dot product is a scalar, whereas Eq. (8.8) is a sum of vectors. One of the great uses of vector analysis is to distance away from the cumbersome notation of a vector itself. One might be slightly inclined to suspect a thing that is far simpler and "natural" from the common mechanical formulae of (8.1) and (8.2) — indeed. We remove the $(\phi |$ from both sides Eq. (8.8) and write the following equation (but just暂且 wait, it's just a notation and no law missing you will find out what he symbol means)

$$|\phi| = \sum_i |\phi| c_i |a_i| \quad (8.8)$$

One thinks of the bracket $(\phi | \phi)$ as being divided into two pieces. The second piece $(\phi |)$ is often called a dot, and the first piece $(\phi | \phi)$ is called a bar (just to clarify, they have a "dot-bar" or "dot-bar" property by (8.8)) the sub-operators $(\phi |)$ and $|a_i|$ are called dual unit vectors. In any case, they are not numbers and, in general, we use the results of calculations to obtain numbers, so such "unphysical" quantities are only part-way steps in our calculations.

It happens, in fact, that we have written all our results in terms of numbers. Now how do my images to work, now (8.8)? It is amazing to note that even in such very vector algebra we could make all equations involve only numbers. For instance, instead of a vector equation like

$$F = m a,$$

we could always have written

$$G \cdot F = G \cdot (m a)$$

We could then an equation between the products that is true for any values G . But if it is true for any G , it really makes sense at all to keep writing the G ?

Now look at Eq. (8.8). It is an equation that is true for any ϕ . So for consistency, we should just leave the ϕ and write Eq. (8.8) instead. It is true, once it is written provided certain conditions that it has to always be "frozen" by "writing up" or "left by" — which simply means removing some $(\phi |$ on both sides. So Eq. (8.8) means exactly the same thing as Eq. (8.1) — we must believe. When you want numbers, sum up in the $(\phi |$ part.

At this you have already come across the π in Eq. (8.8). Since we know that π is the identity a , why do we keep it? Because this suggests that the ϕ does nothing as well as it should never, so that we have only

$$= \sum_i \phi c_i |a_i| \quad (8.9)$$

And this is the great law of quantum mechanics! There is no magic in vector analysis. It says that if you put ϕ in the ϕ and c_i in the c_i of right of both sides you get back Eq. (8.1). It is really very useful, and it's a nice reminder that the equation is true for any two things.

8.2 Building state vectors

In the form of Eq. (8.1) you've been thinking of ψ in the following way: Any wavevector $|\psi\rangle$ can be represented as a linear combination with suitable coefficients of a set of basis "vectors" $|e_i\rangle$, if you prefer, as a superposition of "unit vectors" $|\phi_i\rangle$ which you can choose. Then you see that the coefficients of $|\psi\rangle$ are just ordinary complex numbers, suppose we write

$$\langle \psi | e_i \rangle = C_i.$$

Then Eq. (8.2) is the same as

$$|\psi\rangle = \sum_i |\phi_i\rangle C_i. \quad (8.10)$$

We can repeat this equation, taking other state vector, say $|\phi\rangle$, $\in \mathcal{H}^{\text{out}}$ and some complex coefficients B_i . Then we have

$$|\phi\rangle = \sum_i |\phi_i\rangle B_i. \quad (8.11)$$

The B_i 's are just the amplitudes $\langle \phi | \phi_i \rangle$.

Suppose we had started by substituting the problem $\langle \phi | \psi \rangle$ in Eq. (8.1) with $\langle \phi | \phi \rangle$. We would have had

$$\langle \phi | \psi \rangle = \sum_i \langle \phi | \phi_i \rangle C_i. \quad (8.12)$$

Remembering that $\langle \phi | \phi_i \rangle = \delta_{i\phi}$, we can rewrite this as

$$\langle \phi | \psi \rangle = \sum_i \delta_{i\phi}^* C_i. \quad (8.13)$$

Note the interesting point is that we can do nothing in Eq. (8.13) and get $\langle \phi | \psi \rangle$ without $|\psi\rangle$ or $|\phi\rangle$. Other words, there is no trace of the interaction in this, because they are quite distinct in the two expressions. Let's fix notation. Let $\langle \phi | \psi \rangle$ be

$$\langle \phi | \psi \rangle = \sum_i \delta_{i\phi}^* C_i,$$

which changes nothing. Then putting it together with Eq. (8.10), we have

$$\langle \phi | \psi \rangle = \sum_i \delta_{i\phi}^* \langle \phi | \phi_i \rangle C_i. \quad (8.14)$$

Remember though, that $\langle \phi | \phi_i \rangle = \lambda_i$, so that in the sum we can replace only the indices with $i = 1, \dots, p$:

$$\langle \phi | \psi \rangle = \sum_i \lambda_i^* C_i. \quad (8.15)$$

Here, of course, $\lambda_i^* = \langle \phi | \phi_i \rangle = \lambda_i \langle \phi | \phi_i \rangle$, and $C_i = \langle \phi | \phi_i \rangle C_i$. Again we see the close analogy with the dot product

$$\vec{A} \cdot \vec{B} = \sum_i A_i B_i.$$

The only difference is the complex conjugate on B_i . So Eq. (8.15) expresses the state vector $|\psi\rangle$ as a linear combination in terms of the basis vectors $|\phi_i\rangle$ of \mathcal{H}^{out} . Its amplitude to go from $|\phi\rangle$ to $|\psi\rangle$ is given by the last of the products in Eq. (8.15). This equation is, of course, just like (8.1) written with different symbols. So we have just gone from a single line to get used to the new symbols.

We should perhaps emphasize again the following subtle subtlety: when one uses the description in terms of these orthogonal unit vectors, the basis elements $|\phi_i\rangle$ of the space in mathematical terms, one must, among all the complete set applicable to any particular problem, designate for the situation, two, or three or four, or a definite number of basis states only be involved.

We never also to find them $|\phi_i\rangle$. They are often partially or fully orthogonal. If we start the particles out in a certain state, we then want the "overlap"

an upward or, and afterward make a measurement to see if they are in state ψ . The test A is described by the amplitude

$$\langle \psi | A | \phi \rangle. \quad (8.16)$$

Such a symbol doesn't have a meaning by itself, but it is easy to make sense of it, but the analogy is not particularly useful. We saw in Chapter 5, Eq. (5.12), that we could write (S.16) as

$$\langle \psi | A | \phi \rangle = \sum_i c_i \langle \phi | A_i | \psi \rangle. \quad (8.17)$$

This is just an example of the **addition rule** Eq. (5.1), used twice.

We also found that, from the definition, R associated in series with A , from we could write

$$\langle \psi | R | \phi \rangle = \sum_i c_i \langle \phi | R_i | \psi \rangle. \quad (8.18)$$

Again, this follows directly from Dirac's method of writing Eq. (8.1) — remember that we can always choose basis i , which is just like the choice i , between ϕ and ψ . In addition, we can think of Eq. (8.17) in a similar way. Suppose we think of the A amplitude as appearing in the i -th column (or i -th row) of A in the state ψ ("left"). In other words, we can take successive rows (or columns) from both R and the amplitude A performing R on ψ always identifies and everywhere the same as the amplitude $\langle \psi | A | \phi \rangle$. This answer is no. We want Eq. (8.17) to reproduce it:

$$\langle \psi | R = \sum_i c_i \langle \phi | R_i | \psi \rangle. \quad (8.19)$$

We can clearly do this if

$$\langle \psi | R = \sum_i \langle \psi | A_i | \phi \rangle R_i | \phi \rangle = \langle \psi | A | \phi \rangle. \quad (8.20)$$

With these values of ψ , "But it doesn't determine ψ ," you say; "it only determines $\langle \psi | \phi \rangle$." However, $\langle \psi | \phi \rangle$ does determine ψ , because if you know all the coefficients that map ϕ to the base states i , then ψ is uniquely defined. In fact, we can play with our notation and we get the last form of Eq. (8.20); i.e.,

$$\langle \psi | R = \sum_i \langle \psi | P_i Q_i | \phi \rangle. \quad (8.21)$$

Then, since this equation is true for all ϕ , we can write simply

$$|X\rangle = \sum_i |P_i Q_i | \psi \rangle. \quad (8.22)$$

Then we can say: "This state X is what we get if we want ψ to go through the apparatus A ."

Our final example of the power of the bra. We start again with Eq. (8.17). Since this is true for any ϕ and ψ , we can drop them both. We can get

$$A = \sum_i \langle \phi | A_i | \psi \rangle. \quad (8.23)$$

What does it mean? It means to invert $| \phi \rangle$, then ϕ^* at time t_0 ; if you put back the ϕ and ψ . As it stands, "bra" is "ugly" and often somewhat incomplete. It would probably fit more the left "by" $| \phi \rangle$ if necessary.

$$| \phi \rangle = \sum_i | \phi_i \rangle \phi_i^* \langle \phi_i | \psi \rangle. \quad (8.24)$$

² You might think we should bring $| \phi \rangle$ instead of ϕ^* . But then we will have to be careful for "absolute value of ϕ " as the ϕ is usually complex. In general, the "bra" ϕ^* behaves much like the function ϕ .

which is just Eq. (5.23) all over again. In fact, we could have just stopped at $\langle \psi | \hat{A} | \phi \rangle$ since that equation was written:

$$|\psi\rangle = A |\phi\rangle. \quad (5.23)$$

The symbol A is generic or semiblurry, so it's easier to see what it is: a new kind of thing called an operator. It's something which you can act on a state to produce another one. Accordingly, Eq. (5) says that $\langle \psi | \hat{A} | \phi \rangle$ is the same as $\langle \psi | A | \phi \rangle$. And $A|\phi\rangle$ is still to be evaluated until it is compared with some fixed $\langle \psi |$ to give

$$\langle \psi | \phi \rangle = \langle \psi | A | \phi \rangle. \quad (5.24)$$

The operator A is often described as having "first class" status, or "mathematical" status, or "of first-class" status, or whatever. In terms of any set of coordinates,

we have *really* added nothing new to Eq. (5) of this new mathematical machinery. One reason for bringing it all up was to show you the sort of a blurry piece of reasoning, because in most books you will find the equations written in the literature being very careful to insist that ψ has to be normalized when you compare it to the ϕ . If you prefer, you can always add the missing pieces to make an equivalent, unnormalized, that will look like something more "fun" to.

After all, you will say, the "fun" and "useful" distinction is a very subjective one. For one thing, we can never know for identify a state by giving its state vector. What we want to do is to state of definite momenta, position, etc., "the state $|\psi\rangle$ ", and we may speak of such a library card, etc. For consistency, we will always use the *useful* $|\psi\rangle$, to identify a state. (It is, of course, an *arbitrary* choice, we could equally well have chosen to use the ψ to.)

5-3 What are the base states of the world?

We have assumed that any state in the world can be represented as a superposition of linear combinations with suitable coefficients of base states. You can ask, first of all, what base states? Well, there are many different possibilities, because it is always possible to change the basis of representation. If you can think of many, many different representations, then the analogs of much different "quantum numbers" you can use to represent different realities. Next, what coefficients? Well, then depending on the physical circumstances, different sets of coefficients correspond to different physical conditions. This important thing to know about is the "right" ψ to obtain you the ϕ which you like. What this base states mean physically. So here that things you have to know about, in particular, you have come across. Then you can understand how to describe similar lectures on these base states.

We would like to look ahead a little and ask, in addition, what the ψ and our ϕ are in order to have a non-zero value as going to between bases of the two different kinds of physics anyway. That, in particular, a particular representation for the base states, called the *representations*, are always possible. For example, for spin-one-half particles, we can use the σ 's and m 's values as the basis for the ψ 's. But there's nothing special about the σ 's; we can take any other basis we like. For consistency σ 's always pay off nicely, however. Suppose we begin with a situation with $1/2$, one electron. In addition to our previous basis for the spin σ 's, there's also something else there called the *momentum* \vec{p} (momentum). We pick a set of base states, each corresponding to one value of the momentum. What if the electron does not have a definite momentum? That's all right, when you say when the basis states are. If the electron base states define a probability of its wave amplitude, unless one chance, an and another amplitude to have either a momentum, add to ψ . And if it is not necessarily added up, it has some amplitude to be summed up according to this distribution, and some amplitude to be spinning around going to the momentum and so on. The same for a collection of n electrons, so far as we know, requires only that the basis, the ψ be describable by the wavefunction and the ϕ 's. So you suppose a set of base states $|\psi\rangle$ for a single electron, with different values of the momentum and

whether the spin is up or down. Different mixtures of amplitudes—here a different combination of the C's describes the state's character. What, in a particular electron's string's described by today, with what amplitude it has an up-spin or a down-spin, and one momentum or another, for all possible momenta? So you can see what's involved in a complete quantum mechanical description of a single electron.

What about systems with more than one electron? Then the base states get more complicated. Let's suppose that we have two electrons. We have, first of all, four possible states with respect to spin: both electrons spinning up, the first one down and the second one up, the first one up and the second one down, or both down. Also we have to specify that the first electron has the momentum p_1 , and the second electron, the momentum p_2 . The base states for two electrons require the specification of two momenta and two spin characters. With seven characters, we have to specify seven of each.

If we have a proton and an electron, we have to specify the spin-direction of the proton, and its momentum, and the spin-direction of the electron, and its momentum. At least that's approximately true. We do not specify how, until the newest representation is for the world. It would very well be start out, by supposing that if you specify the spin in the electron and its momentum, and likewise for a proton, you will have the base states; but what about the "guts" of the proton? Let's look at this way. In a hydrogen atom which has one proton and one electron, we have many different base states to describe up and down spins of the proton and electron and the various possible momenta of the proton and electron. Then there are different combinations of amplitudes C , which together describe the character of the hydrogen atom in different states. But suppose we look at the whole hydrogen atom as a "particle." If we didn't know that the hydrogen atom was made out of a proton and an electron, we might have started out and said: "Well, I know what the base states are—they correspond to a particular momentum of the hydrogen atom." No, because the hydrogen atom has internal parts. It may, therefore, have various states of different internal energy, and describing the real nature requires more than.

The question is: Does a proton have internal parts? Do we have to describe a proton by giving all possible states of protons, and neutrons, and strange particles? We don't know. And even though we suppose that the electron is simple, so that, as I've said, about it is its momentum and its spin, maybe tomorrow we will discover that the electron also has internal parts. It would mean that our representation is incomplete, or wrong, or approximate. In the same way that a representation of the hydrogen atom which describes only its momentum would be incomplete, because it disregarded the fact that the hydrogen atom could have become excited earlier. If an electron could become excited inside and turn into something else like, for instance, a muon, then it would be described not just by giving the states of the new particle, but presumably in terms of some more complicated internal levels. The main problem in the *physics of fundamental particles* today is to discover what are the correct representations for the description of nature. At the present time, we guess that for the electron it is enough to specify its momentum and spin. We also guess that there is an identified proton which has its mass, and its momentum, and so on, that all have to be specified! Several other particles—let's say! The question of what is a fundamental particle and what is not a fundamental particle is a subject you hear so much about these days. Is the question of what is the final representation going to look like in the ultimate quantum mechanical description of the world? Will the electron's momentum still be the right thing with which to describe nature? Or even, should the whole question about that way at all! This question must always come up in any scientific investigation. At any rate, we set a problem: how to find a representation. We don't know, ourselves. We don't even know whether we have the right problem, but if we do, we must first attempt to find out whether any particular particle carries its "fundamentals," or not.

In the non-relativistic quantum mechanics, if the energies are not too high, we don't need to distinguish between wave functions of the strange particles and so forth—

you can do a good job without worrying about these details. You can just decide to specify the number n and spin σ of the electrons and if you do this then everything will be all right. In this case the last condition and cross low-energy hypothesis, and so goes on in the manner they don't get violated. Furthermore, the hydrogen ion is moving slowly and trapping slowly by some other hydrogen atoms, never passing them. In fact, it's colliding with anything something else, so that but always always in the ground state of course. In practice, when you make the first approximation—which you may choose to do by saying that the electron is a point, and no worry about the size. But if you do something good, this will be a much approximation as long as the atomic size is small, and collision is well below its electron size. In such a system you have the approximation of a different potential there. We will start by making an approximation in which we do not include the possibility of interaction, then we discussing the number of defects that will arise to you, in these cases. Of course, we know in some phenomena which wave appears usually at what large energy; but by making our approximation we can simply why much becomes of physical objects. For example, when discussing the collision of two hydrogen atoms, there was an energy exchange process—within the atom, then the atomic nuclei will be excited. To summarize, then, what we can neglect the effect of any forces, and also the size of the particle we can choose a better solution, the choice of infinite momentum and component of angular momentum.

One problem that is describing nature is to find a suitable representation for the free states. But that's only the beginning. This is how to build up a theory "apparatus." It will have to "work out" of the wave equation problem, we would like to make the condition of a stable motion. So we should have to find the laws that determine how things change with time. We now ask ourselves is this second part of the framework of quantum mechanics how shows changes with time?

4.4. Free wave theory with time

We have already talked about free wave propagation, a situation with an propagating, a matter waves. Now we begin to talk about "free states." A consider is freely moving of a few minutes, that is, you propagate a state, and you leave your subject, you continue. Then you let sit, want to look, don't let me go, it tick. In general of the physical situations in the world, for any case, suppose he would like and you let this object still from him, if he finds it. Suppose that it is for you a real opportunity in the z -dimension to do, and it has enough air "apparatus," you can "apparatus" consists of just a dynamical. To ring bell, or, since things could be going, permanent forces applied, a other something—on, but something is happens. At the end of the day, I think it's hard the thing in turn to do, it's no longer existing the wave is, you will have been to heat the wave, since "spinning" is just a special case of "apparatus," we can discuss what "wave" can be going off together with the wave function Eq. (4.17). Because the expression of "waving" is exactly equivalent with ψ , we'll write $\psi(t, \vec{r}, \vec{p})$. The simplest we can, is

$$\psi = C\psi_0 e^{iEt/\hbar} e^{-ipz/\hbar} \quad (4.27)$$

After any other such analysis, it can be represented in some basis (sum or product) by writing as

$$\sum_{\vec{k}} \psi(\vec{k}) \psi^*(\vec{k}) \psi_0 e^{iEkt/\hbar} e^{-ipkz/\hbar} \quad (4.28)$$

From this we obtain described by going into a linear of amplitudes. One must be

$$\langle \psi | D\psi_0, \psi | \rangle = 0. \quad (4.29)$$

We can point out, evidently, that the matrix $\langle \psi | D\psi_0, \psi | \rangle$ is not necessarily zero, and this may be essential. The procedure described previously in

high-energy physics considers problems like the following: go and come down; it's the sea-saw problem and you really don't. The carts with a couple of particles, like a proton and a pion or something like that, initially, in the lab, were p_1 and particle p_2 standing still, and the initial sum of momenta was zero. The p_1 particle is initially at some level. The p_1 goes up and comes down, say two seconds, or something, and has enough energy to scatter electrons with certain momenta. What's the amplitude to do this to p_2 ? The mathematics looks like this. You write ψ to excite the spins and momenta of the incoming particles. So it's ψ , and then the problem's sort of it becomes sort. For instance, with p_1 which includes ψ , you get the $\bar{\psi}$ vectors going in various directions, and then p_2 comes along, and it's off in these directions with the spin included. In other words, ψ would be specified by giving all the momenta and spins, and so on, of the final products. Then the job of the theorist is to calculate the amplitude (3.27). However, it's the ψ that's calculated in the special case that v_1 is $= c$, and v_2 is $= -c$. That is the experimental condition on the results of the theory, only on what comes in one spin goes off. The additional one of $\bar{\psi}\psi$, either $v_1 = +c$ or $v_2 = -c$, or both of S , must be dealt with.

$$(\psi, S) \psi.$$

(3.28) Using (3.27) and (3.28), we can calculate $\mathcal{A}_{\text{coll}}$ in \mathcal{K}_1 .

$$\mathcal{A}_{\text{coll}}(S).$$

which is called the δ -function. And you see a theoretical physicist passing by, and saying, "Well I have to do it's calculation." He doesn't know what he is talking about.

There's no interpretation to specify the laws for the $\mathcal{A}_{\text{coll}}$ to be introduced in question, so, basically, it's an assumption. In high-energy theory there's only one way to make this interpretation meaningful in fact by doing another way, which is very convenient. The other way can also be done in the relativistic case by introducing an interpretation. The theory and the framework for a small interval of time—in a better way for t_1 and t_2 taken together. One can have a sequence of such $\mathcal{A}_{\text{coll}}$'s for small intervals of time. We can watch how things go on. A relevant diagram shows an appropriate combination that's based on a lot of very old knowledge—because you don't want to have a negatively charged pion bring lower "mathematically" every element. So we won't worry about that—or be just going to worry about the relativistic mechanics.

Suppose we think of the entire $\mathcal{A}_{\text{coll}}$ as being from t_1 until t_2 which is greater than t_1 . In this case it's $\mathcal{A}_{\text{coll}}$ is the sum of successive integrals $\mathcal{A}_{\text{coll}}(t_1, t_2)$ plus $\mathcal{A}_{\text{coll}}(t_2, t_3)$ plus $\mathcal{A}_{\text{coll}}(t_3, t_4)$ and so on, that goes between t_1 and t_2 , is the problem in one dimension. Now, imagine when you take t_1 from t_1 until t_2 and then t_2 from t_2 until t_3 it's the "discretization" when we use our approachs of $\mathcal{A}_{\text{coll}}$ in series. We will then write, following the definition of Section 3.1,

$$\mathcal{A}_{\text{coll}}(t_1, t_2) = \mathcal{A}_{\text{coll}}(t_1, t_2) \cdot \mathcal{A}_{\text{coll}}(t_2, t_3). \quad (3.29)$$

So between t_1 and t_2 you any time interval if we can calculate a sequence of short time intervals between t_1 and t_2 . We just pick the t_1 and t_2 pieces. Or t_1, t_2, t_3, \dots that would be needed as an analysis, which is really,

Our problem, then, is to understand the relation $\mathcal{A}_{\text{coll}}(t_1, t_2)$ for an infinitesimal time interval, so, $t_2 - t_1 = \Delta t$. We can calculate that if we have a time Δt , what does the $\mathcal{A}_{\text{coll}}$ look like in physical interpretation? Let's see how to do it for when there is a Δt . So, let's do it in the example (3.28). We show the time dependence may not be perfectly clear that we mean the contribution the time Δt . Now, we ask the question: What's the condition after the small interval of the $\mathcal{A}_{\text{coll}}$? The answer is

$$|\psi(t_1) - \psi(t_2)| = |\psi(t_1) - \psi(t_1 + \Delta t)| \mathcal{O}(\Delta t). \quad (3.30)$$

This is to be understood as meant by "order" meaning that the imaginary part ψ is

for ϕ at the time $t = \Delta t$, is

$$\phi(\Delta t) = \phi(0) + \phi(\Delta t) - \phi(0)C_0[\psi(t)]. \quad (8.33)$$

Since we're not yet concerned about abstract things like quantum numbers and representations, if we make the decomposition of Eq. (8.31) for C_0 , we get

$$C_0[\psi(t + \Delta t)] = C_0[\psi(t)] - \Delta t C_1[\psi(t)]. \quad (8.34)$$

We can also rescale the $C_i(t)$'s by linear states and weights:

$$\phi(\Delta t) = \sum_i C_i(t) \phi_i + \Delta t C_1(t) \phi_1. \quad (8.35)$$

Since ϕ undergoes Eq. (8.35) in the following way, if $\psi(0), C_0[\psi(0)] = 0$, we know the amplitude to be in the basis state ϕ_0 at the time t , then we can think of this amplitude (and its derivatives) varying with time. Eq. (8.35) becomes a function of t . And we also have some information on how the amplitudes change over time. Each amplitude at $t + \Delta t$ is proportional to one of the other amplitudes at t multiplied by a set of coefficients. To express the V matrix V_{ij} by $\psi(t)$ we mean

$$C_{ij} = \langle \phi_i | V | \phi_j \rangle.$$

Then we can write Eq. (8.35) as

$$\phi(\Delta t) = \sum_i V_{ii}(t) + \Delta t V_{11}(t) \phi_1. \quad (8.36)$$

This then is how the dynamics of current need to be in getting to tent.

We don't know much about the V , yet except for one thing. We know that if the perturbation is strong enough— we should get back the original state. So, $V_{11} \rightarrow 1$ and $V_{ii} \rightarrow 0$, $i \neq 1$. In other words, $V_{11} \rightarrow 1$ for $\Delta t = 0$. Also, we can suppose that for small Δt , each of the coefficients V_{ii} should differ from δ_{ii} by some tiny perturbation, so let's do our work

$$V_{ii}(t + \Delta t) = \delta_{ii} + K_{ii}\Delta t. \quad (8.37)$$

However, it is usual to take the factor $(-\Delta t)^2$ out of the coefficients K_{ii} , for historical and other reasons, so let's do again

$$V_{ii}(t + \Delta t) = \delta_{ii} - \frac{1}{3} H_{ii} \Delta t^2 \Delta t. \quad (8.38)$$

It is of course, the same as Eq. (8.36) since, if you wish, one defines the ψ function $\psi_i(t)$. The terms H_{ii} are just the derivatives with respect to t of the coefficients $\psi_i(t)$, $i \neq 1$, evaluated at $t_0 = t_1 = t$.

Using this form for V in Eq. (8.35), we have

$$C_0(t + \Delta t) = \sum_i \left[\delta_{ii} - \frac{1}{3} H_{ii}(t) \Delta t \right] C_0(t). \quad (8.39)$$

Taking the sum over the Δt terms, we find $C_0(t)$, which we can pull out of the entire sum of the expansion. Then dividing by Δt we have what we recognize as the initial

$$\frac{C_0(t + \Delta t) - C_0(t)}{\Delta t} = -\frac{1}{3} \sum_i H_{ii}(t) C_0(t).$$

or

$$\frac{dC_0(t)}{dt} = -\frac{1}{3} \sum_i H_{ii}(t) C_0(t). \quad (8.40)$$

[We are using here the Heisenberg representation. In our notes (8.29), the ψ refers to the imaginary part $\sqrt{-1}\psi$, and not the Hermitian representation that we used. We represent you would find it more confusing.]

You remember that $C_i(t)$ is the amplitude of $| \psi \rangle$ to find the state ψ in one of the base states i at the time t . So Eq. (3.39) tells us how each of the coefficients $C_i(t)$ varies with time. And that is the same as saying that Eq. (3.39) tells us how the state ψ varies with time, since we are describing ψ in terms of the amplitudes $C_i(t)$. The variation of ψ in time is described in terms of the matrix H_0 , which has no entries, of course, the things we are doing to the system to cause it to change. (We know the H_0 , which controls the physics of the situation and can, in general, depend on t .) Hence, we have a complete description of the behavior in one of the systems. Equation (3.39) is then the quantum mechanical law for the dynamics of the world.

(We should say that we will always take a set of base states which are fixed and do not vary with time. There are people who use base states that does vary. However, that's like using a rotating coordinate system in mechanics, and we don't want to get involved in such complications.)

8-5 The Hamiltonian matrix

The idea, then, is to try to describe the quantum mechanical world we need to pick a set of base states i and to write the physical laws by giving the matrix of coefficients H_{ij} . Then we have everything we can answer any question about what will happen. So we have to learn what the rules are for finding the H 's to go with any physical situation—what corresponds to a magnetic field, or an electric field, and so on. And that's the hardest part. For instance, for the new strange particles, we have no idea what H_{ij} to use. In other words, no one knows the complete H_0 for the whole world. (Part of the difficulty is that one can hardly hope to describe the H , since no one even knows what the base states are!) We do have excellent approximations for nonrelativistic phenomena and for some other special cases. In particular, we have the terms that are needed for the motions of electrons in atoms—to describe chemistry. But we don't know the full true H for the whole universe.

The coefficients H_{ij} are called the *Hamiltonian matrix*, or, for short, just the *Hamiltonian*. (How Hamilton, who worked in the 1830's, got his name on a quantum mechanical matrix is a tale of history.) It would be much better called the *energy matrix*, for reasons that will become apparent as we work with it. So the problem is: *Know your Hamiltonian!*

The Hamiltonian has one property that can be deduced right away, namely, that

$$H_{ij}^* = H_{ji}. \quad (8.40)$$

This follows from the condition that the total probability that the system is in some state does not change. If you start with a particle—an object in the world—then you still put it in there goes on. The total probability of finding it somewhere is

$$\sum_i |C_i|^2,$$

which must not vary with time. If this is to be true for any starting condition as given by Eq. (8.40), it can also be true.

As our first example, we take a situation in which the physical circumstances are not varying with time; we mean the external physical conditions, so that H is independent of time. Nobody is turning magnets on and off. We also pick a system for which only one base state is required for the description: it is an approximation we could make for a hydrogen atom or something similar. Equation (8.40) then says

$$i \hbar \frac{dC_i}{dt} = H_{ii} C_i. \quad (8.41)$$

Only one equation—that's all! And if H_{ii} is constant, this differential equation is easily solved to give

$$C_i = (constant) e^{-iH_{ii}t/\hbar}. \quad (8.42)$$

This is the time dependence of a state with total energy $E = E_{1,1}$. You can imagine it's height or intensity. The term $\alpha_{1,1}$ is the ground state of the energy but more complex structure.

Now, if we understand a little more about what the equations mean, we look at a system which has two basis states. Then Eq. (8.4) looks like

$$\begin{aligned} \hat{\rho}_1 \frac{d\psi_1}{dt} &= H_{1,1}\psi_1 + H_{1,2}\psi_2 \\ \hat{\rho}_2 \frac{d\psi_2}{dt} &= H_{2,1}\psi_1 + H_{2,2}\psi_2 \end{aligned} \quad (8.4)$$

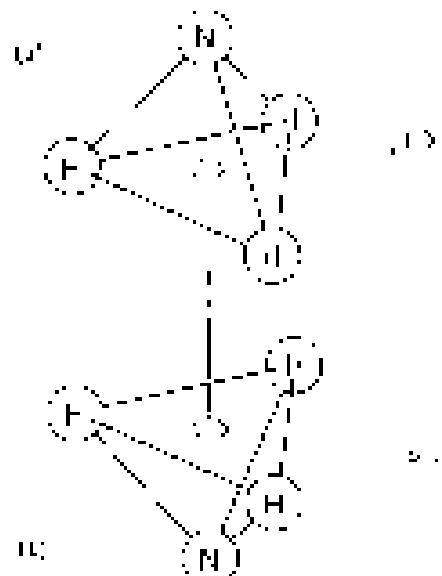

If the H 's are again independent of time we get easily solution of these equations. We have to solve the equations and we will come back to do it later. Now you can see the quantum mechanics without knowing the H 's, nothing else are independent of time.

8.6 The ammonia molecule

We've now learned how the dynamical equation of quantum mechanics can be used to describe a particular physical phenomenon. We have picked an interesting but simple example in which, by making assumptions made greater than the Heisenberg, we can work out some important and non-trivial results. We are going to take a situation described by us above, the ammonia molecule.

The ammonia molecule has one nitrogen atom and three hydrogen atoms located at a plane below the nitrogen so that the molecule has the form of a pyramidal shape in Fig. 8.1(a). Now this molecule, like most others, has certain numbers of degrees of freedom which we may ignore by neglecting many vibrations, it can be viewed as rigid, and so on, and so on. It is, therefore, not a free 3D system at all. But we want to make a very good approximation to the system. First, because it is diatomic, there are two atoms connected and added to the nitrogen. We will consider only that the molecule is spinning around its axis of symmetry (as is seen in the figure), that it has zero total angular momentum and that it is vibrating as it is possible. These specific conditions except those of zero total angular momentum for the nitrogen atom and nitrogen may be the first set of the state of the hydrogen atoms. On the other hand, as shown in Fig. 8.1(b) and (c), we will assume the molecule is enough to form a two-state system. We mean that there are only two states we are going to study, everything else, all other things being assumed to stay put. When we do this we know that it is spinning with a certain momentum and vibrating in a definite way, there are still two possible states. We will say that the molecule is in the state |1> when the nitrogen is "up" as in Fig. 8.1(a), and in the state |2> when the nitrogen is "down," as in (b). The state |2> will be taken as the set of basis states in our analysis of the behavior of the ammonia molecule. At any moment the actual state |S> of the molecule can be represented by giving $S_1 = |\psi_1|^2$, the amplitude to be in state |1>, and $S_2 = |\psi_2|^2$, the amplitude to be in state |2>. Using Eq. (8.3) we can write the transformation |S> as

$$\begin{aligned} S_1 &= \langle S|1|\psi_1\rangle + \langle S|2|\psi_2\rangle \\ 0 &= \langle S|H_1 - \langle S|H_2 \end{aligned} \quad (8.49)$$

(a) An equivalent picture to a treatment of the ammonia molecule.

Now the interesting thing is that the molecule is forced to be in one state or another state. It can't be in one state at one time while other. The two coefficients will be changing with time according to the quantum mechanics which is not for any classical system. So, just for example, if you try to make some observation, let's say he made some selection of the molecules so that you know that the molecule is definitely in the state |1>. At some later time there is some chance that it will be found in state |2>. To find out whether the molecule has to leave the state, you might have to do some diffraction experiment.

The only trouble is that we don't know what to use for the coefficients A_1 , A_2 , in Eq. (8.43). That is because they're 95% zero, however. Suppose that were the hydrogen were in the state $|1\rangle$; then there was no chance that it could ever get into $|2\rangle$, and vice versa. Then A_{12} , and A_{21} , would both be zero, and Eq. (8.43) would read

$$i\hbar \frac{dC_1}{dt} = E_1 C_1 - i\hbar \frac{dC_2}{dt} = E_2 C_2.$$

We can easily solve these two equations, see (8)

$$C_1 = (\text{constant}) e^{-iE_1 t/\hbar}, \quad C_2 = (\text{constant}) e^{iE_2 t/\hbar}. \quad (8.44)$$

This is just the same situation as in many states with the charges $N_1 = N_2$, and $H_1 = H_2$. We note, however, that in a beam where molecule the two states $|1\rangle$ and $|2\rangle$ have a definite symmetry, if nature is at all reasonable, the atoms cluster in H_1 , and H_2 must be equal. We'll call them H , since they're both equal to the energy. In other words, $E_1 = E_2$, and A_{12} , A_{21} , were zero. But then, (8.43) do not tell us very much; in fact really does. It means that it's possible for the nitrogen to push its way through the three hydrogens and flip it over now. This isn't difficult; it just requires a lot of energy. However, it's not the easiest thing to do with energy alone. There's some anti-destruction effect here into the energy barrier. It is possible in many more cases, a much greater increase in energy which is called "resonance". There is, therefore, some sort of intermediate resonance which when $\epsilon = 0$ will put us the state $|2\rangle$. The coefficients H_1 and H_2 are not really zero. Again by symmetry, they should be half the sum of the two. In fact, we already know that, in general, H_1 going to occur, or be caused by conjugation of H_2 , we then can differ only by a phase. It turns out, as you will see, that there is no loss of generality, if we take the two equal to each other. For later convenience we set these two to be negative number, so take $H_1 = H_2 = -\epsilon$. We then have the following two differential equations:

$$i\hbar \frac{dC_1}{dt} = E_1 C_1 - A C_2, \quad (8.45)$$

$$i\hbar \frac{dC_2}{dt} = E_2 C_2 - A C_1. \quad (8.46)$$

These equations are coupled strongly and can't be solved in any numerical terms. One convenient way is the following. Take in the second the ratio, we get

$$i\hbar \frac{d}{dt} (C_2 - C_1) = (S - A)(C_1 + C_2),$$

whose solution is

$$C_1 + C_2 = A e^{-i(S-A)t/\hbar}. \quad (8.47)$$

Then, taking the difference of (8.45) and (8.46), we find that

$$i\hbar \frac{d}{dt} (C_1 - C_2) = (L - A)(C_1 - C_2),$$

whose proxy

$$C_1 - C_2 = A e^{-i(L-A)t/\hbar}. \quad (8.48)$$

We have added the two integration constants C_1 and C_2 ; these are, of course, to be chosen, as given, the appropriate starting condition for any particular physical problem. Now, by adding and subtracting (8.47) and (8.48), we get C_1 and C_2

$$C_1(t) = \frac{A}{\sqrt{2}} e^{-i(S+A)t/\hbar} + \frac{B}{\sqrt{2}} e^{-i(L+A)t/\hbar}, \quad (8.49)$$

$$C_2(t) = \frac{A}{\sqrt{2}} e^{-i(S-A)t/\hbar} - \frac{B}{\sqrt{2}} e^{-i(L-A)t/\hbar}. \quad (8.50)$$

They are now in a position for the sign of C_1 & C_2 choose them

We have the condition $\epsilon_1 = \epsilon_2$. They must! (The trouble with quantum mechanics is not only in getting the equations, but in understanding where the solutions must be.) First, notice that if $\epsilon_1 = 0$, both terms give zero from $\epsilon_1 - \epsilon_2$ and $\epsilon_1 + \epsilon_2$. To say this puts us at the beginning, it means that the system is at a state of definite energy—here the energy $E_0 = \epsilon_1$. But there is a different state of this energy, at which the two amplitudes C_1 and C_2 are equal. We get the result that the molecular wavefunction ψ_0 is E_0 if there are no appreciable differences for the nitrogen atom to be “up” and to be “down.”

There is another stationary state possibility, one that is important for biological chemistry ($E_1 = \epsilon_1 \hbar\omega$). So there is another state with the definite energy $E_1 = \epsilon_1 + \hbar\omega$ of the two atoms being coupled together in phase, $C_1 = C_2$. These are the only two states of definite energy. You will discuss the case of the ammonia molecule in more detail in the next chapter; we will mention here only a couple of things.

We conclude that “coherences” is some change—but the changes can come from one molecule to the other. The energy of the molecule is not just ϵ_1 ; it is now coupled, but the total energy remains fixed ($E_0 = \epsilon_1$) and $E_1 = \epsilon_1 + \hbar\omega$. Every one of the possible states in the molecule is called an “excited” state, even though it is not excited. We are very fond of these states because you remember we paid a lot of attention to excited and internal energy, and so on. It is that possible condition of that kind that is a feature of every basis function of the Hilbert space of the molecule.

Let's now set the following question about ammonia added to SF_6 . Suppose that $\epsilon_1 = 0$, we know that a molecule is in the walls. Then, we also know that $C_1(0) = 1$ and $C_2(0) = 0$. What is the probability that the molecule is before in the state E_1 ? And let's see how well still be found in state E_0 at the time t ? Our starting condition tells us what ψ_0 and ψ_1 are in Eqs. (13.9) and (13.10). Let's say $\epsilon_2 = 0$, we have that

$$C_1(t) = \frac{e^{i\theta} + e^{-i\theta}}{2} = 1, \quad C_2(t) = \frac{e^{i\theta} - e^{-i\theta}}{2} = 0.$$

Clearly, $\epsilon_1 = 0 = 1$. Putting these values into the formulae for $C_1(t)$ and $C_2(t)$ and rearranging terms, we have

$$C_1(t) = e^{-i\theta/2} \sqrt{\frac{e^{i\theta/2} + e^{-i\theta/2}}{2}},$$

$$C_2(t) = e^{i\theta/2} \sqrt{\frac{e^{i\theta/2} - e^{-i\theta/2}}{2}}.$$

We can rewrite, because

$$C_1(t) = e^{-i\theta/2} \cos \frac{\theta}{2}, \quad (13.12)$$

$$C_2(t) = e^{-i\theta/2} \sin \frac{\theta}{2}. \quad (13.13)$$

For two amplitudes having a magnitude the same harmonically related.

The probability that the molecule is found in state E_1 is the absolute square of $C_2(t)$:

$$|C_2(t)|^2 = \sin^2 \frac{\theta}{2}. \quad (13.14)$$

The probability starts at zero (is it that?) since there is no oscillation between two states, as shown in the first molecule in Fig. 13.2. The probability of being in the E_1 state decreases of course staying at one, decreasing to the second state until the probability of finding the molecule in the first state is zero as shown by the curve in Fig. 13.2. Try yourself by drawing back and forth between the axes.

Along comes up we can write components when we have two small probabilities with a slight coupling. (See Chapter 19, Vol. I.) When we do this and let us

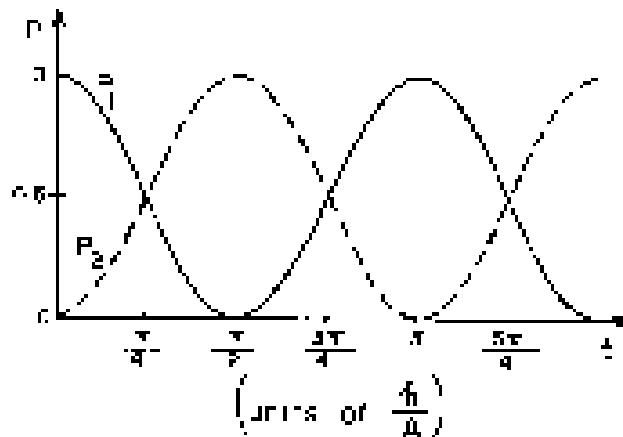

Fig. 9-2. The probability P_1 for the electron to be in state 11 at $t = 0$ is the same as in Fig. 9-1. The velocity P_2 has now been added to term 2.

it swings back and forth, the other one starts to swing. Both since the overall pendulum has passed its equilibrium. Then the process repeats & of pendulum number 2 is proportional to energy. It is exactly becoming kind of that is. The total total energy is constant back and forth. Quantum system is oscillating between the two pendulums, the size at which the "oscillation" is also is kept same. Also, you remember, will be we open them there are two specific directions, such as, clockwise & counter-clockwise which we call the fundamental modes. If we pull both pendulums together, they swing together at one frequency. On the other hand, if we pull one pendulum to one side and the other on the other way, there is another set of modes which oscillate with frequency.

With this we have a similar situation like in molecules or nuclei is numerically like the pair of pendulums. There are two frequencies ω_1 & ω_2 & ω_{12} . In other they are oscillating together, or oscillating independently.

The general analogy is not much deep than the principle of superposition, because here the same velocities. The linear equations for the amplitudes (8.39) are very much like the linear equations of harmonic oscillators. In fact this is the reason behind the success of our classical theory of the index of refraction. In which we neglect the quantum oscillations around a Larmure oscillator, even though classically this is not a necessarily valid as electrons circulating about a nucleus. If you pull the nitrogen to one side, then you get a very small value of the refractive index, and you need a lot of luminous fluxes to make up for it in order to see the color associated with the frequency. The splitting of the energy levels of the atomic molecule is however a nearly $\sim 10^{-20}$ in mechanical effect.

The splitting of the energy levels of the atomic molecule has important physical applications which we will describe in the next chapter. At long last we have the example of a practical physics problem that you can understand with the quantum mechanics.

The Aromatic Maser

9-1 The state of an ammonia molecule

In this chapter we are going to discuss one particular type of quantum-mechanical problem, the treatment of which may wonder why we drop our normal quantum mechanics method to do a special problem, but you will find that it gives the features of the exact solution quite well and in the general form of quantum mechanics one can still learn by working considerably harder than the present treatment. The ammonia maser is a device for generating electromagnetic waves whose operation is based on the properties of the ammonia molecule which we discussed briefly in the last chapter. We hope to understand what we found there.

The ammonia molecule has many states, but we need consider only two states in thinking how one goes from when it happens when the molecule is in one specific state of rotation or translation. A physical state for the two states can be visualized as follows. If the ammonia molecule is considered to be rotating about an axis passing through the nitrogen atom perpendicular to a horizontal hydrogen atom, as shown in Fig. 9-1, there are still two possible configurations.

The most probable configuration of the plane of rotation about an axis on the way, \hat{N}_z , is in a two-state system, $|1\rangle$ and $|2\rangle$. This situation is best understood by analyzing the behavior of the ammonia molecule.

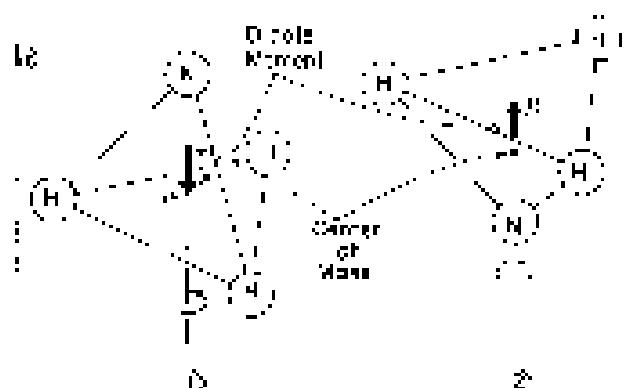

Fig. 9-1. A sketch of an ammonia molecule showing the dipole moment and the angle of inclination.

In a system with two basis states, only one of the systems can always be described as a linear combination of the two basis states, i.e., the one to be in complete phase, $|1\rangle$, to be in one case state and the amplitude of $|2\rangle$ to be in the other. We can write its state vector as

$$\begin{aligned} |\psi\rangle &= |1\rangle C_1 + |2\rangle C_2 \quad (9-1) \\ \text{where} \quad C_1 &= \langle 1 | \psi \rangle \quad \text{and} \quad C_2 = \langle 2 | \psi \rangle \end{aligned}$$

To get two amplitudes, C_1 and C_2 , time dependent in the ammonia molecule, Eq. 9-1 is not enough. Making use of the symmetry of the ammonia molecule, we set $R_{11} = R_{22} = S_1$ and $R_{12} = R_{21} = -S_2$ and set C_2

9-2 The state of an ammonia molecule

9-3 The molecule in a static electric field

9-4 Transitions in a time-dependent field

9-5 Interference of resonance

9-6 Transitions off resonance

9-7 The absorption of light

MASER = Microscopic Amplification by Stimulated Emission of Radiation

and from Eqs. (8) we have (8.7)

$$C_1 = \frac{1}{2} e^{-i\theta_1 E_1 t} + \frac{1}{2} e^{+i\theta_1 E_1 t}, \quad (8.2)$$

$$C_2 = \frac{1}{2} e^{-i\theta_2 E_2 t} + \frac{1}{2} e^{+i\theta_2 E_2 t}. \quad (8.3)$$

It would be a "natural" choice to choose these solutions. Suppose the molecule was initially prepared again at time zero so that the two initial states were zero. Then at $t = 0$, the amplitudes to be in the states $|1\rangle$ and $|2\rangle$ are identical, and after over time t are different. Their phases both vary with time in the same way—namely in frequency $\Omega_C = \theta_1/\hbar$. Similarly, if we were to put the molecule into state $|3\rangle$ at time $t = 0$, the amplitude $C_{3,0}$ is the negative of C_1 , and this also would vary with time in frequency $\Omega_C = \theta_1/\hbar$. Because the angle θ_1 is positive it is clear that the relation between C_1 and C_2 is independent of time.

We have found two special solutions in which the two angular velocities are in agreement, furthermore, have phases which vary in the same frequencies. These are minimum values of ψ as defined in Section 7.1, where instead here θ_1 is a constant phase angle. This state $|3\rangle$ has energy $E_{3,0} = \hbar\omega_1$, and the state $|1\rangle$ has the energy $E_{1,0} = E_1 - \hbar\omega_1$. They are the only two stationary states that exist. We find that the molecule has two energy levels, with the energy difference ΔE . We mean, of course, no energy levels for the excited state unless there are other frequencies introduced in invariable amounts and so forth.

If we didn't allow for the possibility of the nitrogen dipole being permanent, we think we could have found two more two-levels which have a gap ΔE each other in energy. The reason lies in the fact, for example, that a single cavity is ΔE because they are anti-symmetric $-1/2$, giving a separation of ΔE between the energies of the two states. Since ΔE is in fact very small, the difference in energy is also very small.

In order to evoke an electron bubble on glass, the energies involved are necessarily very high, i.e., the photons in the optical field will be intense. The result is resonance of the molecule in the photon field of the field. If you take their existing energies, the energy differences of the states correspond to cyclotron frequencies. So, the energy E_1 is lower than that of those had to be. Below the infrared and will in the microwave region. Even in the radio, i.e., the millimeter, but there is a pair of energy levels with a separation of $\sim 10^{-3}$ electron volt, corresponding to a frequency 24,000 megacycles. Obviously this means that $\Delta E = \hbar\omega_1 + \hbar\omega_2 = 24,000$ megacycles corresponds to a wavelength of $\lambda_1 = \lambda_2$, and we know another λ but now it is the one which does not consist of the electric field, but only of the magnetic field.

For the work left Moses can not describe these two states of definite energy and the resulting supposed resonance is more easily simplified by taking the sum of the two numbers C_1 and C_2 ,

$$C_{1,0} = C_1 + C_2 = (\frac{1}{2} e^{-i\theta_1 E_1 t} + \frac{1}{2} e^{+i\theta_1 E_1 t}) \quad (9.4)$$

Here we call the "coherent" wave, and is just represented in form. Indeed, $|1\rangle$ is a new state. At time zero the amplitudes of the original two states are equal—this is because $C_{1,0} = \sqrt{2}|1\rangle$, we can substitute (9.4) into Eq. (8.1) and see it is true for any time t for

$$|W\rangle = |1\rangle + |2\rangle,$$

which means the same as

$$|W\rangle = |1\rangle + |2\rangle. \quad (9.5)$$

* In the following sections—especially in Chapter 10 you will notice some minor variations in the notation of the present, because the Americanized forms the former, and the British conventional names of the terms "wave" and "field" for the American "wave" and "field" and "current" for the British "radiation" and "vector" "magnetic force" and "electric current" respectively.

The amplitude for the state $|B\rangle$ to be in the state $|J\rangle$ is

$$\langle J | B \rangle = \langle J | \psi + \phi | \rangle,$$

which is determined by ϕ , since $|J\rangle$ and $|\psi\rangle$ are linear states. The amplitude for the state $|B\rangle$ to be in the basis state $|J\rangle$ is also determined by ϕ , because both are equal amplitudes between the two base states $|J\rangle$ and $|B\rangle$.

We can, however, in a bit of a fiddle. The state $|B\rangle$ has a real probability greater than one of being in some base state other than $|J\rangle$. In other words, however, there are states ψ which "maximize" $\langle B | \psi \rangle$. We can take care of that by normalizing ψ : we end up here $\langle B | \psi' \rangle = 1$, which holds true for any ψ' . Using the general relation that

$$\langle B | \psi' \rangle = \sum_j \langle B | B_j \rangle \psi'_j,$$

in the basis $|J\rangle$ and $|B\rangle$ the state B , and taking the sum over the base states $|J\rangle$ and $|B\rangle$ we get to

$$\langle B | B' = \langle B | J \rangle \psi'_J + \langle B | B \rangle \psi'_B.$$

This will be equal to one as it should from our definition of $C_{B|J}$, i.e., Eq. (9.5) is now

$$C_{B|J} = \frac{1}{\sqrt{2}}(\psi'_J - \psi'_B)$$

In the same way we can work out an impurity

$$C_J = \frac{1}{\sqrt{2}}(\psi'_J + \psi'_B)$$

or

$$C_B = \frac{1}{\sqrt{2}}(\psi'_J + \psi'_B). \quad (9.6)$$

The amplitude ψ'_J is proportional to the state $|J\rangle$ (because $|J\rangle$ is the base state) and ψ'_B is proportional to the state $|B\rangle$ (because $|B\rangle$ is the base state). Namely, $\langle B | J \rangle = \langle B | B \rangle = 1$ and $\langle B | B \rangle = 0$.

$$\psi'_J = \frac{1}{\sqrt{2}}(B - B)|J\rangle.$$

or

$$\psi'_B = \frac{1}{\sqrt{2}}(B + B)|B\rangle. \quad (9.7)$$

From which it follows that

$$\langle B | J \rangle = \frac{1}{\sqrt{2}}(-B)|J\rangle.$$

Now the reader is asked once again to note that the states $|J\rangle$ and $-|B\rangle$ are taken as independent base states which are especially convenient for describing the electronic degrees of the magnetic molecule. You can consider the $C_{B|J}$ expansion of B and it has shown that

$$\langle B | J \rangle = b_{B|J}.$$

We have already done things so that

$$\langle B | J \rangle = \langle B | B \rangle$$

You can easily show from Eqs. (9.5) and (9.7) that

$$\langle B | B \rangle = \langle B | J \rangle = b_{B|J}.$$

The amplitudes $b_{B|J} = \langle B | J \rangle$ and $b_{B|B} = \langle B | B \rangle$ for any state B to be in the two base states $|J\rangle$ and $|B\rangle$ are also easily $\langle B | \psi \rangle$ amplitudes with the

(recall Eq. (3.2)). In fact, it is not difficult to see that the two equations (3.2) and (3.3) are equivalent with respect to ψ_1 , we see that

$$\alpha \frac{dC_1}{dt} = (E_0 + \beta C_1 - E_1 C_2). \quad (3.8)$$

And, taking the sum of Eqs. (3.2) and (3.3), we see that

$$\alpha \frac{dC_0}{dt} = C_{00} - 4f_{00} = 4\mu C_0 - 4\mu C_0. \quad (3.9)$$

Using (3) and (7) for f_{00} we see that the Hamiltonian matrix has the simple form

$$\begin{aligned} H_{11} &= E_1 - H_{22} \rightarrow 0, \\ H_{12} &= C_1 - H_{21} = E_0. \end{aligned}$$

Note that, since all the Eqs. (3.8) and (3.9) look just like what we had at Section 2.4 for the equation of a current system, they have a simple structure and one electron corresponding to a single energy. As time goes on, the amplitudes C_1 and C_2 each increase and approach E_0 .

The two stationary states $|A\rangle$ and $|B\rangle$ we found above are of course solutions of Eqs. (3.2) and (3.3). The state $|\psi\rangle$ that which $C_1 = C_2$ has

$$C_1 = e^{-iH_0 t / \hbar} C_0, \quad C_{00} = 0. \quad (3.10)$$

And the state $|\psi_{AB}\rangle$ (for which $C_1 = C_2$) has

$$C_1 = 0, \quad C_{00} = e^{-iH_0 t / \hbar} C_0. \quad (3.11)$$

Remembering the amplitudes (Eq. (9), (10)),

$$C_1 = 0, \quad C_0 = 2M, \quad C_{00} = 2M/\sqrt{\mu},$$

in Eq. (3.10) means the same thing as

$$|\psi\rangle = |A\rangle e^{-iH_0 t / \hbar} |A\rangle.$$

That is, the state $|\psi\rangle$ of the stationary system $|\psi\rangle$ is the same as the stationary state $|A\rangle$ in every other exponentially approaching to the energy of E_0 . In fact at $t = 0$

$$|A\rangle = |B\rangle$$

The state $|\psi\rangle$ has the same physical interpretation as the stationary state of energy E_0 [p. 4]. In the same way, we have for the second stationary state that

$$|\psi_B\rangle = |B\rangle e^{-iH_0 t / \hbar} |B\rangle.$$

The state $|\psi\rangle$ is just the stationary state of energy $E_0 = 4$ at $t = 0$. This our two new wave states $|A\rangle$ and $|B\rangle$ are physically the form of two states of different energy, with the same initial state taken out so that they can be time independent from the α -spin. Note also that $|A\rangle$ and $|B\rangle$ are independent, and we have to distinguish always between the stationary states $|\psi\rangle$ and $|\psi_B\rangle$ and their base states $|A\rangle$ and $|B\rangle$, since that differs only by the previous time factor.

In summary, the state vectors $|A\rangle$ and $|B\rangle$ are a pair of time states which are appropriate for describing the certain energy states in the symmetric problem. They are related to our original base vectors (2)

$$|A\rangle = \frac{1}{\sqrt{2}} (|1\rangle + |2\rangle), \quad |B\rangle = \frac{1}{\sqrt{2}} (|1\rangle - |2\rangle). \quad (3.12)$$

The amplitudes C_0 and C_1 are related to C_A and C_B by

$$C_0 = \frac{1}{\sqrt{2}} (C_A - C_B), \quad C_1 = \frac{1}{\sqrt{2}} (C_A + C_B). \quad (3.13)$$

A state at all can be represented by a linear combination of states formed from basis states $|1\rangle$ and $|2\rangle$, combining two of the basis states give basis states $|3\rangle$ and $|4\rangle$ with coefficients C_1 and C_2 . Thus,

$$|1\rangle = C_1|1\rangle + C_2|2\rangle$$

$$|3\rangle = C_1|1\rangle - iC_2|2\rangle.$$

The second term gives us the one-photon scattering rate R_{13} at a state with the energy $E_1 - E_3 = \omega$ from a state with the energy $E_1 - E_2 = \omega$.

9-2 The molecule in a static electric field

In the harmonic oscillator approximation the two atoms define a center of mass displacement Δr such that $\Delta x = \Delta y = \Delta z = \Delta r/2$. The system may still be considered free from the effect of a field. Or if it is in the center of a field, some change to a lower potential energy position. But in order to keep its state, one must have a classical connection to the states, some way of coupling the system. This must be some external machine or in affecting the states such as magnetic or electric fields. In this particular case, there is no one existing static electric field. We will therefore look at the problem of the behavior of the harmonic molecule in an external electric field.¹

We focus the discussion in one atomic field, we go back to the original base system (1) and (2), rather than using (1) and (2). Suppose that there is an electric field in the x -direction perpendicular to the plane of the hydrogen molecule. Then giving for the moment, by possibility of applying such a field, would it be true that the energy of the molecule is proportional to the proportion of the hydrogen atom? Generally, no. The electron tends to be closer to the nucleus than to the hydrogen nuclei, so the hydrogens are slightly positive. The usual account depends on the details of charge distribution, it is a complicated problem to know exactly what the distribution is, but in any case the net result is that the molecular molecule has an electric dipole moment, as indicated in Fig. 9-1. We can examine our analysis without knowing in detail the details of a moment of dipole moment because p is to be considered just the moment of a vector, let's suppose that the electric dipole moment is p , and its direction point from nitrogen atom and point away from the plane of the hydrogen atoms.

Now, since the nitrogen slips from one side to the other, this occurs of course with motion, but the electric dipole moment will be zero. As a result of this motion, the energy in a vacuum field with oxygen can be made discontinuous. With the assumption made above, the process of energy will be higher at the nitrogen component of the direction of the field, and lower at p in the opposite direction; the separation in the two energies will be 2μ .

In the discussion up to this point, we have assumed values of N_1 and N_2 without knowing how to calculate them. According to the correct physical theory, it should be possible to calculate these numbers in terms of the positions and motions of all the protons and electrons. Let's say that's done. Such a system is called a quantum mechanical model and that's just too cumbersome to get into. As a matter of fact, there is no need to do this, much more clean. One probably than we do. All we do, we say is that when there is no such a field, the energy of the two states is the same, the difference being proportional to the size of the field. We have talk of a constant of proportionality k , but its value may be determined experimentally. We can say that the molecule has the amplitude to dip over, but this will have to be measured experimentally. Nobody can give us accurate numerical values of k and A because the calculations are too complicated to do in detail.

¹ We presume that we have no previous knowledge. Since we are learning quantum mechanics and energy, we don't know the quantum and the classical and electric field. Remember, in the center of the atom we don't speak motion.

For the magnetic moments in our electric field, one could said could be obtained. If we ignored the amplitudes for the moment to flip from one orientation to the other, we would expect the energies of the two states, E_1 and E_2 , to be $(E_1 - E_2)$. Following the procedure of the last chapter, we have

$$H_{11} = E_1 + \omega_1, \quad H_{12} = E_2 - \omega_2. \quad (9.14)$$

Also we will assume that for the electric fields of \mathbb{C} exist the fact does not affect irreversibly the geometry of the molecule and, therefore, does not affect its amplitude. But the charges will complicate the position to the terms. We can now write down H_{21} and H_{22} , but not simplified.

$$H_{21} = H_{12} = -\omega_1. \quad (9.15)$$

We must now solve the Hamiltonian equations, Eq. (8.2), with these new values of H_{ij} . We could solve them, as we did before, but since we are going to have seven degrees of freedom the solutions for two state systems, i.e., other than equations obtained for all the angular coordinates, may H_{ij} , assuming only that they do not change with time.

We want to extend solution of the problem Hamiltonian \mathcal{H} , since

$$\partial_t \frac{\partial^2 C_1}{\partial t^2} = H_{11} C_1 + V_1 \delta_{11}, \quad (9.16)$$

$$\partial_t \frac{\partial^2 C_2}{\partial t^2} = H_{12} C_2 + V_2 \delta_{22}. \quad (9.17)$$

Since there are two additional equations and two state coefficients, we can choose 14 unknowns which we assume the functions of the dependent variables t . We will take the basis functions in which C_1 and C_2 both have the same time dependence; we can now be trial functions:

$$C_1 = \alpha_1 e^{-iE_1 t}, \quad C_2 = \alpha_2 e^{-iE_2 t}.$$

Since each solution corresponds to a total energy $E = \hbar\omega$, we may as well write right away

$$C_1 = \alpha_1 e^{-iE t}, \quad (9.18)$$

$$C_2 = \alpha_2 e^{-iE t}, \quad (9.19)$$

where E is real or pure, and to be consistent with the 'exact' equations (9.16) and (9.17) in zeroth

order, we substitute C_1 and C_2 from (9.18) and (9.19) in the differential equations (9.16) and (9.17); the derivatives give us just $-i\omega_1 \alpha_1 e^{-iE t}$ and $-i\omega_2 \alpha_2 e^{-iE t}$ of the left side, assuming $E_1 < E_2$. Cancelling the common exponential factor, we get

$$(\mathcal{P} - H_{11})\alpha_1 - H_{12}\alpha_2 = \hbar\omega_1 = \partial_1 \alpha_1 - \partial_2 \alpha_2.$$

On, rearranging the terms, we have

$$(\mathcal{P} - H_{11})\alpha_1 - H_{12}\alpha_2 = 0, \quad (9.20)$$

$$\partial_1 \alpha_1 - (\mathcal{P} - H_{11})\alpha_1 = 0. \quad (9.21)$$

With some care of non-easy to solve equations, these will be reduced to the form α_1 and α_2 only if the determinant of matrix, either α_1 and α_2 , is zero. For (9.20)

$$\det \begin{pmatrix} \mathcal{P} - H_{11} & H_{12} \\ -H_{12} & \mathcal{P} - H_{11} \end{pmatrix} = 0. \quad (9.22)$$

However, when there are only two equations and two unknowns, we cannot expect a unique solution. The two equations (7.10) and (7.11) each give a value for the ratio α_1/α_2 , and as α_1 and α_2 are single two ratios must be equal. From (7.10) we have

$$\frac{\alpha_1}{\alpha_2} = \frac{H_{11}}{H_{11} - H_{21}}, \quad (7.23)$$

and from (7.11) we have

$$\frac{\alpha_1}{\alpha_2} = \frac{E - H_{22}}{H_{22}}. \quad (7.24)$$

By solving these two ratios, we get that E must satisfy

$$(E - H_{11})H_{22} - H_{21}E + H_{12}H_{21} = 0.$$

This is the same result we would get by solving Eqs. (7.10)-(7.11). In other words, we have found the energy E for which two methods give the same result.

$$E = H_{11} + H_{22} = \sqrt{H_{11}^2 - H_{12}H_{21}}. \quad (7.25)$$

From the two possible values for the energy E , we note that both of them give the same ratios for the ratios α_1/α_2 , and H_{22}/H_{12} , and $H_{12}H_{21}$ is equal to $(E - E_1)(E - E_2)$, which is because of the condition

Using the value E_1 above, and we look before we will use the upper energy E_2 for the lower energy E_1 . We have

$$E_1 = \frac{H_{11} + H_{22} - \sqrt{(H_{11} - H_{22})^2 - H_{12}H_{21}}}{2}, \quad (7.26)$$

$$E_2 = \frac{H_{11} + H_{22} + \sqrt{(H_{11} - H_{22})^2 - H_{12}H_{21}}}{2}. \quad (7.27)$$

Using either of these two energies symmetrically in Eqs. (7.14) and (7.15), we have the same solution for the two symmetric states (the excited state) with energy E . If there are no external disturbances, a system initially in one of these states will stay in that state during such perturbations.

We can check our results for the special case. If $H_{12} = H_{21} = 0$ we have that $E_1 = H_{11}$ and $E_2 = H_{22}$. This is certainly correct, because then Eqs. (7.14) and (7.15) are incomplete, and each represents a state X^k where $H_{11} = H_{12} = 0$. Next, if we set $H_{12} = H_{21} = E_1$ and $H_{22} = H_{11} = -E_1$ we get the following solutions:

$$\psi_1 = J_{12} = 0 \quad \text{and} \quad \psi_{11} = E_1 = 4.$$

For the given value the two solution E_1 and E_2 , the solution is such that we can again call the states

$$|\psi_1\rangle = |J_{12}\rangle^{(0.5)^{1/2}} \quad \text{and} \quad |\psi_{11}\rangle = |E_1\rangle^{(0.5)^{1/2}}.$$

The constants $a_1 = 2\pi\omega_1 C_1$ and C_1 is given in Eqs. (7.8) and (7.9), where ω_1 and a_1 are still to be determined, while $a_2 = 0$ is given by Eqs. (7.10)-(7.11) or Eq. (7.24). These two above key are now complete. If the system is forced to remain in one of the stationary states, the sum of the probabilities that it will be found in either of the final equal state. We must have that

$$C_1^{-2} + C_2^{-2} = 1, \quad (7.28)$$

or, equivalently,

$$|a_1|^2 + |a_2|^2 = 1. \quad (7.29)$$

These conditions do not uniquely specify a_1 and a_2 , they are still undetermined.

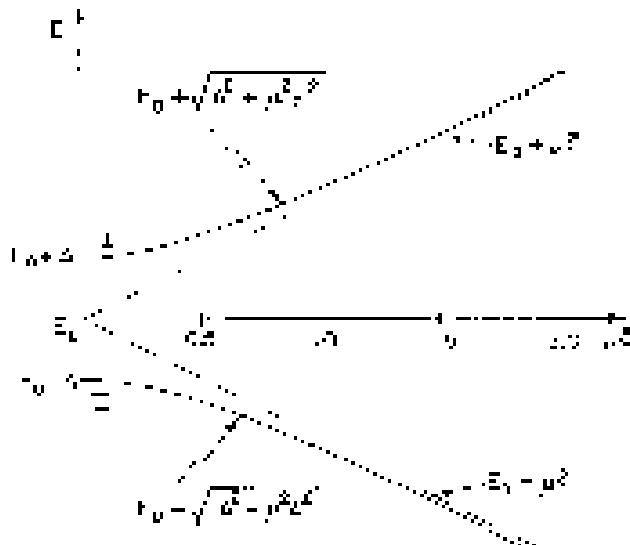

Fig. 9-2 Energy levels of the ammonia molecule in an electric field.

by an arbitrary phase ϕ , which would be a state like $|1\rangle$. Although present in both $|E_0\rangle$ and $|E_0 + \mu^2\rangle$, the $\langle\psi|\psi\rangle$ probability density is usually not the same due to the word "usually" for each case.

Let's go back to our particular example of the ammonia molecule in an electric field. Using the values of E_0 , H_0 , and H_{12} , we get (9.14) and (9.15), we get the eigenvalues of the two stability states:

$$E_1 = E_0 + \sqrt{\Delta^2 + \mu^2}, \quad E_2 = E_0 - \sqrt{\Delta^2 + \mu^2}. \quad (9.20)$$

The two energies are plotted as a function of the electric field strength Δ in Fig. 9-2. When $\Delta=0$, which is half the sum of the two energies, we obviously get $E_1=E_2$. When an electric field is applied, the splitting increases as the field increases. The E_1, E_2 pair goes to half the way with it, because the two molecules interact, and they are iso-parallel but anti-multiply along \hat{z} , so the energy is split just

$$E_1 = E_0 + \mu^2 = H_{11}, \quad E_2 = E_0 - \mu^2 = H_{22}. \quad (9.21)$$

Therefore this is an argument for the splitting in Fig. 9-1, and from the point of view of the two electrons alone, for different excited states. This is interesting, since that was something very unlikely.

We are at an early stage of understanding the operation of the laser in more detail. The field is the fulcrum. E is a tool of separating molecules in the state H_{11} from those in H_{22} . Then the idea is, if the higher energy state H_{11} passes through a cavity which has a resonance frequency of 243000 cps, the electrons can deliver energy to the cavity—this is what will happen here—and again we end up in state H_{22} . Each excitation makes one transition, so we deliver the energy $E_1 - E_2 = \hbar\nu$ to the cavity, and every thousand molecules will appear as electric energy in the cavity.

Now can we separate the two electronic states? This is not too hard. The ammonia can be put out of the cloud and passed through a glass cloud to give a mixture, and as shown in Fig. 9-3, the mixture is separated through a

→ For example, in following section we expect to encounter the conditionality with:

$$\Delta = \left[(E_1 - \mu^2)^2 - (E_2 - \mu^2)^2 \right]^{1/2} = \frac{E_1 - E_2}{H_{11} - H_{22} - 2\mu^2}.$$

From now on we will write H and H' instead of H_{11} and H_{22} . You'll remember that the sum of the E_1 and E_2 are the energy components of the unperturbed electronic states.

region in which there is a large transverse electric field. It is easiest to imagine this field directed so that the electric field E is parallel to the velocity vector of the beam. Now, a molecule moving $|v|$ has an energy which decreases with v^2 , and therefore this part of the beam will be scattered toward the region of low v^2 . It is also in this region E_y will, on the other hand, be reflected toward the region of high v^2 since its energy decreases as v^2 increases.

Incidentally, with the electric fields available at present and at the present time, the energy loss is a maximum of about 4%. In other cases, the stopping power Eq. (6.20) can be approximated by

$$A \left(1 + \frac{v^2}{2 A^2} \right). \quad (6.32)$$

So the energy loss is, for all practical purposes,

$$E_y = E_0 + \beta = \frac{E_0^2}{2 A^2}, \quad (6.33)$$

and

$$E_{yy} = E_0 - \beta = \frac{E_0^2}{2 A^2}. \quad (6.34)$$

Now the energies vary approximately linearly with v^2 . The forces on the molecules are then

$$F = \frac{e}{2A} \nabla E^2. \quad (6.35)$$

Molecular ions, on average, experience a field which is proportional to θ^2 . The coefficient is proportional to the molecule's moments of inertia, and is very high polyatomicity because of the small values of θ in the dense region. Thus, diatomic molecules are unusually sensitive to a static electric field. When you expect, for the dielectric efficiency of 10^4 by θ^2 .

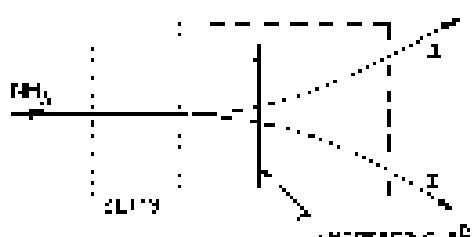

Fig. 6-1. The stopping power may be measured by an array of solid-state detectors having a gradient perpendicular to the beam.

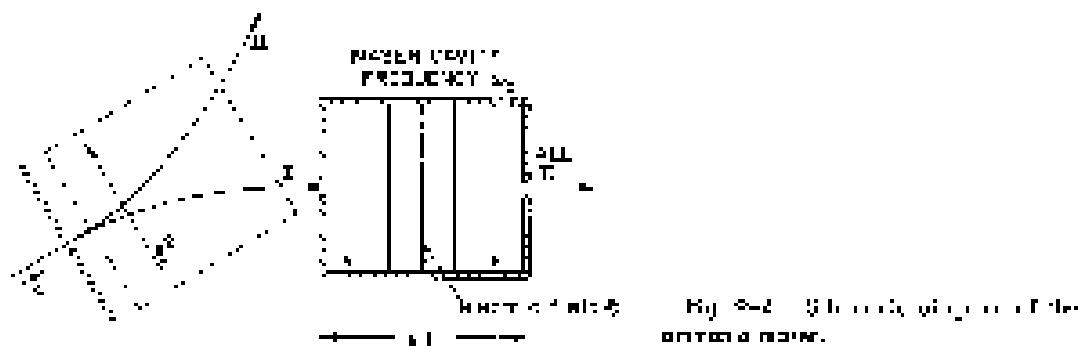

Fig. 6-2. Schematic diagram of the antenna system.

9.2 Transitions in a time-dependent field

In the previous chapter, the problem of an molecule in a state $|j\rangle$ and a constant energy was well discussed, & case in cavity, see below in Fig. 9-4. The other case is discussed. Inside the cavity, there will be a time-varying electric field. In the next problem we must concern to the behavior of a molecule in an electric field that varies with time. We have 2 completely different kind of a problem— one with a time varying Hamiltonian. Since H_0 depends upon t , we may write $H(t)$ and we must determine the time-form of the system under consideration.

To begin with, we must again the equations to be solved

$$i\hbar \frac{dC_1}{dt} = (E_1 - \nu \delta) C_1 - iC_{20}, \quad (9.1a)$$

$$i\hbar \frac{dC_2}{dt} = -iC_{10} + (E_2 - \nu \delta) C_2. \quad (9.1b)$$

To be definite, let's suppose that the electric field is the same (ballistic) for both sites:

$$E = E_0 \exp(i\omega t - k_0 y^{(0)} - eV^{(0)}), \quad (9.37)$$

In 1996, I substituted the frequency $\omega = eV^{(0)}$ by very nearly eV , since the potential is constant at one nanometer (transition $\lambda_{\text{Si}} = 2.35$ nm), but for the time being we want to keep things general, so we'll leave ω having value $eV^{(0)}$. The best way to solve the equations of motion is to find the equilibrium values C_1 and C_2 as we did before, so we will do the two equations about by the methods of 12, and use the definitions of C_1 and C_2 that we had at $\omega = 0$ [P.13]. We get

$$\partial_t \frac{\partial C_1}{\partial t} + iC_1 = 4j(E_0 - eV^{(0)}), \quad (9.38)$$

You'll note that this is almost the Eq. 9.36, except an extra term due to the electric field. Since any j we substitute the two equations (9.36) we get

$$\partial_t \frac{\partial C_2}{\partial t} = (E_0 - 4jC_1) + ieV^{(0)}. \quad (9.39)$$

Now the question is, how to solve these equations? They are more difficult than our earlier set, since j depends on C_1 and, in fact, for a general $j(t)$ the solution C_1 is not representable by elementary functions. However, we can perform an approximation to $j(t)$ if the electric field is small. First, recall what

$$\begin{aligned} C_1 &= i\eta j e^{-i\omega t + i\theta_1} = i\eta e^{-i(\omega t + \theta_1)} \\ C_{11} &= \eta \cos(\omega t + \theta_1) \quad \eta_{11} = \eta \cos(\omega t + \theta_1) \end{aligned} \quad (9.40)$$

If there were no electric field, these equations would be easier with η and η_{11} no longer in their complex conjugates. In 2000, all of the probability $|C_1|^2$ was in state $|1\rangle$ (it is the case when $\omega = 0$) and its possibility of being in state $|2\rangle$ is zero. The square of $|C_1|$ is the probability of being in state $|2\rangle$ or in state $|1\rangle$ is just $|\eta|^2$ or $|\eta_{11}|^2$. For instance, if the system were to start initially in state $|2\rangle$ and η was zero and η_{11} was one, this condition would never change. There would be no chance of the molecule being originally in state $|2\rangle$, over to go to state $|1\rangle$.

Now the idea of solving the equations in the form of Eq. 9.40 is this: if ω is small compared with ω_0 the ω terms can still be written in the form, but then η_1 and η_{11} become slowly varying functions of time, whereas η (nearly constant) becomes rapidly oscillating with the exponential frequency ω , i.e., the phase. We use the last form, η_1 and η_{11} vary slowly, to get an approximate solution.

We want now to substitute C_1 from (9.40) in the left-hand side of (9.38), but we must remember that η_1 is also a function of t . We have

$$\partial_t \frac{\partial C_1}{\partial t} = E_0 \eta_1 e^{-i\omega t} + i\partial_t \frac{\partial \eta_1}{\partial t} e^{-i\omega t}$$

The differential equation becomes

$$\left(E_0 \eta_1 - i\partial_t \frac{\partial \eta_1}{\partial t} \right) e^{-i\omega t} = E_0 \eta_1 e^{-i\omega t} + j_0 e^{-i\omega t} e^{i\theta_1} = j_0 e^{-i\omega t} e^{i\theta_1} (1 + e^{-i\omega t}). \quad (9.41)$$

Similarly, the equation in $\partial C_2/\partial t$ becomes

$$\left(E_0 \eta_{11} - i\partial_t \frac{\partial \eta_{11}}{\partial t} \right) e^{-i\omega t} = E_0 \eta_{11} e^{-i\omega t} + j_0 e^{-i\omega t} e^{i\theta_1} = j_0 e^{-i\omega t} e^{i\theta_1}. \quad (9.42)$$

Now you will observe a second equal term on both sides of each equation. We can cancel terms, and we also multiply the first equation by $e^{i\omega t} e^{i\theta_1}$ and the

stated by (9.40). Remembering that $(\omega - \omega_0) = 2A - \omega_0$, we have finally,

$$\begin{aligned} \frac{\partial^2 Y}{\partial t^2} &= \omega^2 Y e^{i(\omega t - \omega_0 t)}, \\ \frac{\partial^2 y_{12}}{\partial t^2} &= \omega^2 Y e^{-i(\omega t - \omega_0 t)}. \end{aligned} \quad (9.41)$$

Now we have an apparently simple pair of equations - and they are still exactly correct. The derivative of one variable is a function of time only (ωt), multiplied by the second variable; the derivative of the second is a similar time function, multiplied by itself. Although these simple equations cannot be solved in general, we can learn how to solve them in special cases.

We are, for the moment at least, interested only in the case of an oscillating electric field. Taking (9.41) as given, in Eq. (9.37), we find that the equation for y_1 and y_{12} has now

$$\begin{aligned} \frac{\partial^2 y_1}{\partial t^2} + 2\zeta\omega e^{i(\omega t - \omega_0 t)} &= e^{-i(\omega t - \omega_0 t)} p_{11}, \\ \frac{\partial^2 y_{12}}{\partial t^2} - 2\zeta\omega e^{i(\omega t - \omega_0 t)} &= e^{-i(\omega t - \omega_0 t)} p_{12}. \end{aligned} \quad (9.42)$$

Now if ω_0 is sufficiently small, the values of the arguments of Y_1 and Y_{12} are also small. The two $e^{i\theta}$ will not vary much with t , especially for comparison with the exponential factor in the exponential terms. These exponential terms have real and imaginary parts, but now take at the lowest order $\omega = \omega_0$, $\omega_0 \ll \omega$. The term with $\omega = \omega_0$ oscillates very rapidly about its average value of zero and, therefore, does not contribute very much to the average response of the system. So we can make a reasonably good approximation by replacing these terms by their average value, namely zero. We will just leave them in, and take another approximation:

$$\begin{aligned} \frac{\partial^2 Y}{\partial t^2} &= 2\zeta\omega e^{i(\omega t - \omega_0 t)} p_{11}, \\ \frac{\partial^2 Y_{12}}{\partial t^2} &= 2\zeta\omega e^{-i(\omega t - \omega_0 t)} p_{12}. \end{aligned} \quad (9.43)$$

Over the compounding terms, with exponents proportional to $(\omega - \omega_0)$, will also come rapidly unless ω is near ω_0 . Only over the time-scale set by ω_0 does enough time pass for the exponential factor to accumulate. When we integrate the equations over t from $-\infty$ to ∞ , in other words, when a wave electric field the only significant frequencies are those around ω_0 .

With the approximation made in writing Eq. (9.43), the equations can be solved exactly but the work is a bit tedious and, as we want, the first and last time when we take no account problem in the same type. Now ω_0 is not necessarily approximately ω , in fact, not an exact solution for the case of perfect resonance, $\omega = \omega_0$, and an approximate solution for frequencies near resonance.

9-4 Transitions at resonance

Let's take the case of perfect resonance first. If we take $\omega = \omega_0$, the response will be equal to one in both equations of (9.43), and we have just

$$\frac{\partial^2 Y}{\partial t^2} = \frac{2\zeta\omega}{\omega} p_{11}, \quad \frac{\partial^2 Y_{12}}{\partial t^2} = \frac{2\zeta\omega}{\omega} p_{12}. \quad (9.44)$$

If we eliminate p_{12} by adding the two from these equations, we find that each satisfies the differential equation of simple harmonic motion:

$$\frac{\partial^2 Y}{\partial t^2} = \left(\frac{2\zeta\omega}{\omega}\right)^2 Y. \quad (9.45)$$

The general solutions for these equations can be taken as γ of sinus and cosines

As you can easily verify, the following equations are a solution:

$$\begin{aligned}\psi_1 &= \cos\left(\frac{\mu E_1}{\hbar}\right) + \tau \sin\left(\frac{\mu E_1}{\hbar}\right), \\ \psi_2 &= i \sin\left(\frac{\mu E_1}{\hbar}\right) t - i \sin\left(\frac{\mu E_1}{\hbar}\right) \tau,\end{aligned}\quad (9.19)$$

where τ and i are constants to be determined by the particular physical situation.

For instance, suppose that at $t = 0$ our molecular system was in the upper energy state $|E_1\rangle$, where we could replace τ from Eq. (9.19) by $\tau_0 = 1$ and $i\tau = 1$ and $i\tau_0 = -i$. In this situation we would have $\tau = 1$ and $t = 0$, the result being that the molecule is in the state $|E_1\rangle$ or to say it is in the absolute upper state, i.e.,

$$|\psi_1 - \psi_2|^2 = \cos^2\left(\frac{\mu E_1}{\hbar}\right). \quad (9.20)$$

Similarly, the probability that the molecule will be in the lower state is given by the absolute square of ψ_2 :

$$|\psi_2 + \psi_1|^2 = \sin^2\left(\frac{\mu E_1}{\hbar}\right). \quad (9.21)$$

Let us now introduce the time variable, the probability, $P(t)$, is given by simply squaring $|\psi_1 - \psi_2|^2$. The probability to be in state $|E_1\rangle$ will remain constant and back again while the probability to be in state $|E_2\rangle$ goes from zero to one and back. The time variation of the two probabilities is shown in Fig. 9.2. Note again, the sum of the two probabilities is always equal to one, i.e., molecule is always in some state!

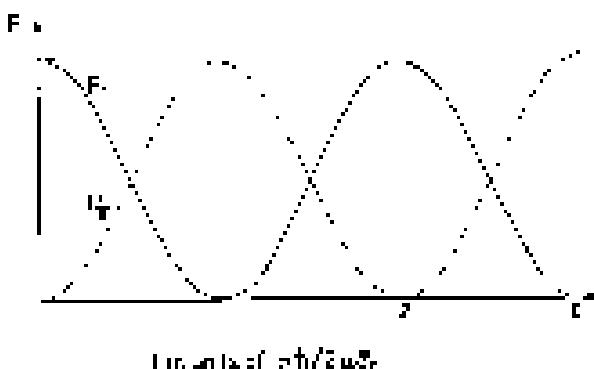

Fig. 9.2. Probabilities for the two states of the diatomic molecule in a sinusoidal electric field.

Let's suppose that it takes the molecule $|E_1\rangle$ the time T to go through one cycle. If we make the cavity gas long enough so that $T/\hbar\mu/E_1^2 = 1/2$, then a molecule which enters in state $|E_1\rangle$ will certainly leave it in state $|E_2\rangle$. If it leaves the cavity in the upper state, it will leave the cavity in the lower state. In other words, if the energy is decreased, and the loss of energy can't go anywhere else but into the environment which surrounds the field. The detectability which you can see gives the energy of the molecule a fed from the oscillations of the cavity is not simple; however, we can't feed the cavity directly because we can't use the principle of conservation of energy. (You could study this if you want, but then we would have to do it with the quantum mechanics of the field in the cavity in addition to the quantum mechanics of the atom.)

In summary, the molecule makes the cavity less cavity oscillating at exactly the right frequency. The excess energy from the upper to the lower state, and the energy released is fed into the oscillating field. If we open the mode, the molecule has enough energy to maintain the cavity oscillations—i.e., providing enough power to keep up for the cavity laser has been pumping enough amounts of excess power. And this is drawn from the cavity. Thus the incident energy is converted from the cavity of unexcited electric magnetic field.

Remember the battery that powers the cavity we were to use a diode which provides the bias so that only one upspin state exists. It is easy to see since that if you were to start with molecules in the lower state, the process will go down and you will end up with all the cavity. Then you cannot heat them so many more because their energy starts too high and energy in, so heating result would happen. To actual operation, it isn't necessary of course to make full T/R cavity w/2. For one other note, keep in mind integer one (that of α), there's some probability for transition from state $|0\rangle$ to state $|1\rangle$ or other values; however, the device isn't 100 percent efficient because of the molecules which have the say β result. They deliver about same energy to the cavity you wish.

In actual fact, the identity of the two molecules is not the same; they have some kind of Maxwell distribution. This means that the ideal conditions of time τ different "electrons" being different, and it is impossible to get 100 percent efficiency for all the molecule to switch. In addition, there is another complication that is easy to take into account, but we don't want to lost it with that the stages. You remember that the electric field in a cavity usually varies from peak amplitude across the cavity. Thus, as the molecules that receive the energy, the electric field at the molecule varies in a way that is more complicated than the simple sinusoidal oscillation in time due to wave function. Clearly, we would have to do a more complicated integration in the time problem exactly, but the general idea is still the same.

The one other way of making measure. Instead of separating the states $|0\rangle$ & $|1\rangle$ from each other by a Stern-Gerlach apparatus, we can have the atoms already in the cavity be exposed to a solid and cold atom beam state. For instance, $E_{\text{beam}} = E_0$. One was being used in the so-called three-state laser. For it when it goes to an atom when has three energy levels, as shown in Fig. 9-2, with the following specific properties. The system will consist of electron (say, light) of frequency ω_0 , and photon the lowest energy level E_0 , the atom, hydrogen by level E_1 and then w/2 quickly and photons at frequency ω_1 and go to the same E_2 same energy E_0 . The only β are a long distance so the separation can be reduced, and the condition that the coupling is weak enough for between states $|0\rangle$ and $|1\rangle$. Although there is obviously no such a "three-state" laser, the laser operation may work just as a two-state system such as we are describing.

A laser (light) at different E_0 called E driven at. Radiation α is just a name working at optical frequencies. The "theory" for a laser uses γ_{01} consists of just two pure numbers between which stimulated waves are generated.

9-5 Transitions off resonance

Finally, we would like to find out how the states work in the circumstance that the cavity frequency is nearby, but not exactly equal to ω_0 . We could solve this problem exactly. In instead of trying to do that, let's take the approximate case that the electric field is small and also the period of time τ is small, so that $\omega_0\tau$ is bounded, as the case. Then, now, in the most important circumstance which we have just worked out, the probability of making a transition is small. Suppose that we start again with $\psi_0 = 1$ and $\psi_1 = 0$. During the time τ we would expect ψ_0 to remain nearly equal to one, and ψ_1 to begin very small compared with ψ_0 . Then the problem is very easy. We can substitute ψ_0 from the current equation for ψ_1 , putting α equal to one and integrating from $t = 0$ to $t = \tau$. We get

$$\psi_1 = \frac{\alpha\psi_0}{\hbar} \left[\frac{1 - e^{i(\omega_0 - \omega_1)\tau}}{1 - e^{-i(\omega_0 - \omega_1)\tau}} \right]. \quad (9.5.1)$$

But ψ_0 , used with Eq. (9.4.10), gives the amplitude to leave molecule excited from the state $|1\rangle$ to the levels ω_1 of the uppermost interval $\Delta\omega$. The probability $P(\psi_1 \rightarrow 0)$ to make the transition is $\sim 1/\tau$.

$$P(\psi_1 \rightarrow 0) \approx |\psi_1|^2 \approx \left| \frac{\alpha\psi_0\tau^2 \sin^2[(\omega_0 - \omega_1)\tau/2]}{1 - e^{-i(\omega_0 - \omega_1)\tau}} \right|^2. \quad (9.5.2)$$

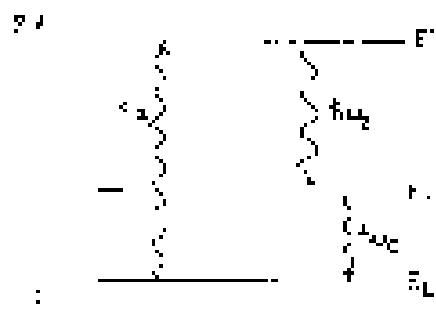

Fig. 9-3. The energy levels of a "three-state" laser.

It is interesting to plot this probability for a fixed length of time as a function of the frequency of the energy in order to see how sensitive it is to frequencies near the average frequency ω_0 . We show an example of $P(\omega) \times N\omega = \text{Fig. 9-4}$. (The vertical scale is logarithmic.) It can be seen by this graph the value of the probability when $\omega = \omega_0$ is unity. We can also calculate this in the Boltzmann theory, so you should already be familiar with it. Then we fully expect the ratio to two for $\omega = \omega_0 + \Delta\omega$ if T is large enough to ignore significant size to large frequency deviations. In fact, however, the greatest part of the area under this curve lies within the range $\pm 10\%$. It is possible therefore that the maximum theoretical probability is better to the level of 10% which is shown in the figure.

Let's examine the implications of our results for a real system. Suppose that the emission makes up in the cavity for a reasonable length of time, say for one millisecond. Then for $N_0 = 24,000$ transitions, we can calculate that the probability for a transition is 6%. In one for a frequency deviation of $\Delta\omega = 500\text{ Hz}$, which is for perhaps 10³. Obviously the frequency must be very close to the typical frequency to sustain reliability. Such an effect is the basis of the great precision that can be obtained with "stabilized" clocks, which work on the same principle.

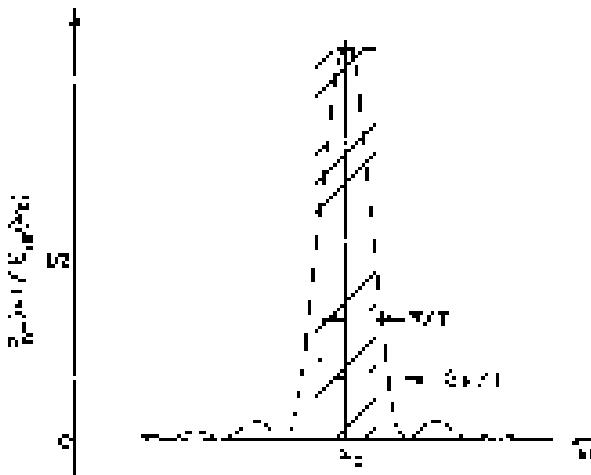

Fig. 9-4. Transition probability for the emitted radiation as a function of the frequency.

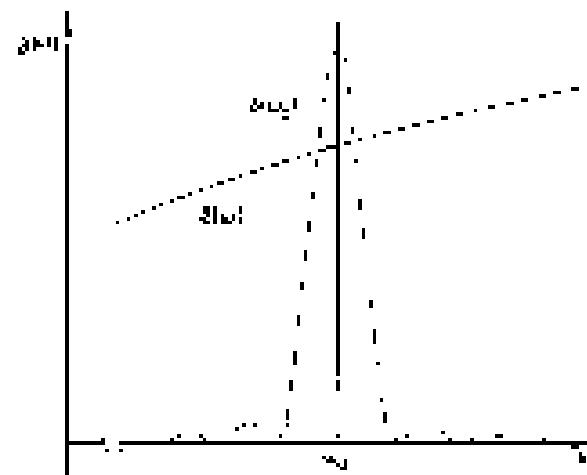

Fig. 9-5. The expected intensity $I(\omega)$ versus approached by the value of ω_0 .

9-6. The absorption of Light

The last result does appear to be more general approach than the one under review. You have noted the behavior of a molecule under the influence of an electric field, whether this field was constant or varying or not. So we could be simply defining a beam of light — microwave frequencies, at the molecule and set it to the geometry of emitting or absorbing. Our equations apply equally well to this case, but let's rewrite the $\langle \sin \theta \rangle$ in terms of the intensity I rather than $\langle E_x \rangle$ and the electric field. This is done in terms γ of the average energy these photons have per second, taken from chapter 27 of Volume II, we can write

$$I = \omega c^2 \gamma / 8\pi c = \frac{1}{2} \omega^2 (\epsilon \times \theta_{max} - \theta_{min})$$

(The maximum value of θ is $2\pi/3$.) The transition probability now becomes,

$$M\Gamma \propto M_0 = \sqrt{\frac{1}{4\pi c^2 \gamma^2}} \frac{\omega^2 \sin [\theta_0 - \omega_0 t] \partial \theta}{\omega - \omega_0/2}, \quad (9.55)$$

*Using the formula $\Gamma_0 = \omega_0 \sin \theta_0/\omega_0 = \gamma$.

Obviously the light striking on such a system is not easily monochromatic. It is, therefore, interesting to take one more path—in that is, to calculate the transition probability when the light has frequency ω_0 per unit frequency interval, covering a broad range rather than $\Delta\omega$. Then the probability of going from $|0\rangle$ to $|M\rangle$ will become an integral:

$$P(0 \rightarrow M) = 2\pi \frac{\omega^2}{4\pi c^2 \hbar \epsilon_0} T \int_{-\infty}^{\infty} d\omega \frac{e^{-i(\omega - \omega_0)t/\hbar}}{(\omega - \omega_0)^2 + \Gamma^2} \rho_M \quad (9.51)$$

In general, ρ_M will vary much more slowly with ω than the sinus parameter here. The raw sinusoid might appear, as shown in Fig. 9.6. In such case, we can let $\rho_M(\omega)$ by its value ρ_M at the center of the sharp resonance curve and take the width of the integral. What replaces is just the integral under the curve of Fig. 9.5, which is, as we have seen, also equal to $2\pi/T$. We get the result that

$$P(0 \rightarrow M) = 4\pi^2 \frac{\omega^2}{c^2 \hbar \epsilon_0 \Gamma^2} \sin^2 \theta \quad (9.52)$$

This is an important result, because it is the whole theory of the absorption of light by any atomic or atomic system. Although we began by considering a state in which state M had a higher energy than state 0 , the sum of our arguments depends on that fact. Equation 9.52 still holds if the state $|M\rangle$ has a lower energy than the state $|0\rangle$ (Section 9.5). It represents the probability for a transition with the absorption of energy from the incident electromagnetic wave. The absorption of light by any atomic system always involves the amplitude for a transition in an oscillating electric field between two states separated by an energy $E = \hbar\omega_0$. For one particular case, it is always worked out in just the way we have done here and given in expression like Eq. (9.52). We, therefore, summarize the following features of this result. First, the probability is proportional to ω^2 . In other words, this is a constant probability per unit time that transitions will occur. Second, this probability is proportional to the intensity of the light incident on the system. Thirdly, the transition probability is proportional to $\sin^2 \theta$, where you remember, as defined, the shift in energy due to the electric field \mathbf{E} . Because of this, ω_0 that appeared in Eqs. (9.3b) and (9.3b) as the coupling term, is responsible for the transition between the otherwise stationary states $|0\rangle$ and $|M\rangle$. In other words, the small t we have been considering, t is the so-called transition time $t = \hbar/\omega_0$ by the coupling interaction term which connects the states $|0\rangle$ and $|M\rangle$. In the general case, we would have this t being replaced by the matrix element $\langle M | H | 0 \rangle$ (see Section 9.6).

In Volume 3 (Section 4.2) I talked about the relations among light absorption, induced emission, and spontaneous emission in terms of the Einstein A -and- G -coefficients. Here, we have to use the quantum mechanical procedure for computing these coefficients. What we have is that $\langle 0 | \rightarrow M \rangle$ for our transition in unit of seconds is proportional precisely to the absorption coefficient A_{0M} of the Tisza radiation theory. For the spontaneous and stimulated transitions, it is too difficult for anyone to calculate. We have taken the matrix element $\langle M | H | 0 \rangle$ as the value that is to be gotten from separation. For simple atomic systems, the A_{0M} which belongs to any particular transition can be calculated from the definition

$$A_{0M} = \langle M | \partial / \partial t | 0 \rangle = H_{0M}, \quad (9.53)$$

where H_{0M} is the matrix element of the Hamiltonian which includes the effects of a weak electric field. This H_{0M} which we in this way is called the electric dipole moment of system. The quantum mechanical theory of the absorption and emission of light is, therefore, reduced to the calculation of the matrix elements for particular atomic systems.

Our study of a single two-state system has led us to an understanding of the general problem of the absorption and emission of light.

Other Two-State Systems

10-1 The hydrogen molecular ion

In the last two chapters we discussed some aspects of the one-magneton theory under the approximation that it can be considered as a two-state system. It is, of course, necessary to re-examine quantum mechanics in terms of realistic vibrational frequencies, and to do so for each of three states of hydrogen must be analyzed in terms of two magneton theories, one because of the spin flip of the nitrogen atom. Here we are going to consider other examples of systems which, as far as the one-magneton theory goes, can be considered as two-state systems. Lots of things will not happen in these cases, but in other states, some of which we will see later, they will now be able to be taken into account. But instead of our examples we will see this in more detail by just thinking about two states.

Now we will move to dealing with two-state systems, the H₂m region, or region I, as just like the one we had in the last chapter. When the Hamiltonian is independent of time, we know that there are two energy levels with different and equal frequencies. Generally, however, we start our analysis with one of these states which is not these stationary states, but since we may, perhaps, have some other simple classical theory. Then, the state in place of the system will be represented by a linear combination of these two states.

For convenience, we will combine the equations from Chapter 9, of the original theory of two states by ψ_1 and ψ_2 . Then the state ψ is represented by the linear combination

$$\psi = \alpha\psi_1 + \beta\psi_2 = \alpha\psi_1|\psi\rangle + |\psi\rangle\langle\psi_1| - \beta\psi_2|\psi\rangle. \quad (10.1)$$

The amplitudes ψ_1 and ψ_2 are denoted C_1 and C_2 respectively in the initial equations:

$$\partial_t \frac{\partial \psi}{\partial t} = \sum_i \partial_i \psi_i, \quad (10.2)$$

where ∂_i is any operator on the values ψ_1 and ψ_2 .

Within the terms of the ψ equation, ∂_i denotes expansion of the two-state combinations ψ_1 and ψ_2 (the stationary states), which we call

$$|\psi_1\rangle = (\psi_1^x e^{-iH_0t/\hbar} - i\psi_1^y) + (\psi_1^y e^{iH_0t/\hbar} + i\psi_1^z),$$

and the conjugate

$$\psi_1^x = \frac{H_{01} - H_{11}}{\hbar} + \sqrt{\left(\frac{H_{01} - H_{11}}{\hbar}\right)^2 - H_{11}H_{01}}, \quad (10.3)$$

$$\psi_1^y = \frac{H_{02} - H_{12}}{\hbar} + \sqrt{\left(\frac{H_{02} - H_{12}}{\hbar}\right)^2 - H_{12}H_{02}},$$

The ψ_1 and ψ_2 basis states of the ψ state have the same time dependence. The three states $|\psi\rangle$, $|\psi_1\rangle$ and $|\psi_2\rangle$ are very closely related; the stationary states are related to the original base states $|\psi_1\rangle$ and $|\psi_2\rangle$ by

$$|\psi\rangle = \alpha|\psi_1\rangle + \beta|\psi_2\rangle, \quad (10.4)$$

$$|\psi_1\rangle = |\psi\rangle\langle\psi_1| + |\psi\rangle\langle\psi_2|,$$

These are complex constants, which satisfy

$$|\alpha_1|^2 + |\alpha_2|^2 = 1$$

$$\frac{\alpha_1}{\alpha_2} = \frac{H_{11}}{H_{22}} \quad (10.5)$$

$$|\beta_1|^2 + |\beta_2|^2 = 1.$$

$$\frac{\beta_1}{\beta_2} = \frac{H_{12}}{H_{22}} = \frac{H_{11}}{H_{11}} \quad (10.6)$$

If H_{11} and H_{22} are equal—so that α_1 is equal to β_1 , and $H_{11} = H_{22} = -A$, that $E_1 = E_2 = A$, $\alpha_{11} = \beta_1 = A$, and the states $|E\rangle$ and $|H\rangle$ are particularly simple:

$$|E\rangle = \frac{1}{\sqrt{2}}(|1\rangle - |2\rangle) \quad |H\rangle = \frac{1}{\sqrt{2}}(|1\rangle + |2\rangle) \quad (10.7)$$

Now we will use these results to discuss a number of interesting examples taken from the fields of chemistry and physics. The first example is the oxygen molecule ion. A positively charged oxygen molecule contains two protons with one electron, occupying its very outer shell. If the two protons are far apart, what state would we expect for this species? The answer is pretty clear. The electron will stay close to one proton and leave a hydrogen atom. This leaves strong, and the other proton will remain alone as a positive ion. So, if the two protons are far apart, we can visualize one physical state in which the electron is "attached" to one of the protons. There is, though, another state of the molecule in that region in which the electron is near the other proton, and the first proton is the one that is un-ionized. We can take these two as our basis states and will call them $|1\rangle$ and $|2\rangle$. Using the rules of $\langle \cdot | \cdot \rangle$ given in Fig. 10-1, for instance, there are really many more than three electrons in the proton, because the ionization can occur at any one of the excited states of the oxygen atom. We are not interested in most varieties of wave functions; we will consider only the situation in which the hydrogen atom is in the lowest state, its ground state—and we will, for the moment, disregard spin of the electron. We can just suppose that for $|1\rangle$ the electron has no spin ("up") along the \hat{x} -axis.⁴

Now to perform an electron-for-a-hydrogen atom requires 13.6 electron-volt energy. Since each of the two protons of the oxygen molecular ion are far apart, it will require about this much energy—which is for a $1s$ proton something like a great deal of energy—to get the electron somewhere near the midpoint between the protons. So it is a surprising discovery, for the first time, to jump from one proton to the other. It is, however, in quantum mechanics, it is possible—but not very easily. There is some small amplitude for the electron to move from one proton to the other. As a first approximation, then, each of our basis states, $|1\rangle$ and $|2\rangle$ will have the energy E_0 , which is just the energy of one hydrogen atom plus one proton. We can take that the $\langle \cdot | \cdot \rangle$ matrix elements H_{11} and H_{22} are both approximately equal to A . The other matrix elements H_{12} and H_{21} , which are the coupling between the two orbitals of "proton," we will again set equal to zero. This is the same spirit as the one we followed in the last two chapters. If we disregard the fact that the electron can flip back and forth, we have been taken exactly the same energy. This energy will, however, be split in a two-energy levels by the coupling of the electron going back and forth—the symmetric probability of the transition, the quantity $\langle \text{spf} \rangle$. So our two energy levels of the system are $E_0 + A$ and $E_0 - A$, and the values of the other two different energies are given in Fig. 10-8.

⁴ This is considerably as large as current superconducting fields. We will discuss the nature of magnetic fields in the chapter four in this chapter, and they will illustrate them in the solid-state atom in Chapter 12.

Electrons, of course, we say that it is proton and a hydrogen ion are just moving near together, the electron will not stay on one of the protons but will flip back and forth between the two protons. If it reaches one of the protons, it will oscillate back and forth between them. It does this, giving a time-varying solution. In order to have the lower energy solution which does not vary with time, it is necessary to heat the system with certain amplitudes for the electrons to have random motion. Remember, thermal motion of electrons were not saying that there is an electric current and a photon. There is only one electron and it has its own amplitude. Fig. 10-3 corresponds to be in either position.

Now the amplitude of the electron which is due to the exchange of the outer core depends on the separation between the protons. As those are protons and together, the larger the amplitude. You remember that we talked in Chapter 10 that the coupling between the proton and the "polarization field" which is called dielectric. We have the same coupling here. The amplitude of the electron will go to zero as the distance between the protons goes over. Since the term δ_0 is proportional to $1/r$, where r is the large when the protons are very far apart, the separation of the energy levels will be yet larger. If the system is in the state of the energy $E_1 = E_0 + A$ increases with decreasing the separation between the two protons. This is because the energy of the electron is increasing due to the influence of the distance. These photons are becoming closer together, there is no problem from putting the photons together. The variation of the two energy levels with the distance between the two protons are shown in Fig. 10-4. We know, there is a mathematical explanation of the hydrogen atom and both the E_1 and E_2 are.

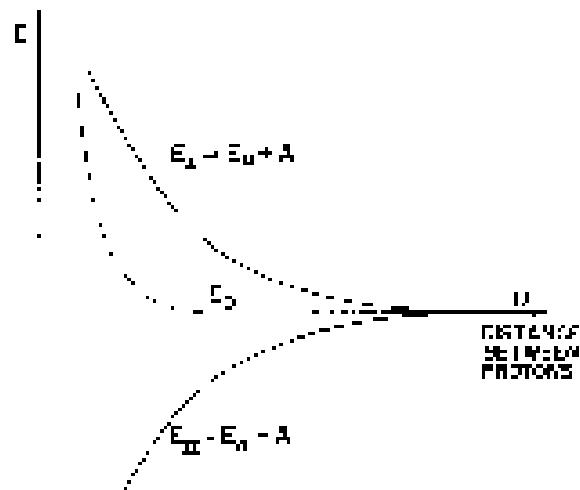

Fig. 10-4. The energies of the two energy levels in the H_2^+ ion as a function of the distance between the two protons.

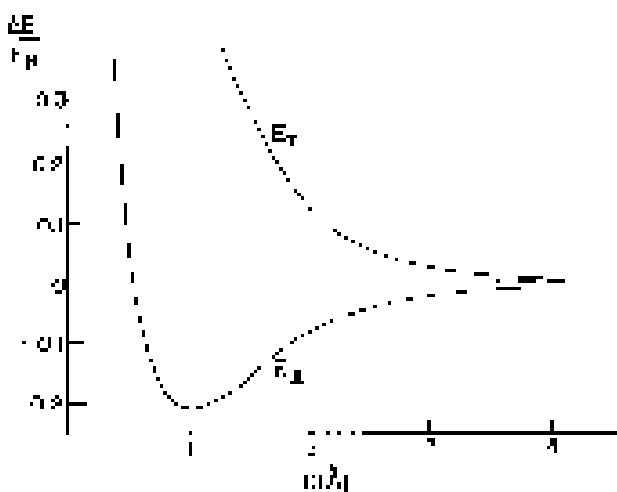

Fig. 10-5. The energy levels of the H_2^+ ion, finite and its separation is denoted. ($E_i = 10.6 \text{ eV}$)

We have, however, forgotten one thing. In addition to the above we have just described, there is also an electrostatic repulsive force between the two protons. When the two protons are far apart, as in Fig. 10-4, the "dielectric" or the central force or there is a negligible electrostatic force. At very short distance, however, the "proton" should begin to feel "proton" the electron distribution, that is it is closer to the proton on the average than to the electron. So there begins to be some sort of electrostatic energy which is, of course, positive. This energy which is in varies with the separation—should be written in Fig. 10-4 or 10-5, we speak, that comes up like the broken line curve in Fig. 10-2 when this happens, first starts low then it will increase a little, goes up, then it will decrease and then the final energy is from this E_1 . When we do this, the energies E_1 and E_2 will vary with the two-proton distance d as shown in Fig. 10-5. (In this figure, we have plotted the results of a more detailed calculation. The interproton distance

brighter than $1.5 \mu\text{J}/\text{cm}^2$, and the excess energy can strip off a hydrogen atom's electron, in which the binding energy of the hydrogen atom, the so-called "ionizing" energy, is 13.6 eV . We see that the state $|1\rangle$ has a minimum-energy point. This will be the equilibrium configuration—minimum-energy condition for BeH_2 ion. The energy of this point is finite, i.e., the sum of a two-electron potential energy and a zero-point energy. The system is bound. A single electron adds to make the two electrons repel each other. A chemist would call this a "molecular hybrid."

This kind of chemical bonding is also often called "electron-mechanical resonance." By analogy with the heat capacity problem we have described before, this name really sounds more mysterious, but it is only a "resonance" if you start from an atomic or ionic state for your basis states, as we did, and if you pick the same H_0 you would find the resonance state, the $|S\rangle$.

We can see at once the very why such a system should have a lower-energy, but a positive, total hydrogen atom. Let's think about an electron and two protons with some fixed, but not too large separation. You remember that with a single proton the electron is represented by a set of the uncertainty principle. It needs to balance between having a low Coulomb potential energy and not being confined in a too small space, which would make the known energy decrease of the uncertainty relation disappear. Now, if there are two protons, there is more room, so the electron can have a less electrical energy. It can spread out, lowering its kinetic energy without increasing its potential energy. The result is a lower energy than a hydrogen atom. Then why does another state, $|1\rangle$, have a higher energy? Notice that this state is the rightmost of the states $|1\rangle$ and $|2\rangle$. Because of the symmetry of $|1\rangle$ and $|2\rangle$, the difference must have zero component, so therefore it cannot fully be seen in the ψ_{12} profile. This means that the electron is somewhat more confined, which adds to a larger energy.

We should say that the approximate treatment of the H_2 ion as a two-electron system breaks down pretty badly near the minimum point, since either of them are at the minimum of the curve of $E(\text{H}_2)$, and so will not give a good value for the total binding energy. For a full calculation, the energies of the two "hybrids" we've given in Fig. 16.11 cannot really explain the experimental quantity. A detailed treatment is needed.

Suggest we ask now what would happen if instead of two protons, we had two different projectiles, say, for example, one proton and one lithium projectile. In such a case, both projectiles still have a single positive charge. In such a case, the two terms R_{11} and R_{22} of the Hamiltonian would no longer be equal, they would be just being different. If it should happen that the difference $(R_{11} - R_{22})$ is an absolute value, much greater than $4\pi\epsilon^2/(M_1 + M_2)$, then the curve looks just very weak, as we see in the following way.

If we put $R_{11}, R_{22} = 1.1 \times 10^{-10}$ in Eq. (16.3) we get

$$E = \frac{R_{11} + R_{22}}{2} - \frac{R_{11} - R_{22}}{2} \sqrt{1 + \frac{4\pi^2\epsilon^2}{(M_1 + M_2)^2}}$$

With $R_{11} + R_{22}$ much greater than $4\pi\epsilon^2/(M_1 + M_2)$ this expression is very nearly equal to

$$\frac{1}{2}(R_{11} + R_{22})$$

The two energies are then

$$\begin{aligned} E_1 &= R_{11} + \frac{\epsilon^2}{(M_1 + M_2)^2} \\ E_{22} &= R_{22} + \frac{\epsilon^2}{(M_1 + M_2)^2} \end{aligned} \quad (16.2)$$

The difference vanishes just the energies R_{11} and R_{22} of the isolated atoms, plus apart only slightly by the fly-by amplitude α .

The energy difference $E_1 - E_{22}$ is

$$(R_{11} - R_{22}) + \frac{2\pi^2\epsilon^2}{(M_1 + M_2)^2}$$

The distance separation from the Rb atom of the electron is no longer small (≈ 2.1 , it is smaller by the factor $A/(R_{H2}) = B_{H2}$), which we are now taking to be much less than one. As in the dependence of $E_0 = 1/r_0$ on the separation of the two nuclei is much smaller than for the H_2 case. It is also reduced by the factor $A/(R_{H2}) = B_{H2}$. We see that the binding of atoms with different nuclear charges is generally very weak.

In our theory of the H₂ ion we have discovered an explanation for the decrease in the ΔE due to the fact that the two protons involved in effect act as active 'bonds' between the two protons which can be present even when the protons are at large separations. The attractive force comes from the reduced energy of the system due to the possibility of the electron jumping from one proton to the other. In such a jump the system changes from the configuration hydrogen atom, proton to the configuration (proton, hydrogen atom) or switches back. We can write the process symbolically as

$$(H, p) \leftrightarrow (p, H)$$

The energy shift due to this process is proportional to the amplitude of the two electrons whose energy is $-kE$ (the binding energy of the hydrogen atom) and goes from one proton to the other.

For large distances R between the two protons, the interaction potential energy of the electron is nearly zero over most of the space it must go when it makes its jump. In this case then the electron moves nearly like a free particle in empty space but with a negative energy. We know from in Chapter 3 (Eqn (3.1)) that the energy with some constant of proportionality to get them one plus the absolute distance energy is proportional to

$$\frac{p^2}{r} - \frac{1}{r}$$

where p is the momentum corresponding to the infinite energy. In the present case (using the non-relativistic formula) p is given by

$$\frac{p^2}{2m} = -kE \quad (10.10)$$

This gives a finite bound in infinite numbers.

$$p = \sqrt{2mkE}$$

(the other sign for the radial part is unimportant).

We should expect then, that the amplitude A for the H₂ ion will vary as

$$A \sim \frac{\sqrt{-2k^2 E^2 m}}{R} \quad (10.11)$$

at large separation R between the two protons. The energy shift due to the electron hopping is proportional to A , so there is a force pulling the two protons together which is proportional to large R (to the derivative of (10.10) with respect to R).

Finally, as an example, we should remark that the two-proton interaction potential is still too exact since which gives a dependence of the energy on R . We have neglected it until now because it is usually a low-order perturbation. The exception is just for R at very large distances where the energy of the exchange term is not suppressed exponentially to very small values. The new effect we are thinking of is the electrostatic attraction of the nuclei by the hydrogen atoms which remain static in the same way that the nuclei do not move in our theory. The two protons make an electric field E varying as $1/R^2$ at the two hydrogen atoms. The nuclei becomes polarized, taking on net induced electric moments proportional to R . The energy of the system is E_0 which is proportional to $1/R^2$ or $1/R^3$. So there is a $-kE$ in the energy of the system which decreases with red double power of the distance. It is a correction to E_0 . This energy called well

distance more slowly than the with β given by (10.10). At some large separation R , it becomes the only remaining component, because the interaction of energy with β is zero, therefore the energy decreasing term. Even though the electrostatic term has the same sign as the bare α' the bare α' the force is attractive, so the energy is negative and smaller for the two stationary states, whereas the different contributions from β gives opposite signs for the two stationary states.

10-2 Nuclear forces

We have seen that the system of a hydrogen atom has a total *negative* energy of interaction due to the exchange of the single electron, which makes it large enough to form a H^- .

$$\frac{e^2 \alpha'}{R} \quad (10.11)$$

such a $\alpha' = -\sqrt{2\pi}/(m_e R)$. (Remember why this is an *exchange* of a "virial" electron between atoms—the electron has to jump across a barrier where it would lose a tiny bit energy. More specifically, a "virial exchange" means that the production involves a *symmetric* exchange, interchanging between an *interacting* state and a *noninteracting* state.)

Now we might ask the following question: Could it be that there is between a $n=1$ state of particles p and $n=2$ another origin? What about, for example, the nuclear force between a neutron and a proton, or between two protons? Is it also due to *exchange*? The name of Yukawa is associated with the force he wrote, the nuclear force is due to a similar exchange effect—only, in his case, due to the virtual exchange, not of an *exotic*, but of a new particle, which is neither a "meson," nor a "baryon." Today, we would identify Yukawa's meson with the ρ meson (a "pion") produced by high-energy collisions of protons or deuterons.

Let's see, as an example, what kind of a force we would expect from the exchange of a positive pion (ρ^+) and $n=2$ between a neutron and the $n=1$ electron. Just as a hydrogen atom H^+ can go to a g^- state by giving up an electron:

$$H^+ + e^- \rightarrow g^- \quad (10.12)$$

a scalar ρ^+ can go into a neutral π^0 by giving up a π^0 meson:

$$\rho^+ \rightarrow \pi^+ + \pi^0 \quad (10.13)$$

So if we have a proton at r_1 and a neutron at r_2 separated by the distance R , the proton can "lose" its ρ^+ by emitting it, ρ^+ , which is then absorbed by the neutron in a "turning it into a proton." This is an energy of interaction α' of the two nucleon (plus pion) system which depends on the amplitude A for the pion exchange, just as we found for the electron exchange in the H^- case.

In the process (10.13), the energy of the ρ^+ is transferred to one of the pions by the ρ^+ scattering (antirelativistically), and emitting the rest energy $m_\rho^2 c^2$ of the electron, and the electron loses negative kinetic energy (imaginary contribution \rightarrow in Eq. (10.9)). In the nuclear process (10.12), the proton and neutron have a more rapid transfer, so they $\rightarrow \pi^0$ with zero gain in energy. The relation between the total energy E and the incompatibility (or δ) will be discussed.

$$E^2 = p_{\rho^+}^{2c^2} + m_\rho^2 c^2$$

Since E is scalar (and $m_\rho^2 c^2$ is symmetric with ρ), the ρ energy can be again imaginary:

$$y = i m_\rho c$$

Using the same arguments we gave for the amplitude that a bound electron would penetrate the barrier, the cross-section, as p varies, we would find that the rate of exchange amplitude \propto other quantity \propto $y^2 \propto 1/R^2$ (Eq. 10.10).

$$\frac{\sigma \propto \pi y^2}{y} \quad (10.14)$$

the interaction energy is proportional to λ , and so works in the same way. Yet the energy variation is the sum of the scattered momenta divided by mass two volumes. Indirectly, we obtain this same formula starting directly from the differential equation for the motion of a proton in free space (see Chapters 26, Vol. II, §2, §§4, 6).

We can, following the scheme of Feynman, discuss the interaction between two protons (or between two neutrons) which results from the exchange of a virtual pion (π^0). The basic process is now

$$p^+ + \bar{p}^+ \rightarrow \pi^0. \quad (16.1)$$

A pion and an electron virtual π^0 , but the pions and a proton. If we have two protons, proton No. 1 can emit a virtual π^0 which is absorbed by proton No. 2. At the end, we still have two protons, but this is scattered differently from the E_2 law. This is the J^P law in a different situation—the proton—electron coupling. We assume. Now we are assuming that a proton is emitted without carrying its charge e . Such processes are, in fact, observed in $p\bar{p}$ and $n\bar{n}$ collisions. The process is analogous to the ionization electron emits a photon and ends up still in electron:

$$e \rightarrow e + \text{photon}. \quad (16.2)$$

We do not feel the photons emitted by electrons, unless they are emitted so often they are detectable, and then emission does not change the "masses" of the electrons. Coming back to the two proton case, we can imagine energy which arises from the amplitude of the one-pion-exchange process, given which nucleon emits (with its existing momentum) a virtual pion field is absorbed. This amplitude is again conserved in (16.1), without the loss of the normal even. All the symmetries give an equal interaction energy for both nucleons. Since the nuclear charge symmetry of the Coulomb effect between neutron and proton, between proton and proton, between neutron and neutron are the same, we conclude that the sum of the charged and neutral parts should be the same. Experimentally, the cross-sections are nearly equal, and no real difference is found when one varies either their electric fields (see Chapters 10, 11, of Vol. II).

There are other kinds of particles, like Δ -mesons—which can be used to penetrate the nucleus. It is also possible to have pions to be exchanged at the same time. But all of these other exchanges “objects” have a total mass M , greater than the pion mass, and lead to terms in the exchange amplitude which vary as

$$\frac{1}{M^2} \sim \frac{1}{m^2},$$

These terms die out faster and faster as increasing M than the pion mass. Thus the pion theory, being the lowest mass terms, can for large enough values of R justify the one-pion-exchange theory. And, indeed, these experiments which involve nuclear interactions using at large distances, show us that the interaction comes from the one-pion-exchange theory.

The classical theory of electricity and magnetism, the so-called electrostatics is interaction and the radiation of light by an accelerated charge are closely related—the first one of the two well-known laws. Yet have seen in Chapter 10 that light can be represented as the wave propagation of the harmonic oscillations of the classical electromagnetic fields E and B . Alternatively, the quantum theory can be derived by it, starting with the quantum mechanics—another—so-called Dirac theory. We emphasize in Vol. II, §3, that the two otherwise prima facie always give identical predictions. Can the general point of view be carried through completely to include all electromagnetic effects? In particular, we want to describe the electromagnetic field precisely in terms of Dirac particles—that is, in terms of photons, what is the evidence here for this?

From the “quantum” point of view the two-body interaction between two electrons comes from the energy of a virtual photon. One electron emits a photon—say in beam α (Fig. 16.1), which goes over to the second electron, β , and is absorbed in the reverse of the interaction. The interaction energy is again given

by a formula like (10.14), but now with α replaced by the mass of the photon which is e^2 . So the virtual exchange of a photon between two electrons gives an interaction energy that varies simply inversely as R , the distance between the two electrons, just the normal Coulomb potential energy. In the particle¹⁷ theory of electromagnetism, the process of virtual photon exchange gives rise to all the quantum-mechanical interactions.

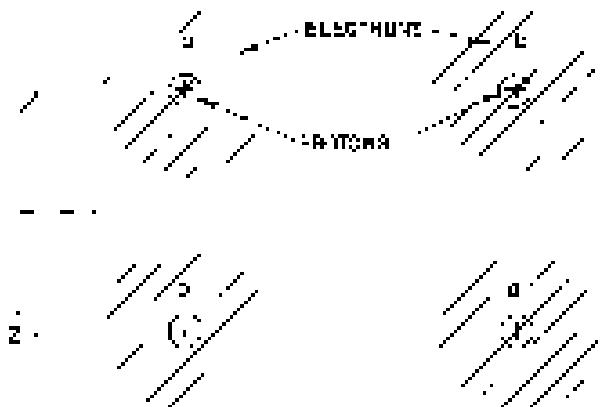

Fig. 10.4. A set of basis states for the H_2 molecule.

10-3 The hydrogen molecule

As our next two-particle system we'll look at the neutral hydrogen molecule. This is naturally more complicated than hydrogen because there are electrons again. We start by thinking of what happens when the two protons are well separated. Only one of the two electrons is odd. To keep track of them, well call one of them "electron 1" and the other "electron 2". We can again imagine two possibilities. One possibility is that "electron 1" is grouped with the first proton and "electron 2" is around the second, as shown in Fig. 10.4(1). We can equally well hydrogen atoms. We will call this state |1>. There is another, the possibility that "electron 1" is around the first proton and that "electron 2" is around the second. We call this state |2>. Now the symmetry of the situation. These two possibilities should be energy levels, at similar, but as we will see, the energy of one hydrogen atom. We could mention that there are many other possibilities. For example, "electron 1" might be near the first proton and "electron 2" might be in another state around the new center. We'll discuss that kind of case, since it will certainly have a large change from one of the large coherent oscillations between the two electrons. For your familiarity, we could have to include such cases, but we can get the essentials of the molecular binding by considering the two cases of Fig. 10.4. To do approach, let us call ψ_1 the wave function for state |1> and ψ_2 the wave function for state |2>, and let ψ be the total wave function:

$$|\psi\rangle = \sum_i |\psi_i\rangle |s_i\rangle$$

To proceed, we assume—as usual—that the wave amplitude A_{11} for the electron 1,1 state through the interacting atom and hydrogen nuclei. This "readily" exchange means that the energy of the ground state, as we have seen, is rather exact the system. As for the hydrogen molecule, i.e., the splitting, is very small when the distance between the hydrogen atoms. As the protons approach each other, the amplitude for the electron 1,1 goes back and forth decreases, so the splitting increases. The reason of this behavior is quite simple: that there's an attractive force which pulls the atoms together. Again the energy levels are when the protons are very close together, because of the coulomb repulsion. The zero point in total wave function would have energy which vary with the separation as shown in Fig. 10.5. At a separation of about 0.75 Å, the zero energy

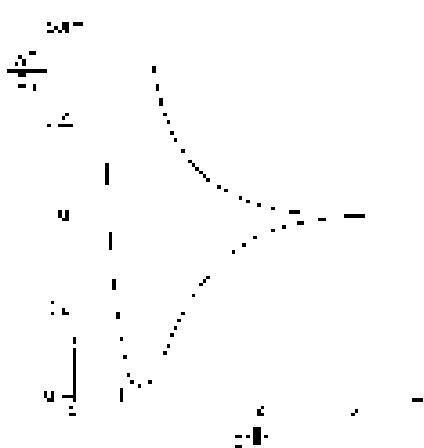

Fig. 10.5. The zero-point energy E_0 of the H_2 molecule for different distances. ($m_e = 0$; $R_0 = 1.2 \times 10^{-8} \text{ cm}$)

In *hydrogen combination*, this is the pre-reaction disease of the two hydrogen molecules.

Now you have probably seen thinking of an oxygen atom. What about the fact that the *w-electrons* we had in 1g₁ are now? We have been talking from previous chapters about 1g₁, "but there really is no such 1g₁—tell what is what." And we have said in Chapter 4 that the electrons which are fermion particles. If there are two electrons being run together by exchanging the electrons, the wave amplitudes will interfere with the same sign. This means that the wave of a *w-electron*, i.e., which, the sign of the amplitude must be +. We have just concluded, however, that the bound state of the hydrogen molecule would be $\psi = -\psi_1$.

$$\psi = \frac{1}{\sqrt{2}}(\psi_1 + \psi_2).$$

However, according to our rules of Chapter 4, this state is not allowed. It is *w-electron* which we get the wave

$$\frac{1}{\sqrt{2}}(\psi_1 - \psi_2),$$

and we get the same sign instead of the opposite one.

But hydrogen does not run if both electrons have the same spin. Let us then if both electrons have spin up (or both have spin down), the wave state for *w-electron* is

$$\psi = \frac{1}{\sqrt{2}}(\psi_1 - \psi_2)$$

for this state, an in-phase state of the two electrons gives

$$(\psi_1 - \psi_2)$$

which is $= \psi_1$, as required. So *w-electron* hydrogen comes pair to each other with their spins pointing in the same direction, they can go to the state $|1\rangle_1$ and not state $|1\rangle_2$. $|1\rangle_1$ under this state, E_1 is the lower energy state. The curve of energy versus r has no minimum. The two hydrogen will always repel and ψ_1^2 will form a molecule. So we conclude that the hydrogen molecule cannot exist with parallel electron spins. And that is right.

On the other hand, for a site M it is relatively easy to make fermion wave functions. In fact, if we interchange which location we call M and which we call N we get exactly the same state. We saw in Section 4.1 that if two Fermi particles are in the state $|1\rangle_1$, they annihilate instead of going $|2\rangle_1$, the bound hydrogen molecule and two free electrons, ψ_1^2 spin up are one with each other.

The whole story of the hydrogen molecule is really completed more completely if we want to include the problem of spin. But then no longer right to think of the molecule as a two-state system. It should really be looked at over all spin states—there are three possible spin arrangements for each *w-electron* states, $|1\rangle_1$ and $|2\rangle_1$ so we want to take things a little finer by neglecting the spins. Our first conclusions are, however, correct.

We find that the *w-electron* wave—the only fermion state of the H₂ molecule has the same character with some exception. The total spin angular momentum of the atom is zero. On the other hand two empty hydrogen atoms or hyper-pairing—*w-electron* is definitely unconstitutional, e.g., must have higher spin-bound state energy than the atoms alone will do. There is an interesting correlation between the atoms and the energies. It gives another illustration of something we mentioned before, which is that there appears to be an “in reaction” energy between two spins because the case of parallel spins has a higher energy than the opposite case. In a certain sense you could say that the spins like to react or interact in certain ways, giving an attractive potential in Fermi energy, but because there is a long-range Coulomb force, but because of the restricted principle,

We saw in Section 10.3 that the binding of two electrons by a single electron pair is likely to be stronger than that of two pairs by two electrons. Suppose that in bromoethane in Fig. 10.4 were replaced by say two ions with identical inner shells with a single innermost shell, and that the binding energies of an electron at the two sites are different. The energies of a pair of 1⁻ and 2⁻ would still be equal because in each of these sites we have one electron bound to each pair. Therefore, we design here by splitting proton bond 10.4 into two separate bonding is equivalent to the most extreme valency limit, i.e., having roughly twice as many H atoms as do the 'steps' of ten electrons. Although two atoms can be bonded together by valency sharing, it is relatively rare when we do this, and the result is very weak.

Finally, we want to mention that if the energy of attraction for an electron in one nucleus is much greater than to the other, then what we have will be different sharing rather than with a pair of ten electrons. Since one nucleus of C may be a positive and has a much stronger attraction for an electron than does bromine, it may seem bizarre that the total energy is still fairly low even when the electrons are stuck to a single electron pair nucleus A. This strong attraction may force the electrons to form the mutual repulsion of the two molecules. If it does, the lower energy state is as shown: large enough to bind both electrons at a binding distance to form a single compact molecule that is chemically inert. The molecule looks like a neutral ion with a positive end. This is, of course, what happens in a "ionic" molecule like NaCl. You can imagine all the gradients between covalent bonding and ionic bonding possible.

You can now begin to see why it is that much of the basis of chemistry can be clearly understood in terms of a quantum mechanical description.

10.4 The benzene molecule

Chemists have invented nice diagrams to represent complicated organic molecules. Now we are going to draw one of the most interesting of them—the benzene molecule shown in Fig. 10.6. It contains six carbon and six hydrogen atoms in a symmetrical ring. Each horizontal diagram represents a row of electrons, with spins opposite, along the covalent bond lines. Each hydrogen atom contains one electron and each carbon atom contains two lone electrons to make up the total of 12 electrons in each of the six covalent bonds. These are not enough bonds that are so tightly bound that they are not appreciably involved in the overall binding. So with six in the home representation, or w/ 12 electrons, we can interpret this as meaning that there are no paired electrons between the four pairs of carbon atoms.

This is a mystery about the benzene molecule. We know, however, that while energy alone should be required to form a branched compound, because the chlorine has saturated the energies of various compounds while needs pieces of training—such as those that cause the energy of resonance (and by a dynamic theory, are so far we can interpret, to double the total energy we should expect for the benzene

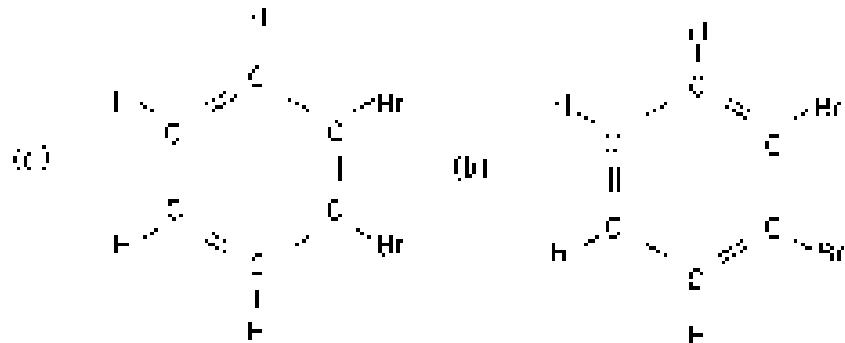

Fig. 10.7. Two possibilities of the benzene molecule. The two bonds could be satisfied by a single bond or by a double bond.

unstable. The actual energy of the pentadienyl cation, however, is much lower than we get by such a calculation; it is only slightly higher than we would expect from what is called the "vertical ionization potential,"¹ Using a double bond system which is not in such a trap is easily attacked chemically because it has a lower the high-energy— π —double bonds can be easily broken by the addition of other hydrogens. But at higher the ion is *very* permanent and hard to break. In fact, bonds between two π -systems have much lower energy than you would calculate from the bare potential.

Then there is another mystery. Suppose we replace two adjacent leg edges by horizontal ones to make ethylene-trimethylene. There are two ways to do this, as shown in Fig. 10-5. The structure could be (a) the separation of a double bond as shown in part (a) of the figure, or it could form the two ends of a single bond as in (b). One would think that these diisobutene-isomers should have different forms, were they real. There is only one such diisobutene!†

Now we want to know about these isomers—and perhaps you have already guessed this by noticing that one, the "ground state" of the hexene molecule is really a three-leg system. We need imagine that the double bonds would be in either of the two arrangements shown in Fig. 10-6. You may not really think so, but they should have the same energy. In fact, they should. And for this reason they must be analyzed as a two-state system. But with appropriate *orbital configuration of the whole set of electrons*, there is some possibility of that the vertical ionization potential of one arrangement to the other is so close that the electrons can move from one to the other.

As we have seen, the ground state triplet makes a mixed π -hexene energy is lower than you would calculate by looking separately at either of the two isomers in Fig. 10-5. Below them are two enthalpy states, one with a π -hexene and one with an energy below the enthalpy value. Recall why. In the hexene state (lowest energy), a hexene molecule is in the possibilities shown in Fig. 10-5, but it has the amplitude $\langle \psi_1 | \psi_2 \rangle$ which is each of the states shown. It is the only wave function involved in the chemistry of benzene at normal temperatures. Fortunately, the upper state also exists, because it is the hexene because has a strong absorption for ultraviolet light in the frequency $\nu = 142 \times 10^{12} \text{ cm}^{-1}$. You will remember this in ammonia, where this absorption, back and white, these subjects, the energy separation is in the microwave region. In benzene, the absorption is one and because they are much lighter, they find it easier to fly back and forth, which makes the oscillations very much longer. The result is that the energy difference is much larger, about 1.5 eV, which is the energy of an ultraviolet photon.

What happens? We submit our request! Again the two "models" (a) and (b) in Fig. 10-5 represent the two stable and close energy isomers. The only difference is that the two have states which with enough energy cause transitions. The lowest energy π -hexene does not involve a π -hexene combination of two states, but with unequal amplitudes. The amplitude for state (b) might have a large probability like $\sqrt{2}/3$, say, whereas state (a) might have a small probability

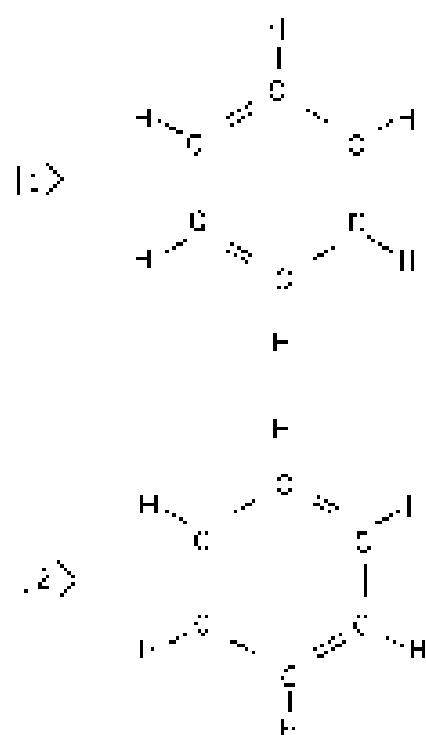

Fig. 10-6. A set of four states for the benzene molecule.

† We are over-simplifying a little. Originally, the extreme changes that these could bring to some of the hexene isomers, would cause the electrons on adjacent carbon atoms (or two others) to swap with the electrons on adjacent carbon atoms (or two others) and so forth. Then since the hexene species in nature are *resonance structures*, however, they would only these forms—that is why we find all the endo-ene-alkanes.

‡ If not too long and not too intense. A emission of ultraviolet light would very easily is the loss of electrons and return to hexene, but not the displacement of the electron between the two atoms. The hexene is then definitely substituted, as in δ,γ furan. Eq. (9) for the probability of a transfer of the triple bond to the π -hexene ligand is (law 16d). If these were the only states, the chance of a transfer would have to be about 1 in 10000. As it happens there are several hexene states with the same base state (such as three hexene states in the hexene shown) and the ratio of any state of hexene are slightly different from the two states found. The ratio of hexene states (at the transition) is not known, but we can assume it is proportional to the absorption of ultraviolet light.

$\psi_1/\sqrt{2}$. We can't say this state without more information, but note: the two energies E_1 and E_2 , are no longer equal, but the simple fact C_1 and C_2 no longer have equal weight. This makes, of course, this one of the two possibilities—the figure is more likely than the other—but the electrons are much more except ψ_1 from the $\psi_1 + \psi_2$ and $\psi_1 - \psi_2$ blocks. So here, the center state has different amplitudes like ψ_1 and ψ_2 with possibly our loss of a higher energy. There is only one lowest state, and so we see the naive idea of "local charge" bands would be right.

10-5 Dyes

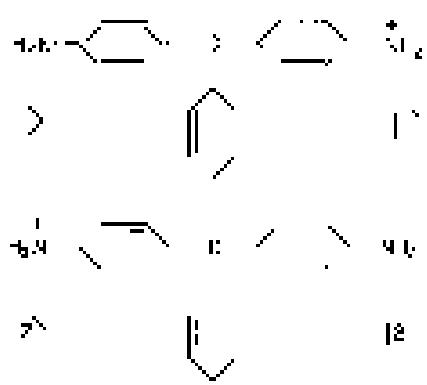

Fig. 10-2. Four resonance states for the molecule of the dye molecule.

We will give you one more chemical example of the resonance phenomenon this time on a larger molecular scale. It has to do with the dyes, dyes. Many dyes—let's see, most artificial dyes, I mean—have one characteristic: they have a kind of symmetry. Figure 10-2 shows an ion of a particular type called magenta, which has a purplish red color. The molecule has three ring structures, two of which are benzene rings. The third is not exactly the same as a benzene ring but not exactly nonbenzenoid, the ring. This figure shows two equilibrium stationary points, and we would guess that they should have equal energies E_1 . There is a certain amplitude that all the electrons can "tip" from one condition to the other, without the position of the "center" (position of the opposite end) with so many electrons involved, the flipping amplitude is considerably less than it is in the case of benzene, and the difference is in energy between the two is very, very small. Then, unfortunately, there are two stationary states ψ_1 and ψ_2 which are the sum and difference combinations of the two low states shown in the figure. The energy separation of ψ_1 and ψ_2 is enough to be equal to the energy of a photon in the visible region. There comes light on the molecule, and it is a very strong absorption at one frequency, and it appears to be highly colored. That's what it looks like.

An other interesting feature of such a dye molecule is that in the two case states shown, the center electric charge is located at different places. As a result, the molecule should be a rough testbed for a static electric field. We can get a similar effect in the ammonia molecule. To carry on the analysis by using exactly the same mathematics, provides work on the numbers E_1 and E_2 . Generally, these are obtained by putting experimental data. If we make measurements with many atoms, it is often possible to guess what will happen with some related dye molecule. Because of the large shift in the position of the center of electric charge, the value of μ in formula (10-20) is large, and this results in a high probability for absorbing light of the characteristic frequency ν_{ch} . Therefore, it is not only colored but very strongly so; it can absorb λ visible at about ϵ of light.

The rule of hopping—any, therefore, ψ is very sensitive to the complete structure of the molecule. By changing ψ , the energy splitting and with it the color of the dye can be changed. Also, the molecule does not have to be perfectly symmetrical. We know, even if the molecule has no mirror axis with slight modifications, even if there is some small asymmetry present, ψ_1 , ψ_2 can get some modification of the values by introducing slight asymmetries in the molecule. The example, an even important one, methylene green, is very green or blue-green, but has two of the cyano groups replaced by CH_3 . It's a different color because the ψ_1 is shifted and the flip flop ψ_2 is changed.

10-6 The Hamiltonian of a spin one-half particle in a magnetic field

Now we would like to discuss a two-state system involving an object of spin one-half. Some of you may well say, has been another electron example, but using it again may help to make some ideas perhaps a little clearer. We can think of it, electron, as just an $s = 1/2$ system. Although we will be talking in this chapter about "one-electron," when we find a $s = 1/2$ system for any spin one-half particle, suppose we choose for our base states ψ_1 and ψ_2 the states of ψ_1 and ψ_2 occupied at the electron spin $s = 1/2$ and $-1/2$.

In the previous section, we saw that the wave functions for two electrons in a magnetic field along the \hat{z} -axis were called $|+ \rangle$ and $|-\rangle$. In earlier chapters, we kept the notation of the chapter consistent, though, so we call this "up" and "down". From the time-symmetric state $|2\rangle$, the "up" and "down" refer to the angular momentum in the \hat{z} -direction.

Any possible value ϕ for the electron can be expressed as in Eq. (7.10), say giving the amplitude C_1 for the electron to be in state $|+\rangle$, and the amplitude C_2 that it is in state $|-\rangle$. To treat this problem, we will need to know the Hamiltonian for the two-state system that we have chosen to represent a magnetostatic. We begin with the contribution of a magnetic field in the \hat{x} -direction.

Remember that the \hat{x} -axis is the direction of the component B_x . From the definition of the two basis states (and the spins parallel and antiparallel to B_x) we know right away they are already stationary states with a definite energy in the \hat{x} -magnetic field. State $|+\rangle$ corresponds to an energy equal to $-e\hbar\omega$ and state $|-\rangle$ to $+e\hbar\omega$. The hamiltonian must be very simple in this case since C_1 or amplitude to have state $|+\rangle$ is not affected by C_2 , and vice versa.

$$\begin{aligned} h_1 \frac{dC_1}{dt} &= C_1 E_1 = -e\hbar\omega C_1, \\ h_2 \frac{dC_2}{dt} &= B_x C_2 = +e\hbar\omega C_2. \end{aligned} \quad (7.19)$$

In this special case, the Hamiltonian is

$$\begin{aligned} H_{1x} &= -e\hbar\omega, & H_{2x} &= 0, \\ H_{2x} &= 0, & H_{1x} &= +e\hbar\omega. \end{aligned} \quad (7.20)$$

So we know what the hamiltonian is due to magnetostatic in the \hat{x} -direction, and we know the energies of the stationary states.

Now suppose the field is not in the \hat{x} -direction. What is the hamiltonian? How are the basis elements changed if the field is not in the \hat{x} -direction? We are going to make an assumption here, the \hat{x} -is-a-kind-of-supposition principle for the form of the hamiltonian. More specifically, we want to assume that if two magnetic fields are superposed, the total is the hamiltonian simply added unless one field B_x has a plus B_x and the other has B_y . For a plus B_x then the total is H_x and H_y ; the basis is simply the same. This is sensible because if we consider only terms in the \hat{x} -direction, it's evident no other B_x are included. So let's assume that H is just $H_x + H_y$ the field B . That's all we need to be able to find the H_{ij} for any magnetic field.

Suppose we have a constant field B . We could take B to be along \hat{x} , its direction, and we would have found two stationary states with energy $-e\hbar\omega$ and $+e\hbar\omega$ respectively. Now if B is at a different orientation θ , it's not the \hat{x} -axis. Our assumption of the energy levels will be sufficient but, however, not quite the "full" form H ,

$$E_1 = -e\hbar^2\omega_x^2 + \eta_1^2 + \eta_2^2 \quad (7.21)$$

and

$$E_2 = +e\hbar^2\omega_x^2 + \eta_1^2 + \eta_2^2.$$

The rest of the proof is easy. We have here the formulas for the energies. We want a hamiltonian where η_1 , η_2 , and ω_x are what will give the new energies as calculated in our general formula of Eq. (7.10). The problem lies the θ -direction. First notice that the energy splitting is consistent with an average potential energy. Taking Eq. (7.21) we immediately find the expected

$$H_{12} = -H_{21}$$

which checks with what we already know about η_1 and η_2 are both zero.

[†]We are calling the resulting η_1 and η_2 "average" or energy of the magnetic moment instead of the $\sqrt{\eta_1^2 + \eta_2^2}$ to keep things simple, especially for the first part of the proof.

in that case $H_{11} = -\mu B_1$ and $H_{22} = \mu B_2$. Now if we equate the averages of $\langle H_{ij} \rangle$ (0.2.16) to what we argue from Eq. (10.10) we have

$$\left(\frac{n}{2} - \frac{H_{12}}{2}\right)^2 = H_{11}^2 = \epsilon^2(B_1^2 + B_2^2 + B_3^2) \quad (10.20)$$

(we have also made use of the fact that $H_{12} = H_{21}$, so that $H_{12}H_{21}$ can also be written as H_{12}^2). Again for the special case of a field in the x -direction, this gives

$$\epsilon^2(B_1^2 + B_2^2) = H_{11}^2 = \epsilon^2 B_1^2.$$

Thus B_1 , H_{11} must be zero in this special case, which means that H_{11} cannot have any terms in B_2 . (Remember we have said that all terms in H_{11} lie in B_1 , B_2 and B_3 .)

So far then, we have determined that H_{11} and H_{22} have to be $\pm B_1$, while H_{12} and H_{21} are not. We can make a simple guess as will satisfy Eq. (10.20) if we do this:

$$\begin{aligned} H_{11} &= \pm \mu B_1 \\ H_{22} &= \pm \mu B_1 \\ \text{and} \quad H_{12} &= \epsilon^2(B_1^2 + B_2^2) \end{aligned} \quad (10.21)$$

And it turns out (and that's not only my way to do it) that

"Well" you say "What's not linear in B ? So (10.21) gives $H_{12} = \mu(B_1^2 + B_2^2)$ " Not necessarily. There is another possibility which is linear in B ,

$$H_{12} = \mu(B_1 + B_2).$$

There are, in this, several other possibilities too, but given μ , we can always

$$H_{12} = \mu(B_1 + B_2),$$

where ± 1 is some arbitrary sign. Which sign should there should be? Well, as you can see you can change either sign and my phase you want, and the physics does not care, always be the same. So the choice is a matter of convention. I hope already we have chosen to use the minus sign and we take $\epsilon^2 = -1$. We might as well follow suit and write

$$H_{11} = -\mu B_1 + iB_2, \quad H_{22} = -\mu B_1 - iB_2.$$

Finally, all these quantities are related in a consistent manner, and of the arbitrary choices we made in Chapter 6,

to generate them based for an electron in an arbitrary magnetic field, is, then

$$\begin{aligned} H_{11} &= -\mu B_1, \quad H_{22} = -\mu B_1 + iB_2, \\ H_{12} &= -\mu(B_1 + iB_2), \quad H_{21} = -\mu B_2. \end{aligned} \quad (10.22)$$

And the equations for the amplitudes C_1 and C_2 are

$$\begin{aligned} \frac{dC_1}{dt} &= -iB_2 C_1 - (\mu - i\mu) C_2, \\ \frac{dC_2}{dt} &= -i\mu B_2 + iB_1 C_1 - \mu C_2. \end{aligned} \quad (10.23)$$

So we have discovered the "equations of motion for the spin state" of an electron in a magnetic field. We can test them by making some physical measurements, but the real test of any Hamiltonian is to see if specific gas problems in agreement with experiments. According to the tests that have been made, these equations are right. In fact although we made our elements only be constant, fitting the hydrogen we find evidence is enough for magnetic fields which vary with time. So we can now use Eq. (10.23) to look at all kinds of interesting problems.

10-7 The spinning electron in a magnetic field

Example: Let's say the electron has a constant field in the \hat{x} -direction. There are just the two stationary states with energies $E_{\pm}\mu_B$. Suppose we add a small field in the \hat{z} -direction. Then the equations look like our old two-state problem. We get the Landau levels again, more, and new energy levels are split a time for it is open. Now let's let the component of the field vary with time—say, as $B = B_0 \sin \omega t$. The equations are then the same as we had when we put an oscillating electric field in the \hat{x} -direction (discussed in chapter 9). You can work out the details in the same way. You will get the result that the oscillating field causes transitions from the $+$ state to the $-$ state—and vice versa. When the horizontal field oscillates with the natural frequency $\omega_0 = 2eB_0/\hbar$, this gives the maximum instantaneous energy of the magnetic resonance frequency ω_0 described in chapter 15 of Fermi's book.

It is also possible to make a magnet which does a spin precessing system. A Stern-Gerlach apparatus is used to produce a beam of particles following \hat{x} or \hat{y} , the \hat{z} -direction, which are to interact with an external magnetic field. The oscillating fields in the cavity can couple with the magnetic moment and induce oscillations which give energy to the cavity.

Now back to our preceding question. Suppose we have a magnetic field. At other points in the direction where polarization is \hat{z} and azimuthal angle is ϕ , as in Fig. 10-3. Suppose additionally that there is a current which has been produced with by spin oscillating along this field. What are the amplitudes C_1 and C_2 for such an electron? In other words, taking the sine of the electron ψ , we want to write

$$\psi = C_1 e^{iE_1 t} + C_2 e^{iE_2 t},$$

where E_1 and E_2 are

$$E_1 = E_0(\rho), \quad E_2 = \omega^2 |\psi|,$$

(here by $| \psi |$ and $| \psi |^2$ we mean the same thing we used to call $| + \rangle$ and $| - \rangle$ for real wave functions, see).

The answer to this question is obtained by generalizing to two-state systems. First we know that since the electron's spin is $\pm \hbar/2$ and it is in a stationary state with energy $E_0 = \pm \mu_B$, therefore both C_1 and C_2 must vary according to $e^{iE_0 t} (\propto \cos)$, and their coefficients a_1 and a_2 are given by (10.21), namely,

$$\frac{a_1}{a_2} = \frac{H_{12}}{E_0 - H_{11}}, \quad (10.24)$$

An added condition is that a_1 and a_2 should be normalized so that $|a_1|^2 + |a_2|^2 = 1$. We can take H_{12} and H_{11} from (10.22) using

$$B_x = B_0 \cos \theta, \quad B_y = B_0 \sin \theta \cos \phi, \quad B_z = B_0 \sin \theta \sin \phi.$$

So we have

$$\begin{aligned} H_{11} &= -\mu_B B_0 \cos \theta \\ H_{12} &= -\mu_B B_0 \sin \theta \cos \phi + i \mu_B B_0 \sin \theta \sin \phi. \end{aligned} \quad (10.25)$$

The last factor in the second equation is, incidentally, $i^2 = -1$ (a simpler writing).

$$H_{12} = -\mu_B \sin \theta \sin \phi. \quad (10.26)$$

Using these in the expression in Eq. (10.16) and canceling out the numbers after the decimal point, we get

$$\frac{a_1}{a_2} = \frac{\sin \theta \sin \phi}{-\cos \theta}. \quad (10.27)$$

With this ratio and the normalization condition, we can find both a_1 and a_2 . This is not hard, for we can make a selection with a little trick. Notice that

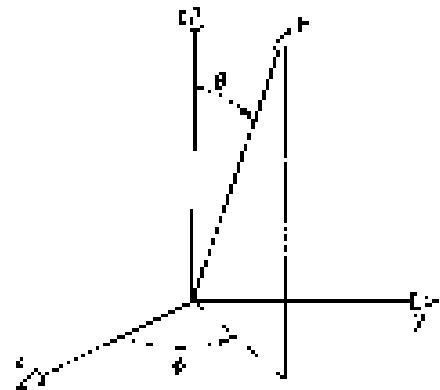

Fig. 10-3. The magnetic field \vec{B} in a rotating frame. The field \vec{B} is defined by the polar angles θ and ϕ in the coordinate system $x-y-z$.

$\hat{S}_z = \cos\theta = 2 \sin^2(\theta/2)$, and $\hat{C}_{12} = \hat{C}_1 \sin(\theta/2) \cos(\theta/2)$. Then Eq. (10.27) is equivalent to

$$\frac{\alpha_1}{\alpha_2} = \frac{\cos^2(\theta/2)}{\sin^2(\theta/2)}. \quad (10.29)$$

Several possibilities exist:

$$\alpha_1 = \cos \frac{\theta}{2} e^{i\phi}, \quad \alpha_2 = \sin \frac{\theta}{2}. \quad (10.29)$$

Now, Eq. (10.28) and this makes

$$|\beta_1|^2 = |\alpha_1|^2 = 1.$$

At this stage, multiplying by $e^{i\phi}$ is allowed, because arbitrary phase factors don't change anything. I myself personally prefer to make Eqs. (10.28) and (10.29) look like multiplying both by $e^{i\theta/2}$. So the form usually seen is

$$\alpha_1 = \cos \frac{\theta}{2} e^{-i\phi/2}, \quad \alpha_2 = \sin \frac{\theta}{2} e^{-i\phi/2}, \quad (10.30)$$

and this is the answer to our question. The spin vector and its components along the x -axis and y -axis are given up at this stage, because we know that its spin $\frac{1}{2}$ along the z -axis and α_1, α_2 amplitudes C_1 and C_2 are just α_1 and α_2 times $e^{i\phi/2}$.

Now we notice an interesting thing—the wrong half of the information has disappeared from us, see Eq. (10.29). This is clearly the same as multiplying that agrees to zero. The message that we have to search is general: the question of how to represent a particle whose spin is $\frac{1}{2}$ is an arbitrary task. The amplitudes of (10.30) are the projection amplitudes for spin $\frac{1}{2}$ particles propagating to the projective σ_z spin states we gave in Chapter 6 (Eqn. (6.32)). To spin $\frac{1}{2}$ particles, we can now give the amplitudes for several basis of spin $\frac{1}{2}$ particles in an elliptical state, particular Stern-Gerlach filter.

For $\sigma_z = +\frac{1}{2}$ say, we start with an input state $\psi_{in} = \alpha_1 |+\rangle + \alpha_2 |-\rangle$ and the spin does not. If $\sigma_z = +\frac{1}{2}$, represents state $+\frac{1}{2}$ spin up channel ψ_{out} , which makes the polar angles S and ϕ well defined, then in the middle part of the sum, we have

$$(+\epsilon) + \epsilon^* = \cos \frac{\theta}{2} e^{-i\phi/2} + (-\epsilon) |+\rangle = \sin \frac{\theta}{2} e^{-i\phi/2}. \quad (10.31)$$

This result is equivalent to what we began in the sum, Eq. (6.32), by partly ignoring the parameter ϕ . If you need to skip Chapter 6, you won't have lost anything important!

As in the Example 8.3 back again at the start of this section, a number of times. Suppose that we consider the following problem. We start with an electron whose spin is in some given direction, i.e., the σ_z in a magnetic field in the z -direction (Eq. 10.29 numbers), and then we want to know what is the σ_x direction. Again let's remember the rule by the Pauli combination $\psi_{out} = C_1 \psi_{in} - i C_2 \psi_{in}$ for this problem. However, the states of σ_z are unique and always have the form $|+\rangle$ and $|-\rangle$, so C_1 and C_2 only vary in phase. We know that

$$C_1(0) = C_1(0)e^{-i\phi/2} = C_1(0)e^{i\phi/2},$$

and

$$C_2(0) = C_2(0)e^{-i\phi/2} = C_2(0)e^{i\phi/2}.$$

Now initially we set the initial spin up σ_z was set in a given direction. This means that initially C_1 and C_2 are two numbers given by Eq. (10.29). After we wait a period of time T , the new C_1 and C_2 are the same two numbers multiplied respectively by $e^{i\phi/2T}$ and $-e^{i\phi/2T}$. What value is $\phi/2T$? It's $\pi/2$. That's why it's exactly the same as the angle θ we've struggled hard to find the sum of $C_1 \hat{S}_x T \psi_{in} + C_2 \hat{S}_y T \psi_{in}$, the angle of the last but one amplitude. This means that all the terms of the sum

cancel.

2. the same spin represents an electron having spin direction which differs from the original direction, say by a rotation about the \hat{z} -axis through the angle $\theta = \pi/2$. As we discussed in problem 10.1, we can also say the direction in the spin space is the angular vector $(\sin \theta, 0, \cos \theta)$ in the x - y - z axis. This result we discuss in several cases previously in the beginning and right now more. Now we have additional examples and accurate quantum mechanical description of the propagation of atomic magnetism.

It is interesting that the systems that we see here have no joint use. For the spinning electron in a magnetic field can be applied to any two-state system. This means that by making a quantum field analogy to the spinning electron, any particular two-state system can be solved by just putting $\psi = f(\theta, t)$ where $t = \tau/\omega_0$ so that the sum of energy so that $H_{\text{tot}} = H_{\text{ext}}$ is equal to zero or that $H_{\text{tot}} = -H_{\text{ext}}$. Thus any two-state problem is basically the same as the electron in a magnetic field. All you have to do is write $\psi = f(\theta)$, with $\partial/\partial\theta$ and $-\partial/\partial\theta = \partial\theta/\partial t$. Right? So similar what the physics is going to be—any number methods, or whatever you can think, it has a corresponding effect on problem. So it was not easy to make up problem to answer, we have solved all the state problems.

Now we have the general solution to the problem. Suppose you have come close to start with that this spin "is" in one direction and you get a constant field at last point in some other direction. You just need to understand that if the spin of ψ with the same angular velocity and equal to a constant times the vector B (initially $\psi = \psi_0 e^{i\omega_0 t}$) as you write with the θ , you have to make the use of the relation to keep ψ parallel with B , and keep changing the speed of rotation so that it is always perpendicular to the field and B , see Fig. 10-11. If you look along Ch. 20, will the ψ with certain final orientation of the spin axis, and the angle $\theta_1, \theta_2, \theta_3$ are just given by the angle between ψ and B ? Just to make this simple. You see it's another geometry problem to keep track of when you do the propagation resulting. Although it's easy to see what's involved, this geometry problem (of finding the norm of ψ in a relation with a varying angular velocity vector) is not easy to solve especially in the general case. Anyways, we can do it without, by given condition in any particular problem. In the next chapter we will talk more about the mathematical techniques for handling the important issue of a spin-orbit coupling and, therefore, for handling n -state systems in general.

21

More Two-State Systems

II-1 The Pauli spin matrices

We continue our discussion of two-state systems. At the end of the last chapter we were talking about a spin and all particles in a magnetic field. We described the spin state by giving its amplitude C_1 , that the z-component of spin angular momentum is $|1/2\rangle$ and the anisotropy $\langle \hat{S}_z \rangle$ was $-h/2$. In earlier chapters we have called these basis states $|+\rangle$ and $|-\rangle$. We will now go back to that notation, although we may occasionally find it convenient to use $|+\rangle$ or $|-\rangle$, and $|+\rangle$ or $|-\rangle$ interchangeably.

We saw in the last chapter that when a spin interacts with a magnetic moment μ is in a magnetic field $\mathbf{B} = (B_x, B_y, B_z)$, the amplitudes $C_+(t)$ and $C_-(t)$ are connected by the following differential equations:

$$\begin{aligned} i\hbar \frac{dC_+}{dt} &= -i(B_x C_+ + (B_y - iB_z)C_-), \\ i\hbar \frac{dC_-}{dt} &= -i((B_x + iB_y)C_+ - B_z C_-). \end{aligned} \quad (II.1)$$

In other words, the Hamiltonian matrix H_{ij} is

$$\begin{aligned} H_{11} &= -iB_y & H_{12} &= i(B_x - iB_z) \\ H_{21} &= -i(B_x + iB_y) & H_{22} &= -iB_z. \end{aligned} \quad (II.2)$$

And $(II.1)$ and $(II.2)$ are of course the same as

$$i\hbar \frac{dC_i}{dt} = \sum_j H_{ij} C_j, \quad (II.3)$$

where i had ± 1 take on the values $i = +1$ and $-i = -1$ (Fig. 1 and 2).

The two-state system of the electron spin is so important that it is very useful to know exactly how we are writing things. We will now make a little mathematical digression to show you how people usually write the equations of a two-state system. It is done this way: first, note that each term of the Hamiltonian is proportional to μ and to some component of \mathbf{B} ; we can then "cancel μ " and write that:

$$H_{ij} = -i(\epsilon_{ij} B_x + \alpha_i B_y + \beta_{ij} B_z) \quad (II.4)$$

where ϵ_{ij} is now physical (here, ϵ is obtained from means m), the coefficient is α_i , β_{ij} , and ϵ_{ij} . There are $N \times N = 12$ of them, can be figured out so $(II.4)$ is identical with $(II.2)$.

Let's see what they have to do. We start with $\alpha_i = 0$; B_x appears only in H_{11} and H_{22} , everything will be R.K. If

$$\begin{aligned} \epsilon_{11} &= 1, & \epsilon_{22} &= 0, \\ \alpha_{11} &= 0, & \alpha_{22} &= -1. \end{aligned}$$

We often write the matrix H_{ij} as a table like this:

$$H_{ij} = \begin{pmatrix} \epsilon_{11} & H_{12} \\ H_{21} & \epsilon_{22} \end{pmatrix}.$$

Review Chapter 23, Vol. I, Physics 102

† The second article, as printed on the 2nd reading of the book. It is close to my original notes; however, I have not checked it.

For the Hamiltonian we can substitute back in the magnetic field \mathbf{B} . This is interesting:

$$H_0 = \frac{1}{2} \begin{pmatrix} -\omega_B & \omega(B_x - iB_y) \\ \omega(B_x + iB_y) & +\omega_B \end{pmatrix}$$

In the same way we can write the coefficients σ_i^x as the matrix

$$\sigma_i^x = \frac{1}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (1.3)$$

Multiplying with the coefficients of H_0 , we get that the terms of σ_i have to be

$$\sigma_{11}^x = 0, \quad \sigma_{12}^x = 0,$$

$$\sigma_{21}^x = 0, \quad \sigma_{22}^x = 0.$$

Or, in shorthand,

$$\sigma_i^x = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}. \quad (1.4)$$

Finally, looking at B_y , we get

$$\tau^2 - \omega_B - \sigma_{12}^y = 0,$$

$$\sigma_{12}^y = 0, \quad \sigma_{21}^y = 0;$$

or

$$\sigma_i^y = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}. \quad (1.5)$$

With these three signs missing, Eqs. (1.12) and (1.13) are identical. To have room for the subscripts $(+)$ and $(-)$, we have shown which signs go with which component of \mathbf{B} in \mathbf{B}_1 , \mathbf{B}_2 , \mathbf{B}_3 , and \mathbf{B}_4 respectively. Usually, however, one finds the signs omitted.

It's easy to verify that they are there. And the σ_i 's can be written as (Table 1.1). Table 1.1 (1.1) is written:

$$\sigma_i^z = -\sigma_1 \sigma_2 \sigma_3 + \sigma_2 \sigma_3 \sigma_1 + \sigma_3 \sigma_1 \sigma_2. \quad (1.6)$$

Because the sigma matrices are so important, they are used all the time by the professionals. We have put them together in Table 1.1. (Anyone who is going to work in quantum mechanics has to memorize them. They are also in the book just mentioned over the physicist who invented them.)

In the text we have included an "easy" system matrix which is useful if we want to calculate the energy of a system with two spin degrees of freedom, or if we want to choose a different zero energy. For such situations we take $\mathbf{E}_1, \mathbf{E}_2, \mathbf{E}_3$ to be the first equation (1.11) and \mathbf{E}_4, \mathbf{C} to be the second equation. We can include this in the new table (in) if we define the *spin matrix* " Γ " as follows:

$$\Gamma = \sigma_i^z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad (1.7)$$

and reverse Eq. (1.8) to

$$H = \mathbf{E}_1 + \mu_B \mathbf{B}_1 - \mu_B \mathbf{B}_2 + \mu_B \mathbf{B}_3. \quad (1.8)$$

Usually, the unknown Γ is not given but like E_0 is automatically understood implicitly. In which case, the equations simply

$$H = \mathbf{E}_1 + \mu_B \mathbf{B}_1 - \mu_B \mathbf{B}_2 + \mu_B \mathbf{B}_3. \quad (1.11)$$

One reason the spin matrices are useful is that expressed by the matrix Γ we can be interested in terms of them. A vector \mathbf{v} and its conjugate \mathbf{v}' has four numbers in it, say,

$$\mathbf{v} = \begin{pmatrix} v_1 & v_2 \\ v_3 & v_4 \end{pmatrix}.$$

M can always be written as a linear combination of Pauli matrices. For example,

$$M = a \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix} + b \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} + c \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} + d \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}.$$

There are many ways of doing it, but one special way is to say that M is a certain amount of σ_x , plus a certain amount of σ_y , and so on. That is:

$$M = aI + b\sigma_x + c\sigma_y + d\sigma_z$$

where the "coefficients" a , b , c , and d may be positive or complex numbers.

Since any two-by-two matrix can be represented in terms of the Pauli matrices and the identity matrix, we have all that we need for any two-state system. We know what the two-state system—its wavefunction evolution, the measured energy, the Hamiltonian, everything can be written in terms of the sigma's. Although the sigma's seem to have a particular significance in the physical problem of magnetism in a magnetic field, they can also be thought of as just useful matrices, which can be used for any two-state problem.

For instance, in the case of blocking Larmor motion, and a photon can be thought of as interacting with either of two states. We say the photon (photon or electron) is a two-state system. In this case, two states with respect to the charge. When blocked in the $|+\rangle$ state, the $|-\rangle$ state can represent the photon and the $|+\rangle$ state can represent the hydrogen. People say that you can obtain two "hydrogen-like" states.

Since we will be using the properties of the "algebra" of the common mathematics of two-state systems, let's review quickly the common rules of matrix algebra. By the "sum" of any two square matrices we mean what was obvious in Eq. (II.2). In general, if we "add" two matrices A and B , the "sum" C means that each term C_{ij} is given by

$$C_{ij} = A_{ij} + B_{ij}$$

Each term of C is the sum of the terms in the same cells of A and B .

In Section 4-5 we have already mentioned that the rule of a sum is "zero sum." This concept will be useful calculating with the sigma matrices. In general, the "product" of two matrices A and B (in that order) is defined to be a matrix C whose elements are

$$C_{ij} = \sum_k A_{ik}B_{kj} \quad (\text{II.12})$$

The pattern of products of terms taken in pairs from the i th row of A and the j th column of B . If row indices are written out in tabular form as in Fig. II-1, there is a good "system" for getting the terms of the product matrix. Suppose you are calculating C_{12} . You run your left index finger along the second row of A and your right index finger down the first column of B , multiplying out pair and pairing as you go. The bars used to indicate zero to do it in two digits.

$\begin{pmatrix} A_{11} & A_{12} & A_{13} & A_{14} \\ A_{21} & A_{22} & A_{23} & A_{24} \\ A_{31} & A_{32} & A_{33} & A_{34} \\ A_{41} & A_{42} & A_{43} & A_{44} \end{pmatrix}$	$\begin{pmatrix} B_{11} & B_{12} & B_{13} & B_{14} \\ B_{21} & B_{22} & B_{23} & B_{24} \\ B_{31} & B_{32} & B_{33} & B_{34} \\ B_{41} & B_{42} & B_{43} & B_{44} \end{pmatrix}$	$\begin{pmatrix} C_{11} & C_{12} & C_{13} & C_{14} \\ C_{21} & C_{22} & C_{23} & C_{24} \\ C_{31} & C_{32} & C_{33} & C_{34} \\ C_{41} & C_{42} & C_{43} & C_{44} \end{pmatrix}$
$\overbrace{\hspace{10em}}$	$\overbrace{\hspace{10em}}$	$\overbrace{\hspace{10em}}$

$$C_{12} = \sum_k A_{1k}B_{k2}$$

$$= A_{11}B_{12} + A_{12}B_{22} + A_{13}B_{32} + A_{14}B_{42}$$

Fig. II-1. Multiplying two matrices.

It's a bit more complicated for two-system matrices. For instance, if we multiply σ_x times σ_z , we get

$$\sigma_x^2 = \sigma_x \cdot \sigma_z = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix},$$

which is just the unit matrix \mathbf{I} . Or, for another example, it's worth noting

$$\sigma_x \sigma_y = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} \cdot \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} = \begin{pmatrix} i & 0 \\ 0 & -i \end{pmatrix}.$$

Looking at Table 11-1, you see that the product is just i times the unit matrix—just as multiplying two numbers each term of the matrix. Since the products of the sigma taken over and over are important, it's well to remember. We considered them all in Table 11-1, but now we're interested in how they fit in a theory.

There's another very important and interesting point about these σ matrices. We can imagine, if we wish, that the three matrices σ_x , σ_y , and σ_z are analogous to the three components of a vector—it's sometimes called the "magnetic vector," or "angular momentum vector," or "vector-matrix." It is three different numbers, and hence associated with position, or, x , y , and z . With it, we can write the Hamiltonian of the system in a nice form which works in any coordinate system:

$$H = -\mu \mathbf{B} \cdot \mathbf{R}. \quad (11.12)$$

Although we'll see why this has three entries in the representation in which "up" and "down" states have different spin numbers, and a particle's spin σ —we could agree on which the matrix would look like in some other representation. Although it takes a lot of algebra, you can show that they change, among themselves like the components of a vector. (We won't, however, carry around proving it right now. You can check it if you want.) You can use it in different coordinate systems, as though it is a vector.

You remember that the H is related to energy in quantum mechanics. It is, at best, just equal to the energy in the simple situation where there is only one state. Even for two-state systems of the electron spin, where we write the Hamiltonian as in Eq. (11.12), it's like saying that the classical term is for the energy of a charged magnet with magnetic moment μ in a magnetic field B . Classically, we would get

$$E = -\mu \mathbf{B} \cdot \mathbf{R}. \quad (11.13)$$

where \mathbf{R} is the position of the magnet and \mathbf{B} is an external field. We can imagine that Eq. (11.13) can be converted to (11.12) if we replace the classical energy by the Hamiltonian and the classical \mathbf{B} by the \mathbf{B} from Eq. (11.1). Then, after this simple formal substitution, we'll be just the result as a magnetic dipole. It is sometimes said that magnetism in classical physics does not respond to magnetic quantum mechanics. It is really more correct to say that the Hamiltonian which corresponds to the energy and the quantity that can be related to energy has a corresponding matrix.

For example, the magnetic moment can be defined classically by saying that the energy in an external field B is $-\mu \cdot \mathbf{B}$. This defines the magnetic moment μ . Then we look at the formula for the momentum of a test particle in an object in a magnet field and try to identify whatever the charges are and correspond to the various components in the classical formula. That's the trick by which quantum力学和磁矩的对应关系可以被建立起来。

You may say, if you want to understand what a classical vector is, try to do it, and maybe you will discover something that won't break your head. But that's not the idea. They are two *separate* quantum mechanics, a different kind of a theory in different parts of the world. It just happens that there are certain correspondences which are really more than mere coincidences, which things to remember with. That is, you remember Eq. (11.12) because you learned classical physics, 11-4

then if you remember the correspondence principle you have a headache, or something like Eq. (11.13). Of course you're using the quantum mechanics, and the classical mechanics is only an approximation. So there is no mystery in the fact that in classical mechanics there is an equation of motion, or an "acceleration law," which are truly the same fundamental. To reconstruct the original object from the shadow is not possible in any general way, but the shadow does help you to remember what the object looks like. Equation (11.13) is the truth, and Eq. (11.10) is just a guess. Because we learn classical mechanics first, we would like to be able to get the quantum formula from it, but there is no automatic scheme for doing that. We must always go back to the real work and discover the correct quantum mechanical equations. When they come out looking like something in classical physics, we are in luck.

In the shadow concept each hope turns and appears to you to be elaborating the actual trouble down the relation of classical physics to quantum physics. Please notice the circumlocuted sentence of a professor who has really taught quantum mechanics to students who he didn't know them to represent, and they were in graduate school! That boy always seemed to be hoping that somehow symmetry in different ways could be seen to follow as a logical consequence of classical mechanics which they had learned three nights years before. (Perhaps they wanted to make it easier to learn something new.) Then he mentioned the classical formula, Eq. (11.14), in your old notes again, and then with something that it was far too quaint to expect you would be so unwilling to take new symmetric formula, Eq. (11.13), as the basic one.

11-2 The spin matrices no operators

While we are on the subject of undetermined numbers, you would like to be able to still consider ways of writing things—ways which is used very often because it is so simple. It comes directly from the "scatter" introduced in Chapter 8. If we have a system, it is a state $|S\rangle$ which varies with time, we can—as we did in Eq. (8.7)—write the amplitude that the system would be in the state $|S'\rangle$ at $t = \infty$ as

$$\langle S'|S\rangle = \delta(S, S') = \sum_i \langle S|S_i\rangle \delta(S_i, S').$$

The matrix elements $\langle S|S_i\rangle = \delta(S_i, S)$ is the amplitude that the state $|S\rangle$ will be converted into the state $|S_i\rangle$ in the time interval of Δt . We can define this by writing

$$S_i(t) = \delta(S_i, S) = C_i - \int_{-\infty}^t R_i(t') dt'$$

and we expect that the amplitudes $C_i(t) = \langle S|S_i(t)\rangle$ are related by the differential equations

$$\partial_t \frac{dC_i}{dt} = \sum_j R_{ij} C_j. \quad (11.15)$$

If we substitute the amplitudes C_i explicitly, the equation is then appears as

$$\partial_t \frac{d}{dt} \langle S|S\rangle = \sum_i \partial_t \langle S|S_i\rangle \delta(S_i, S). \quad (11.16)$$

Now the matrix elements R_{ij} are also amplitudes which we can write as $\langle S|R_j|S\rangle$ (as differential operators having time rates).

$$\partial_t \frac{d}{dt} \langle S|S\rangle = \sum_i \langle S|R_i|S_i\rangle \delta(S_i, S). \quad (11.17)$$

Please note that $-\partial_t \langle S|R_j|S\rangle$ is the amplitude that under the physical transformation described by R_j a state $|S\rangle$ will change the name of, "generate" the state $|S_j\rangle$. (All of this is implied in the discussion of Section 8.4.)

Now following analysis of Section 9.2, we can drop out the common term $\psi \sim \text{Eq. (11.7)}$ since it is Euler angle θ —and write the equation simply as

$$\Psi \frac{d}{dt} \psi = \sum_i H_i(j) |j\rangle \langle j| \psi. \quad (11.18)$$

Or, using one step further, we can do so much: let us also write

$$A \frac{d}{dt} \psi = H | \psi \rangle. \quad (11.19)$$

In Chapter 9 we pointed out that when things are working the way they *H* in Eq. (11.19) or $H | \psi \rangle$ is called an operator. From now on we will put the line of text “*H* is an operator” to remind you that *H* is an operator and not just a constant. Then we write $\partial_t \psi$. All eight of the two equations (11.18) and (11.19) were originally given using $\psi \sim \text{Eq. (11.7)}$. Eq. (11.19), we can think about it in a different way. For instance, we would observe Eq. (11.18); in this way: “The time derivative of the state vector $|\psi\rangle$ is equal to what you get by operating with the Hamiltonian operator *H* on each basis state, multiplying by the amplitude $\langle j| \psi\rangle$; the $|j\rangle$ is in the state j , and summing over all $|j\rangle$.” Eq. (11.19) describes this way: “The time derivative (change) of a state $|\psi\rangle$ is equal to what you get if you operate with the Hamiltonian *H* on the basis vector $|\psi\rangle$.” Let just a short-hand way of saying what is in Eq. (11.19); now as you will see, it can be a great convenience:

If we wish, we can ignore the “derivation” idea, one more step. Equation (11.19) is true for any wave $|\psi\rangle$. Also on left-hand side $\partial_t \psi$, is also an operator —it’s the equation “differentiable by t and multiply by $i\hbar$ ”. Therefore, Eq. (11.19) can also be thought of as a connection between operators—an operator equation

$$i\hbar \frac{d}{dt} = \hat{H}.$$

The Hamiltonian operator (with $i\hbar$ constant) produces the same results as does when acting on any $|\psi\rangle$. Remember that this equation $i\hbar \frac{d}{dt} = \hat{H}$ (11.19) is *not* a statement that the \hat{H} operator is just the identical operator as $i\hbar \frac{d}{dt}$. It is just $i\hbar \frac{d}{dt}$ the fundamental law of nature—the law of motion—in a quantum system.

Just to get some practice with these ideas, we will show you another way we could get to Eq. (11.18). You know that we can write any state $|\psi\rangle$ as its components into states $|k\rangle$ and $|l\rangle$ (see Eq. (3.5)),

$$|\psi\rangle = \sum_k c_k |k\rangle |\psi_k\rangle. \quad (11.20)$$

so does $|\psi\rangle$ change with time? Well, just take its derivative:

$$\frac{d}{dt} |\psi\rangle = \frac{i\hbar}{\hbar} \sum_k c_k \frac{d}{dt} |k\rangle |\psi_k\rangle. \quad (11.21)$$

Now, before states $|k\rangle$ do not change with time because we are talking about as definite fixed k and the amplitudes c_k are numbers which may vary. So Eq. (11.21) becomes

$$\frac{d}{dt} |\psi\rangle = \sum_k c_k \frac{i\hbar}{\hbar} \frac{d}{dt} |k\rangle |\psi_k\rangle. \quad (11.22)$$

Since we know $i\hbar \frac{d}{dt} |k\rangle$ from Eq. (11.16) we get

$$\begin{aligned} \frac{d}{dt} |\psi\rangle &= \frac{i\hbar}{\hbar} \sum_k c_k \sum_j H_{kj}(j) |j\rangle \psi_j \\ &= \frac{i\hbar}{\hbar} \sum_j c_j |j\rangle H_{jj}(\psi_j) = \frac{i\hbar}{\hbar} \sum_j c_j H_{jj}(\psi_j) |j\rangle \psi_j. \end{aligned}$$

This is Eq. (11.18) all over again.

So we have many ways of writing or the hamiltonian. We can think of the σ 's as "spins" (they're really a bunch of numbers), we can think of the "impurities" of $H[\psi]$, or we can think of the "matrix" H , or we can think of the operator \hat{H} . It all means the same thing.

Now let's go back to our two state system. If we write the Hamiltonian in terms of the sigma operators (and suitable normalized coefficients like α_i etc.), we can directly solve (1.19) for an amplitude $\langle \psi_1 | \psi \rangle$ etc. (as shown in the signature). If you use the operator idea, we can write the equation of motion of wave $|\psi\rangle$ in a magnetic field as

$$\partial_t \frac{\delta}{\delta t} |\psi\rangle = -i(\vec{\sigma}_x \partial_x + \vec{\sigma}_y \partial_y + \vec{\sigma}_z \partial_z) |\psi\rangle \quad (1.20)$$

When we want to "solve" such an equation, we will normally have to expand $|\psi\rangle$ in terms of basis vectors (just as we have to find the expansion of space vector when we want operate (1.19)). So we will usually want to put Eq. (1.20) in the so-called expanded form:

$$\partial_t \frac{\delta}{\delta t} |\psi\rangle = -\mu \sum_i (\vec{\sigma}_x i_x + \vec{\sigma}_y i_y + \vec{\sigma}_z i_z) |\psi\rangle \quad (1.21)$$

Now you will see why one operation is so useful. To use Eq. (1.21) we need to know which components of the σ -operators work on each of the basis states. Let's do that. Suppose we have $|\pm\rangle$ it is a spin vector. So, but what? Well, let's multiply it on the left by $\langle \pm|$, we have

$$\langle \pm | \vec{\sigma}_x | \pm \rangle = \sigma_{x,\pm} = 1$$

Using Table 1.1-1, we see from $\sigma_{x,\pm}$:

$$\langle + | \vec{\sigma}_x | + \rangle = 1 \quad (1.22)$$

Now let's multiply $\langle \pm | \pm \rangle$ on the left by $\langle \mp |$. We get

$$\begin{aligned} \langle \pm | \vec{\sigma}_x | \pm \rangle &= \sigma_{x,\pm} = 1 \\ \langle - | \vec{\sigma}_x | - \rangle &= 0 \end{aligned} \quad (1.23)$$

Here is why one basis vector that satisfies both (1.22) and (1.23), it is $|\pm\rangle$. We know then that

$$\vec{\sigma}_x | \pm \rangle = \pm \langle \pm | \vec{\sigma}_x | \pm \rangle \quad (1.24)$$

By this kind of argument, you can easily prove that all the properties of the sigma operators can be described in the *signature notation* by the set of rules given in Table 1.1-1.

If we have products of $\vec{\sigma}_x$, and if we they appear in a products of $\vec{\sigma}_x$, then when we expand it using the $\sigma_{x,\pm}$ notation, you carry out first the operations with the operators which is further to the right. For instance, by $\vec{\sigma}_x \vec{\sigma}_y \rightarrow \cdot$ we are to understand $\vec{\sigma}_x \vec{\sigma}_y = 0$. From Table 1.1-1, we get $\sigma_{x,\pm} \sigma_{y,\pm} = \pm \delta_{xy}$, so

$$\vec{\sigma}_x \vec{\sigma}_y = \langle \pm | \vec{\sigma}_x | \pm \rangle \langle \pm | \vec{\sigma}_y | \pm \rangle \quad (1.25)$$

Now my number (like i , just i , etc.) might be greater or smaller than one. In this material, an Eq. (1.25) is the general

$$\langle \pm | \vec{\sigma}_x | \pm \rangle \langle \pm | \vec{\sigma}_y | \pm \rangle = \langle \pm | \vec{\sigma}_y | \pm \rangle \langle \pm | \vec{\sigma}_x | \pm \rangle$$

If you do the same thing for $\vec{\sigma}_x \vec{\sigma}_y^{-1} \rightarrow \cdot$, you will find that

$$\langle \pm | \vec{\sigma}_x | \pm \rangle \langle \pm | \vec{\sigma}_y^{-1} | \pm \rangle = \langle \pm | \vec{\sigma}_y^{-1} | \pm \rangle \langle \pm | \vec{\sigma}_x | \pm \rangle$$

Looking at Table 1.1-1, you see that $\vec{\sigma}_x \vec{\sigma}_y$ carried by $\langle \pm | \vec{\sigma}_y | \pm \rangle$ gives us what you get if you swap $\vec{\sigma}_x$ with $\vec{\sigma}_y$ and multiply by $-\delta_{xy}$. We can, therefore, say,

Table 1.1-2
Properties of the *signature*

σ_x	$\langle \pm \vec{\sigma}_x \pm \rangle = 1$
σ_y	$\langle \pm \vec{\sigma}_y \pm \rangle = 0$
σ_z	$\langle \pm \vec{\sigma}_z \pm \rangle = \pm 1$
σ_x^{-1}	$\langle \pm \vec{\sigma}_x^{-1} \pm \rangle = -1$
σ_y^{-1}	$\langle \pm \vec{\sigma}_y^{-1} \pm \rangle = 0$
σ_z^{-1}	$\langle \pm \vec{\sigma}_z^{-1} \pm \rangle = 1$

Let's suppose $\hat{A}_0 = \hat{B}_0$, it's identical with the operator \hat{M}_z , now write this statement as an operator equation:

$$\hat{A}\hat{C}_0 = \hat{B}_0. \quad (11.29)$$

Notice that this equation is identical with one of the matrix equations of Table 11.2. So again we see the correspondence between the matrix and Schrödinger picture of view. Furthermore the equations of Table 11.2 can, therefore, also be considered as equations about the same operators. You can check and may the initial follow from Table 11.2. It is true when working with these things, how to keep track of whether a quantity like \hat{A} is an operator or a number. All the quantities are the same either way as Table 11.2 is the right operators, or the right numbers as you wish.

11-3 The solution of the two-state equations

We can now write any two-state equation in various forms. For example, since we

$$\begin{aligned} i\hbar \frac{d\hat{C}_0}{dt} &= \sum_j H_{0j} \hat{C}_j \\ \text{or} \quad i\hbar \frac{d\hat{C}_0}{dt} &= H_0 \hat{C}_0. \end{aligned} \quad (11.30)$$

The last term means *no coupling*. For a spin one-half particle in a magnetic field, the Hamiltonian H is given by Eq. (11.6) or by Eq. (11.1).

If the field is in the \hat{z} -direction, then, as we have seen several times by now—the solution is $C_0 = C_0(\cos \omega t, \sin \omega t)$, whatever it is, processes around the \hat{z} -axis (just as if you were to turn the physical object we rotate it). In the moment the \hat{z} -axis is at an angle θ relative to twice the magnetic field times $\mu\hbar$. The same is true as before for a magnetic field in any other direction because the process is independent of the coordinate system. Now take a situation where the magnetic field varies from B_0 to B_1 in a smooth, elicited way, then we can analyze our situation in the following way. Suppose you start with the spin in the \hat{z} -direction and you have an x -magnetic field. The spin starts to turn. Then if the field is turned off, the spin stops turning. Now if the field is turned on again processes about \hat{x} , and so on. Now suppose we let the fields vary in time, you can figure out what the final state is—along which axis it will point. Then you can refer this state back to the original $| + \rangle$ and $| - \rangle$ with respect to \hat{x} by using the projection formulas we saw in Chapter 10 (in Chapt. 6). If the state ends up with its spin in the direction (B_x, B_y) , it will have an up-amplitude $\cos(\theta/2)e^{-i\phi/2}$ and a down-amplitude $\sin(\theta/2)e^{+i\phi/2}$. That's pretty good. Let's work this out of the solution of the differential equations.

The solution just described is sufficiently general to take care of any reasonable system. Let's take an example of two numbers making up—including the effects of an electric field. If we describe the system in terms of the states $| + \rangle$ and $| - \rangle$ the equations look like this:

$$i\hbar \frac{d\hat{C}_0}{dt} = -\Gamma_1 \hat{C}_1 - \omega \hat{C}_{11}, \quad (11.31)$$

$$i\hbar \frac{d\hat{C}_{11}}{dt} = -\Delta \hat{C}_{11} - \gamma \hat{C}_{11}.$$

You say, "But, I remember there was some A_0 in there." Well, we have added the ω in to energy to make the \hat{E}_0 , etc. etc. (You can always do that by changing the \hat{A} 's amplitudes by $e^{i\omega t}$ some time t , $e^{-i\omega t}$ later, and get rid of any constant energy.) Now if our expanding equations always have the same solutions, then we really can't care to divide twice... If we look at these equations and look at Eq. (11.1) then we can make the following identification. Let's call $| + \rangle$ the state $| + \rangle$ and $| - \rangle$ the state $| - \rangle$. What does we mean this? we are thinking of a wavefunction in space so that $| + \rangle$ and $| - \rangle$ has anything to do with the space. It is purely artificial.

We have an *arbitrary* spin; then we might "call the antinodal electron representation in space," or something—a three-dimensional "Vigint"—in which being " $\hat{\sigma}_z$ " corresponds to "having the molecule in the state $|z\rangle$ " and being " $\hat{\sigma}_{\pm}$ " doing just only basis movements having a coordinate in the states $|+y\rangle$, $|+x\rangle$. Then, the equations will be identical as follows. First of all, you see that the Hamiltonian can be written in terms of the sigma matrices as

$$H = \frac{1}{2}m + \mu\hat{\sigma}_z \quad (1.13)$$

(m , perhaps, is often zero, $\mu\hat{\sigma}_z$ in Eq. (1.13) corresponds to $-i$ in Eq. (1.22), and $\mu\hat{\sigma}_z$ corresponds to $-i\omega$). In our "model" above, then, we have a current i flowing along the z-direction. If we have an electric field E which is changing with time, then we have a $\partial E/\partial t$ field along the z-direction which varies in proportion. So the current of an electron is a constant field with a constant component in the z-direction and at oscillating frequency ω (or resistance to oscillating frequency ω) due to the derivative of the current with respect to the oscillating electric field. Unfortunately, we do not have the time to go any further into the details of this correspondence, or a work-out of the technical details. We only wished to make the four basic assumptions of Fermi's theory become analogous to a spin one-half object precessing in a magnetic field.

11-4 The polarization states of the photon

There are a number of other interesting systems which are interesting to study, and the first one we would like to look at is the photon. To describe a photon we must first give its vector momentum. For a monochromatic frequency, it is represented by the momentum, so we don't have to say also what the frequency is. After all, though, we can have a property called the polarization. Imagine then that there is a photon coming at you with a definite momentum in two axes (which we'll take the same thing out of this discussion to start with) in a linear wave of momentum space. Then there are two directions of polarization. In the classical theory, light can be described as having an electric field which oscillates periodically in an electric field with amplitude vertically (for instance); if the two kinds of light are called rectangular and unpolarized light, the light can also be polarized to some other direction, which we call up from the unpolarization as a final—the z-direction and down in the y-direction. Or if you take the x and the y components out of given by 90° you get an electric field that rotates, the light is elliptically polarized. (There is just a quick reminder of the coherent theory of polarized light that we studied in Chapter 11, Vol. I.)

Now, however, suppose we have a single photon—just one. There is no electric field that we can discuss in the sym way—all we have is one photon. But a photon has a very important of the classical parameters of polarization. There must be at least two different kinds of photons. At first you might think that there are infinitely many, after all, the electric waves can point in all sorts of directions. We can, however, describe the polarization of a photon as a two-state system. A photon can have the same state as the state $|x\rangle$ or $|y\rangle$; we call the polarization state of each one of these photons to be an $\alpha\beta$ state which obviously is a polarized light. On the other hand, by $\beta\beta$ we mean the polarization state of each of the photons in a unpolarized beam. And we can take $|x\rangle$ and $|y\rangle$ as our basis states of a photon of given energy, in passing along you in p ; we will call this polarization. So there are two base states, $|x\rangle$ and $|y\rangle$ and they are all that are needed to cover nearly photons at all.

For example, if we have a piece of polarized set with its axis to pass light parallel in x , at $\alpha\beta$ and the radiation and we send in a photon which we know is in basis $\beta|1\rangle$, it will be absorbed by the photon. If we send in a photon of which we know is in the state $|x\rangle$, it will come right through as $|x\rangle$. If we take a glass of water which takes a beam of polarized light and splits it into an $|x\rangle$ beam and an y beam, that piece of water is the complete top of a Stern-Gerlach apparatus which splits a beam of electrons into the two states $|x\rangle$ and $|y\rangle$. So every-

ding we did before with particles and Stern-Gerlach apparatuses, we can do again with light and pieces of calcite. And when light goes through a piece of polarized it "samples" both axes to decide how much energy has gone along each axis or the axis of the polaroid π' to distinguish it from the axes of our base states. See Fig. 11-2. A photon that comes out will be in the state $|x\rangle$. However, any state can be represented as a linear combination of these states, so it is enough for the combination $|y\rangle$, here.

$$|x\rangle = \cos \theta |x\rangle + \sin \theta |y\rangle \quad (11.31)$$

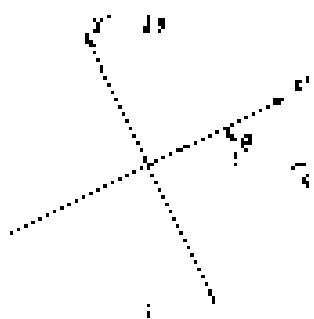

Fig. 11-2. Two polaroids, one light coming to the measurement vector of the other.

That is, if a photon comes through a piece of polaroid set at the angle θ (with respect to $|x\rangle$), it can still be resolved into $|x\rangle$ and $|y\rangle$ beams. In a case of calcite, for example. Or, you can, if you wish, just analyze it in $|x\rangle$ and $|y\rangle$ components in your imagination. Either way, you will find the amplitude due to $|x\rangle$ to be in the $|x\rangle$ state and the amplitude due to $|y\rangle$ to be in the $|y\rangle$ state.

Now we ask this question: Suppose a photon is polarized in the x -direction by a piece of calcite set at the angle θ and before the polaroid of the angle $\theta/2$ —as in Fig. 11-3, what will happen? With what probability will it get through? The answer is the following. After it goes through the first polaroid, it is definitely in the state $|x\rangle$. The second polaroid will let the photon carry on if it is in the state $|x\rangle$; that is, if it is the state $|x\rangle$, because $|x\rangle$ has total probability that it evolution appears to be in the state $|x\rangle$. We ask that equality from the absolute equation of amplitude $(x|x)$ that is present in the state $|x\rangle$ is also in the state $|x\rangle$. Whereas in $|y\rangle$? Inserting Eq. (11.31) by $|x\rangle$ to get

$$(x|x') = \cos^2 \theta (x|x) + \sin^2 (x|y).$$

Because $(y|y) = 0$, from the physics—it may mean if $|y\rangle$ and $|x\rangle$ are base states and $(x|x) = 1$. So we get

$$(x|x') = \cos^2 \theta,$$

and the probability is $\cos^2 \theta$. So, for example, if the first polaroid is set at 30° , a photon will get through $1/4$ of the time, and $1/4$ of the time it will fail the selection by being absorbed again.

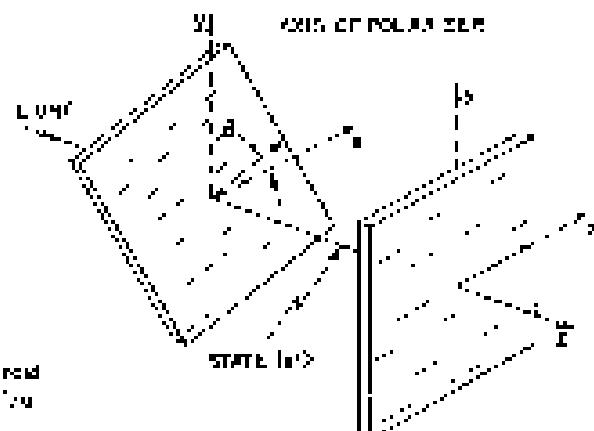

Fig. 11-3. Two stages of selection with angle $\theta/2$ between pieces of calcite.

Now let us see what happens classically in the same situation. We work now a beam of light with a double "tail" which is passing in some wave in another "sec transposed". After it goes through the first polaroid, the electric field is oscillating in the x -direction with a size E_0 ; we would draw the field as an oscillating vector with a peak value E_0 , in a diagonal like Fig. 11-4. Now when the light arrives at the second polaroid, only the component $E_0 \cos \theta$ of the field is left, gets through. The intensity is proportional to the square of the field and therefore $I = E_0^2 \cos^2 \theta$. So the energy passing through is $\cos^2 \theta$ smaller than the energy which was entering the first polaroid.

The classical picture and the quantum picture give similar results. If you were to throw 10 billion photons, the survival probability and the average probability of each one going through is, say, 5/8, you would expect 3/8 of 10 billion would pass through. Likewise, the energy that they would carry would be 5/8 of the energy that you are expected to pass through. The classical theory says nothing about the statistics of the photons; it simply says that the energy carried through will be precisely 5/8 of the energy which you were sending in. That is, it's more improbable if there is only one photon. There is no such thing as 5/8 of a photon. It is either off there, or it isn't there. In Quantum mechanics, it is off the $\pm 5/8$ of the time. The relation of the two theories is clear.

What about the other kinds of polarization? For example, right-hand circular polarization? In the classical theory, right-hand circular polarization has equal complex components x and y , which are 90° out of phase. In the quantum theory, a right-hand circularly polarized (RHC) photon has equal amplitudes to be polarized $|x\rangle$ or $|y\rangle$, and the amplitude is $\sqrt{2}/2$ out of phase. Calling a RHC photon state R and a LHC photon state L , we can write (see Vol. 1, Section 11.1)

$$\begin{aligned} |R\rangle &= \frac{1}{\sqrt{2}} (|x\rangle + i|y\rangle), \\ |L\rangle &= \frac{1}{\sqrt{2}} (|x\rangle - i|y\rangle). \end{aligned} \quad (11.24)$$

The $1/\sqrt{2}$ is put in to get normalized states. With these states you can calculate any linear or interference effects you want, using the laws of quantum theory. If you want, you can also choose $|R\rangle$ and $|L\rangle$ as base states and represent every thing in terms of them. You only need to show that $\langle R|R\rangle = 0$, which you can do by taking the conjugate form of the first equation above (see Eq. (8.12)) and multiplying it by the other. You can resolve light into x - and y -polarizations, or the x' - and y' -polarized basis, in the right and left polarizations as a basis.

Just as an example, let's try to turn our formulae around. Can we express the state $|x\rangle$ as a combination of light and left? Yes, here it is:

$$\begin{aligned} |x\rangle &= \frac{1}{\sqrt{2}} (|R\rangle - |L\rangle), \\ |y\rangle &= -\frac{i}{\sqrt{2}} (|R\rangle - |L\rangle). \end{aligned} \quad (11.25)$$

Proof. Add and subtract the two equations in (11.24). It is easy to go from one basis to the other.

One curious point has to be made, though. The photon is right-circularly-polarized, it shouldn't have anything to do with the x and y axes. If we were to look at the same thing from a coordinate system turned at some angle about the direction of flight, the light would still be right-circularly polarized—and similarly for left. The right and left circularly polarized light are the same for any such rotation; the definition is independent of the choice of the x -direction (except that the phase difference is given by i , but that doesn't take any axes to define it). Much easier than a proof, isn't it? Just a matter of what you call the x , and the y , and x' together you call. Did I get which direction of x ? I think "and" and "..." and "..." don't always mean the same thing, but if you put them back together again and get x , we can answer the question in general by writing out the state $|R\rangle$, which represents a photon RHC polarized in the frame x', y' . In that frame, you would write

$$|R'\rangle = \frac{1}{\sqrt{2}} (|x'\rangle + i|y'\rangle).$$

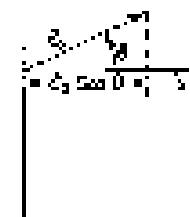

Fig. 11.4. The classical probability of the electric vector E .

How does each state look in the frame x, y ? Just substitute $\sqrt{2}$ from Eq.(11.32) and the corresponding $|y\rangle$ —we didn't write it down—but it is $(-\sin\theta, \cos\theta)$. Then

$$\begin{aligned} R_0 &= \frac{1}{\sqrt{2}} (\cos\theta |x\rangle + \sin\theta |y\rangle) = \cos\theta |x\rangle - i\sin\theta |y\rangle, \\ &= \frac{1}{\sqrt{2}} (\cos\theta + i\sin\theta) |x\rangle + i(\cos\theta - i\sin\theta) |y\rangle \\ &= \frac{1}{\sqrt{2}} (|x\rangle + i|y\rangle) (\cos\theta + i\sin\theta) \end{aligned}$$

The first term is $e^{-i\theta}|R\rangle$, and the second is $e^{+i\theta}|R\rangle$; our result is then

$$|R\rangle = e^{-i\theta}|R\rangle + e^{+i\theta}|R\rangle \quad (11.35)$$

The states $|R\rangle$ and $|R\rangle$ are the same except for the phase factor $e^{-i\theta}$. If you work out the sum $|R\rangle + |R\rangle$, you get that

$$|L\rangle = e^{-i\theta}|L\rangle \quad (11.36)$$

Now comes another surprise. If we add $|R\rangle$ and $|L\rangle$, we get something different from what we get when we add $|R\rangle$ and $|R\rangle$. For instance, the expectation value is $\langle L | (11.36), \cos\theta$ of $|L\rangle$ and $|L\rangle$ but a typical calculation is the sum $\langle L | (11.36)$ of the phase-shifted $|L\rangle$ backwards and $|L\rangle$ with -90° forward. That is just what we would get from the sum $|R\rangle + |R\rangle$ and $|L\rangle + |L\rangle$ in the second, angle $\theta = 90^\circ$ and east's right. An equalization of charges that is the same as the polarization in the original frame. So it is not exactly true that a stationary polarized photon looks the same for any set of axes. In short, these phase relations of the right and left circularly polarized components break off the polarization.

11.5 The nuclear K-meson

We will now describe a two-state system in the world of three-body particles—a system for which quantum mechanics gives a most remarkable prediction. To describe it completely would involve us in a lot of detail about particle systems, so we will, reluctantly, leave that out entirely. We can only give a outline of how a certain discovery was made—to show you the kind of reasoning that was involved. It begins with the discovery by Gell-Mann and Okubo of the octet of baryon states and of a new law of conservation of strangeness. It was with Gell-Mann and Pais we are studying the consequences of this new rule that they came up with the really interesting and remarkable phenomenon we are going to describe. First though, we have to tell you a little about "strangeness".

We must begin with what are called the strong interactions of nuclear particles. These are the interactions which are responsible for the strong nuclear force—as distinct, for example, from the relatively weaker electromagnetic interactions. The interactions are “strong” in the sense that if two particles get close enough to the point where $r \approx 10^{-15} \text{ m}$ with about a billion proton exchanges, either to nuclei or very nearby

to a similar system, we find (in Chapter 8) that a spin-orbit coupling when we repeat the construction above, the laws—then we get the “three nucleons” $|N\rangle$. In particular, when we work down at Section 5.7 on the $|+-+$ and $+--$ states of a quark-antiquark system’s wavefunction. The answer is a gluon loop which has however, no “color” here.

We can tell that the nature of this coupling is different from what we expect since at this point in our development, we argue that your spin-orbit coupling will, Section 11.6. If you are sufficiently curious, you may wish to come back to it later. We give it here because it is a beautiful example—taken from recent work in high-energy physics—of how one can start with our formulation of the quantum mechanics of two-particle systems

The nuclear particles themselves were to called a "weak interaction." By effect of this change can happen, such as beta decay, but also very slowly on a nuclear scale—the weak interactions are feeble, many orders of magnitude weaker than the strong interactions and good much weaker than electromagnetic interactions.

When the strong interactions were being studied with the big accelerators, people were surprised to find that certain things that "should" happen—had were reported to happen—but did not occur. For instance, in some interactions a particle of a certain sign the not appear when it was expected. Fermi and his team noticed that many of these predicted happenings could be explained if made by inventing a new conservation law: the conservation of strangeness. They proposed that there was a new kind of attribute associated with each particle—which they called its "strangeness" number—and that in any strong interaction, the "quality of strangeness" is conserved.

Suppose, for instance, that a high-energy negative K-meson with, say, an energy of many GeV collides with a proton. Most of the interaction may focus many other particles—mesons, baryons, lepton particles. Some particles are of the "strange" type indicated in Table 2-2 of Vol I. It is observed, however, that only certain combinations appear, and never others. Two certain conservation laws were already known to apply. First, energy and momentum are always conserved. The total energy and momentum of the system must be the same as before the event. Second, there is the conservation of electric charge which says that the total charge of the outgoing particles must be equal to the total charge carried by the original particles. In our example of a K-meson and a proton colliding, together, the following two cases do occur:

$$\begin{aligned} \text{K}^- &+ p \rightarrow p + K^- + \pi^+ + \pi^0 \\ \text{or} \quad K^- &+ p \rightarrow \Sigma^- + \pi^+ \end{aligned} \quad (11.3F)$$

We should never get:

$$K^- + p \rightarrow p + K^+ + \pi^0 \quad \text{or} \quad K^- + p \rightarrow \Lambda_0 + \pi^+ \quad (11.3G)$$

because of the conservation of charge. It was also known that the number of baryons is conserved. The number of baryons must be equal to the number of baryons in. For this law, an exception of a baryon is possible as mentioned before. This means that we can—and do—see

$$\begin{aligned} \text{K}^- + p &\rightarrow K^0 + \pi^0 \\ \text{or} \quad K^- + p &\rightarrow \bar{\nu} + \pi^0 + p + \bar{p} \end{aligned} \quad (11.4A)$$

(where $\bar{\nu}$ is the antineutrino, which carries a negative charge). But we never see

$$\begin{aligned} \text{K}^- + p &\rightarrow K^- + \pi^0 \\ \text{or} \quad K^- + p &\rightarrow K^- + \bar{e} \end{aligned} \quad (11.4B)$$

even when there is plenty of energy, because baryons would not be conserved.

These laws, however, do not explain the strange fact that the following reactions—which do not immediately appear, to be especially different from some of those in (11.3A) or (11.4B)—are also never observed:

$$\begin{aligned} \text{K}^- + p &\rightarrow \bar{\nu} + K^0 + K^0 \\ \text{or} \quad K^- + p &\rightarrow \gamma + \pi^0 \quad (11.4C) \\ \text{K}^- + p &\rightarrow \Lambda^0 + K^0 \end{aligned}$$

The explanation is the conservation of strangeness. With each particle goes a number—the strangeness S , and there is a law that in any strong interaction, the

Table 14-4

ANSWER *pass sentence(s) of the s⁺ and the t⁺s*

and a range of other molecular-level categories that exist. The postural anticipations (β_1 , β_2 , γ and δ are omitted from \mathbf{B}_1^*) and the transitions ($\pi = \pi^1$, π^- ; all have the same geneses) combine to make \mathbf{K}' and \mathbf{R}' because both have 217 geneses + 1; and \mathbf{K}' and \mathbf{T}' (the anti- \mathbf{K}') if the α^1 and α^2 genes are in \mathbf{K}' , \mathbf{K}' has 220 geneses + 1. There is also a gene with strangeness = 1—the hyper-kidneyed hairpin—and perhaps others as yet unknown. We have listed most of these components in Table 11-4.

Let's see how the strangeness conservation works in some of the reactions we have written down. Consider with a K⁻ and a proton, we have a total strangeness of $f = -1 + 0 = -1$. The conservation of strangeness says that the strangeness of products after the reaction must also add to -1 . That is to say, that is to let the reactivities of π^+ , π^- and π^0 be a , b , c . But in the reactions of (1), (2) the strangeness of the right hand side is zero in each case. Such reactions can't conserve strangeness and strangeness. Nobody knows. Nobody knows why not. We just have to go along with it.

Now let's look at the following reaction in the π^+ channel. You might, for instance, put a Λ^0 source plus a deuteron. Key words: two neutral particles. Now what would S do you add? Since the Λ strangeness is +1/2, the π^+ and Λ^0 have a strangeness of -1 and +1/2. In the first spectator reaction, the strangeness must change. So if particle one has strangeness = +1/2, it must be the Λ^0 . The reaction is

三

$S \cdot S + 2 = 1$!!! (incorrect)

If $\mathbf{t} \in \mathbb{R}^4$ and there is a slot of the \mathbf{b}^k , the component on the right would be $-\mathbf{t}^k$ — which means that not permit, since the string term on the left side is zero. On the other hand, a \mathbf{R}^4 can be produced in $\mathcal{O}(N^2)$ iterations, with \mathbf{t} .

$$\beta = 0, \quad \delta = 2, \quad \alpha = \pm 1 = \pm 1$$

9

$S = +1 + \dots$ $\theta = -1$

You may be thinking "What's all this stuff, because how do you know whether β is R^1 or R^2 ? They look exactly the same." They are superpositions of each other, so they have exactly the same mass, and both have zero electric charge.

Fig. II-5. High-energy events as seen in a hydrogen bubble chamber. (a) A p -nucleus interaction with a hydrogen atom produces a \bar{K} particle and a π^+ meson. Both particles decay in the chamber. (b) A \bar{K}^0 meson interacts with a proton producing a π^+ meson and a K^- particle which then decays. The decay products are shown. Their thermal trajectories are indicated by light dashed lines.

How do you distinguish them? By the particle they produce. For example, a \bar{K}^0 interacting with a nucleon becomes a π^+ and a K^- , see Fig. II-6:

$$\bar{K}^0 \rightarrow \pi^+ + K^-$$

and a K^0 meson. There is no way a K^0 can produce a particle which interacts with ordinary matter (protons and neutrons). So the experimental distinction between the K^0 and the \bar{K}^0 would depend on one of the two possibilities will not interfere with each other.

One of the predictions of the strangeness theory is that this will not occur. You can have high-energy nuclear \bar{s} -particle production with a nucleon. You know that the neutral kaons do; going into other states or maybe will never produce a \bar{s} . The experiment didn't do something like this. You can also have a \bar{K}^0 meson turn into a large hydrogen bubble chamber. A p -track appears, but sometimes else a pair of tracks appear (a proton and a π^+) indicating that a \bar{s} -particle has disappeared¹ (see Fig. II-5). Then you know that the \bar{K}^0 somewhere must have come from s .

You can, however, figure out where it is going by using the conservation law of momentum and energy. The weak interaction law, by disintegrating into two charged particles, as shown in Fig. II-6(a), so the \bar{K}^0 goes there, doing its best interaction with all the hydrogen nuclei (protons), scattering perhaps some other particles. The prediction of the strangeness theory is that it will always produce a \bar{s} -particle in a simple reaction like this.

$$\bar{K}^0 \rightarrow p \rightarrow \bar{K}^0 + \pi^+$$

Enough of K^0 mesons yet? This is the only s -channel \bar{K}^0 meson we have in the event sketched in Fig. II-5(b), in which the \bar{K}^0 is far because it decays into a K^0 meson. That's the first part of our story. That's the conservation of strangeness.

The conservation of strangeness is, however, not perfect. There are very slow disintegrations of the strange quarks (the s -quarks taking a long time, 10^{-10} to 10^{-12} second in which the s -quarks are not destroyed). These involve the "slow" decays. For example, the K^0 disintegrates into a Λ^0 and a $\bar{\Lambda}^0$ mesons ($\sim 7 \times 10^{-12}$

¹ Except, of course, if you measure the K^0 or other particles with a low enough resolution of $\frac{1}{2}$. We can think of situations in which the s channel might go to another s -channel strange particle.

² The first s -particle decays slowly since each interaction is so long it need not be completed. The decay products are either a p and a π^+ , or a n and a μ^0 . The lifetime is 2.7×10^{-10} sec.

³ An important limit for strange interconversion is given in Fig. II-7(a).

with a lifetime of 10^{-10} secnd. That was, in fact, the way K-mesons were first seen. Notice that this decay reaction

$$K^0 \rightarrow \pi^+ + \pi^-$$

does not conserve strangeness, so it cannot go "fict" by the strong interaction; it can only go through the weak decay process.

Now the K^0 also decays in the same way— $K^0 \rightarrow \pi^+ + \pi^-$ —and also with the same lifetime

$$K^0 \rightarrow \pi^+ + \pi^-.$$

Again we have a weak decay because it does not conserve strangeness. There's a principle that for any reaction, there is the corresponding reaction with "barred" indices by "antimatter" and vice versa. Since the K^0 is the antiparticle of the \bar{K}^0 , it should decay into the antiparticles of the π^+ and π^- ; but the antiparticle of a π^- is the π^+ (Or, if you prefer, vice versa.) It turns out that for the processes it doesn't matter which one you call "barred." So as a consequence of the weak decay, the K^0 and \bar{K}^0 can go into the same final products. When "barred" through their decays— π^+ in a bubble chamber, they look like the same particle. Only their strong interactions are different!

At last we are ready to describe the work of Gell-Mann and Pais. They discovered that since the K^0 and the \bar{K}^0 each contain two states of two σ -mesons, there must be some coupling between a K^0 state and its \bar{K}^0 , and also that a K^0 can turn into a \bar{K}^0 . Writing the reactions as new decay mechanisms, we would have

$$K^0 \rightarrow \pi^+ - \pi^- \rightarrow \bar{K}^0. \quad (1.43)$$

These reactions imply that there is some amplitude per unit time, say $-i/4t$ times $(K^0)^\dagger \Psi | \bar{K}^0 \rangle$, that a K^0 will turn into a \bar{K}^0 through the weak interaction responsible for this decay into two π -mesons. And there is the corresponding amplitude $(\bar{K}^0)^\dagger \Psi | K^0 \rangle$ for the reverse process. Because matter and antimatter behave in exactly the same way, these two amplitudes are numerically equal; we'll call them both A :

$$(K^0)^\dagger \Psi | \bar{K}^0 \rangle = (K^0)^\dagger \Psi | K^0 \rangle = A. \quad (1.44)$$

Kerr and Gell-Mann and Pais—here is an interesting situation. When people have been calling two distinct states of the world—the K^0 and the \bar{K}^0 —should really be considered as one two-state system, because there is an amplitude to go from one state to the other. For a complete treatment, our world, of course, has to deal with more than one particle, because there are four states of π 's, and so on. But since they were mainly interested in the reaction of K^0 and \bar{K}^0 , they did not have to complicate things and could take the approximation of a two-particle system. The other states were taken into account... to the extent that their effects appeared implicitly in the amplitudes of Eq. (1.44).

Accordingly, Gell-Mann and Pais analyzed the neutral particle as a two-state system. They began by choosing as their two basis states the states $| K^0 \rangle$ and $| \bar{K}^0 \rangle$. (From here on, the story goes very much as it did for the hydrogen molecule.) Any state $|\psi\rangle$ of the neutral K-particle could then be described by giving the amplitudes C_1 if you're in your first state, C_2 if you're in your second state:

$$C_1 = (K^0)^\dagger \Psi \langle \cdot \cdot \cdot | K^0 \rangle, \quad C_2 = (\bar{K}^0)^\dagger \Psi \langle \cdot \cdot \cdot | \bar{K}^0 \rangle. \quad (1.45)$$

The next step was to write the Hamiltonian equations for this two-state system. If there were no coupling between the K^0 and the \bar{K}^0 , the equations would be simply

$$\begin{aligned} i \frac{dC_1}{dt} &= E_1 C_1, \\ i \frac{dC_2}{dt} &= E_2 C_2. \end{aligned} \quad (1.46)$$

but since there is the amplitude $\langle K^0 | W | \bar{K}^0 \rangle$ for the K^0 to form a \bar{K}^0 , there would be the additional term

$$\langle K^0 | W | \bar{K}^0 \rangle C_1 = 4C_1$$

added to the right-hand side of the last equation. And similarly, the term $4C_{-}$ should be inserted in the equation for the case of change ΔC_{-} .

The last result. When the two-pion state is taken into account, the additional amplitude for the K^0 to form itself through ΔC_0 is

$$K^0 \rightarrow \pi^+ + \pi^- - K^0.$$

The additional amplitude, which we would write $\langle \pi^+ | W | K^0 \rangle$, is just equal to the amplitude $\langle K^0 | W | \bar{K}^0 \rangle$ since the amplitude to go from an \bar{K}^0 to a pair of mesons is identical for the K^0 and the \bar{K}^0 . If you wish, the argument can be carried out in detail like this. Just write

$$\langle \pi^+ | W | K^0 \rangle = \langle \bar{K}^0 | W | \pi^+ \rangle \langle \pi^- | W | K^0 \rangle$$

$$(147) \quad \langle K^0 | W | \bar{K}^0 \rangle = \langle K^0 | W | \pi^+ \rangle \langle \pi^- | W | K^0 \rangle.$$

Because of the symmetry of the two-pion state

$$\langle \pi^+ | W | K^0 \rangle = \langle 2\pi^- | W | K^0 \rangle,$$

and also

$$\langle K^0 | W | \bar{K}^0 \rangle = \langle K^0 | W | \pi^+ \rangle$$

It then follows that $\langle K^0 | W | \bar{K}^0 \rangle = \langle K^0 | W | K^0 \rangle$, and therefore $\langle \bar{K}^0 | W | K^0 \rangle = \langle K^0 | W | \bar{K}^0 \rangle$, so we will write ΔC_0 . Again, there are two additional amplitudes $\langle K^0 | W | \Delta C_0$ and $\langle K^0 | W | \Delta C_{-}$ having to do with which should be included in the Hamiltonian equations. The first goes to form K^0 or be equivalent to the exchange of ΔC_0 , and the second gives a new term ΔC_{-} in the equation for ΔC_{-} . Reasoning the way, Gell-Mann and Pais concluded that the three-pion vertex amplitudes for the $K^0 \bar{K}^0$ were unchanged by

$$\begin{aligned} iS \frac{\partial \Gamma_0}{\partial t} &= E_0 C_0 + 4C_0 = 4C_0, \\ iS \frac{\partial C_0}{\partial t} &= E_0 C_0 - 4C_0 = 4C_{-}. \end{aligned} \quad (147)$$

Now it is now evident concerning we have said in earlier chapters, that the amplitudes for $\langle \pi^+ | W | \bar{K}^0 \rangle$ and $\langle \bar{K}^0 | W | K^0 \rangle$ which are the source of odd-order, non-hermite complex conjugate. This was true when we were dealing with particles the did not decay. But if there is some decay, and even, therefore, because other — the two amplitudes are not necessarily complex conjugate. So the equality of (147) does not mean that the amplitudes are real numbers; they are in fact complex numbers. The coefficient 4 is, therefore, complex; and we can't just integrate it into the energy E_0 .

Having played often with diagrammatic and with our hermiticity, let the Hamiltonian equations of (147) prove that there was another pair of side terms enough to fit the need to represent the 3-particle system and which would make especially simple its behavior. They said, "Let's take the sum and difference of those two equations. Also, let's measure all the amplitudes from E_0 , and the units for

¹ We are making a simplification here. The γ source we have many states and a moving in various directions of the π mesons, but we should take the right-hand side of the equation after summing up all the γ source amplitudes. The amplitude would still work in the same way, we see.

energy and time that make $\alpha = 1/\gamma$? (That's where modern theoretical physics always goes.) I don't change the physics but makes the equations look a bit simpler from my point of view.

$$i \frac{d}{dt} (K_+ - C_+) = \mathcal{H}(K_+ - C_+), \quad i \frac{d}{dt} (K_- - C_-) = 0. \quad (1.46)$$

It is apparent that the combinations of amplitudes $(C_+ - C_-)$ and $(C_+ + C_-)$ act independently from each other (so a corresponding $i\mathcal{H}$ comes to the secondary states we have been studying earlier). So they conjecture that it would be more convenient to use a different representation for the K-particle. They define new variables:

$$|K_0\rangle = \frac{1}{\sqrt{2}} (|K^+\rangle - |K^-\rangle), \quad |K_1\rangle = \frac{1}{\sqrt{2}} (|K^+\rangle + |K^-\rangle) \quad (1.47)$$

They said instead of thinking of the K^+ and K^- mesons, we can equally well think in terms of the two "particles" (that is, baryons) K_1 and K_2 . (These correspond, of course, to the states we have already called $|C\rangle$ and $|A\rangle$. We are not changing α , it is just because we want some follow the definition of the original K -mesons and the way you will see in physics soon, etc.)

Now Goldstein and Pais didn't do all this just to get different names for the particles – there is some strange new physics in it. Suppose that C_+ and C_- are the amplitudes that come about $\psi(t)$ will be $C_0 \in K_0$, $C_1 \in K_1$:

$$C_0 = \langle K_0 | \psi \rangle, \quad C_1 = \langle K_1 | \psi \rangle.$$

From the equations in (1.46):

$$C_1 = \frac{i}{\sqrt{2}} (C_+ + C_-), \quad C_0 = \frac{i}{\sqrt{2}} (C_+ - C_-). \quad (1.48)$$

Then, the Eqs. (1.47) become

$$i \frac{dC_0}{dt} = 2\mathcal{H}C_0, \quad i \frac{dC_1}{dt} = 0. \quad (1.49)$$

The solutions are:

$$C_0(t) = C_0(0)e^{-i\mathcal{H}t}, \quad C_1(t) = C_1(0), \quad (1.50)$$

where, of course, $C_1(0)$ and $C_2(0)$ are the amplitudes at $t = 0$.

They also note say that if a real K -particle starts out in the state $|K_0\rangle$: $C_0(0) = 1$, then $C_1(0) = 0$, the amplitude at the time zero

$$C_0(0) = e^{-i\mathcal{H}t}, \quad C_1(0) = 0.$$

Remember up the \mathcal{H} is a complex number, so it is convenient to take $\mathcal{H} = \alpha - i\beta$. (Since the imaginary part of \mathcal{H} corresponds to energy loss, we will take $\beta > 0$.) With this substitution, $C_0(t)$ reads

$$C_0(t) = C_0(0)e^{-(\alpha - i\beta)t}. \quad (1.51)$$

The probability of finding a K_0 particle at t is the absolute square of this amplitude, $|e^{-(\alpha - i\beta)t}|^2$. And from Eq. (1.51), the probability of finding the K_1 state at that time is zero. That means that if you make a K-particle in the state $|K_0\rangle$, the probability of finding it in the same state decreases exponentially with time but you will never find it in the $|K_1\rangle$ state (except for a tiny quantum fluctuation). This agrees with the idea $\text{Rate} = 1/2\beta$ which is, experimentally, 10^{-11} sec. We made previous to the video we said that β was complex.

On the other hand, Fig. (1.51) says that if we make a K-particle completely in the K_1 state, it stays that way forever. Well, that's not really true. It's inferred large intervals of time, the interval between, say, the 800 times slower than the

recognition, many we have discussed. So there are some terms small terms we have left out in our approach, i.e., the so long as we are considering only the reaction $K^+ \rightarrow K^+$, the basis "correct".

Now in this history of Gell-Mann and Pais they were interested whether baryons when a π^+ -particle is produced into π^+ , which is a way in reaction. Since it can then have a probability of ~ 1 , it must be produced in the K^0 state. But $K^0 \rightarrow K^+$ is neither a K_1 nor a K_2 but a mixture. The initial conditions are

$$C_1(0) = 1, \quad C_2(0) = 0.$$

But that means—from Eq. (11.29)—that

$$C_1(0) = \frac{1}{\sqrt{2}}, \quad C_2(0) = \frac{1}{\sqrt{2}}.$$

And from Eq. (11.30), that

$$C_1(0) = \frac{1}{\sqrt{2}} e^{-imv/\omega}, \quad C_2(0) = \frac{1}{\sqrt{2}}. \quad (11.31)$$

Now remember that K_1 and K_2 are total contributions of K^0 and K^+ [in Fig. (11.24); the amplitudes were both taken as that $1/2 = 0$ the K^0 particle carried zero quantum by interference leaving only a K^+ alone]. But the K_1 's show coherence with time, and the K_2 's are also now. After $t = 0$ the interference of C_1 and C_2 will give little amplitudes for $\pi^+ + K^0$ and K^+ .

What does all this mean? Let's go back and think of the experiment we sketched in Fig. 11-2. A π^+ -beam has produced a K^0 particle and a K^+ meson which is moving along through the hydrogen in the chamber. As it goes along there is some small interaction between it and with hydrogen nuclei. At first, we thought that elementary considerations would prevent the K particle from taking a π^+ as such an interaction. Now however, we see that that is not right. For although our K particle starts out as a K^0 which cannot make a π^+ , it does not stay that way. After a while, there is some amplitude that it will have changed to the K^+ state. We can, therefore, according to what we have learned along the K -particle track. The content of this happens is given by the amplitude C_2 , which when we use Eq. (11.29) backwards relate to C_1 and C_3 . The relations is

$$C_2 = \frac{1}{\sqrt{2}} (C_1 - C_3) = (\pi^{+} v^{-\omega} - 1). \quad (11.32)$$

As the K nucleus goes along, the probability that it will "act like" a K^+ is equal to $|C_2|^2$, which is

$$|C_2|^2 = 2(1 - v^{-2\omega}) + 2v^{-2\omega} \cos \omega. \quad (11.33)$$

A complicated and strange result!

This then is the remarkable prediction of Gell-Mann and Pais, when a π^+ is produced, the chances that it will turn into a K^+ —as it can subsequently be found to produce a π^0 -meson with time according to Eq. (11.32). The prediction came from using only their logic and the basic principles of the quantum mechanics—were no knowledge at all of the inner workings of the K -particle. Since nobody knew anything about the inner machinery, that is as far as Gell-Mann and Pais could go. They could not give any theoretical values for v and ω . And actually has been able to do so to this date. They were able to give a value of ω calculated from the experimental decay rate of decay into $\pi^+ + \pi^0$ ($2\omega = 0.7$ sec), but they could say nothing about v .

We have plotted the function of Eq. (11.33) for two values of ω in Fig. 11-2. You can see that the $|C_2|^2$ depends very much on the value of ω . There is an K^0 probability at first—the K_1 builds up. If ω is large, the probability would have

large oscillations. It is to recall what will happen in the case of the double slit - the probability will just rise & settle to $\frac{1}{2}$.

Now, typically, in Raman effect we will be traveling at a constant speed near the speed of light - the curves of Fig. 11-6 then can represent the probability distribution of observing a E^2 wave (typical energy of photon) distributions. You can see why the position is unmeasurable quantum. You choose a single source and instead of just choosing one, determine n modes. Simultaneously in this situation, another measurement can tell you the total energy of a particle. This changes the probability - of measuring an effect varies in a strange way as it goes along. There is nothing else; it's like it is tame. And the most remarkable prediction was made solely by applying quantum mechanics of equilibrium.

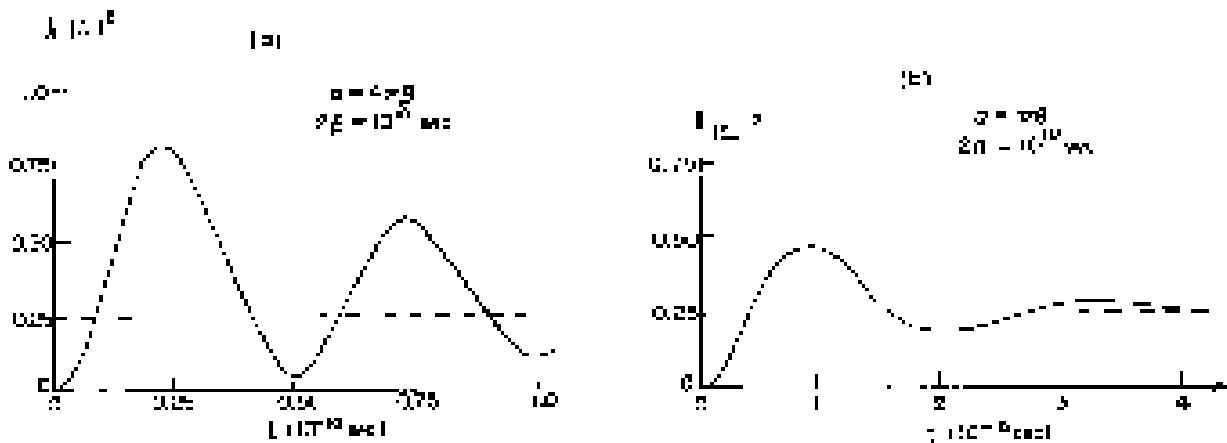

Fig. 11-6. The function of Eq. 11-10 for (a) $\alpha = \beta$, (b) $\alpha = 4\beta$.
 $\text{With } \beta = 10^{-10} \text{ sec}.$

If there is any place where we have a chance, or if the basic principles of quantum mechanics in the present way access the superposition of simple, the weak or these? it is α/β . Despite the fact that this effect has been predicted now for several years, there is no experimental confirmation; that is very clear. These calculations might tell us what value of α/β the experiments find that the effect really occurs. They indicate that it between 30 and 40. Let's hope to experimentally. It would be very nice, of course, to do some exactly to see if the principle of superposition really works in such a mysterious world as the of the strange particles, with unknown reasons for the decay, and unknown reasons for the disappearance.

The paradoxes we have just described is not a characteristic of the way quantum mechanics is being used today in the search for a fundamental theory of the strange particles. All the complicated theories that you may hear about are not much and no less than this kind of elements of nature than using the principle of superposition and other principles of quantum mechanics of the level. Some people claim that they have theories by which it is possible to understand the α/β ratio. I agree, but I say that these theories are completely useless. For instance, the theory that attempts to calculate α/β given the ρ tells us that the value of ρ should be infinite. The set of equations with which they originally start involves two components. They pass from the last ρ 's back to a λ' , and so on. When all worked out, it does indeed produce a pair of equations like the ones we have here, but because there are an infinite number of terms of $\rho = \lambda'$, depending on their number n , averaging over all the possibilities gives an α/β which is infinite. Our nature's ρ is not infinite, so the fundamental theory is not unique. It is not quite remarkable that the phenomena which can be predicted at all can be well by the strange particles come from the principles of quantum mechanics of the level to which you are learning them now.

11.4 Generalization to N-state systems

We have finished with all non-perturbative systems we wanted to talk about! The following sections we will go on to study systems with more states. The connection to N-state systems of the form we have worked out for two states is pretty straightforward. It goes like this:

If a system has N distinct states, we can represent any state $\psi(t)$ as a linear combination of any set of basis states ϕ_i , where $i = 1, 2, 3, \dots, N$:

$$\psi(t) = \sum_{i=1}^N c_i(t) \phi_i(t). \quad (1.57)$$

The coefficients $c_i(t)$ are the amplitudes $\phi_i(t)$. The behavior of these amplitudes c_i with time is governed by the equations

$$i\hbar \frac{dc_i(t)}{dt} = \sum_j H_{ij} c_j \quad (1.58)$$

where the energy matrix H_{ij} describes the physics of the problem. It looks the same as for two states. Only now, there are N energy eigenvalues and basis states, and the energy matrix is H_{ij} , $i, j = 1, \dots, N$. The Hamiltonian is an N by N matrix with N^2 elements. As before, $H_{ii} = E_i$, so it's a diagonal matrix, and the diagonal elements H_{ii} are real numbers.

We have found a general solution to the EEs of a two state system, so for the energy matrix we can just plug in equation (1.58). It is also not difficult to solve Eq. (1.58) for an N state system when H is not time-dependent. Again, we begin by looking for a possible solution in which the amplitudes all have the same time dependence. We try

$$c_i = e^{i\omega t} C_i \quad (1.59)$$

When these C_i 's are substituted into (1.58), the derivatives $i\hbar \omega/c_i$ become just $-i\hbar \omega C_i$. Canceling this common exponential factor from (1.58), we get

$$\dot{E} c_i = \sum_j H_{ij} c_j. \quad (1.60)$$

This is a set of N linear algebraic equations for the N unknowns c_1, c_2, \dots, c_N , and there is a solution only if you are lucky—only if the determinant of the coefficient matrix is non-zero. But this is not necessary to be that sophisticated: you can just start to solve the equations one way you want, and you will find that they can be solved only for certain values of C . (Remember that C is the only adjustable thing we have in the equations.)

If you want to be formal, however, you can write Eq. (1.60) as

$$\sum_j (H_{ij} - \omega_j) c_j = 0. \quad (1.61)$$

Then you can use the rule—if you know ω_j —that no solutions will have a value other than these values of ω for which

$$\text{Det}(H_{ij} - \omega_j E) = 0. \quad (1.62)$$

Each term of the determinant is just H_{ij} , except that E is subtracted from every diagonal element. That is, it looks more just

$$\text{Det} \begin{pmatrix} H_{11} - E & H_{12} & H_{13} & \dots \\ H_{21} & H_{22} - E & H_{23} & \dots \\ H_{31} & H_{32} & H_{33} - E & \dots \\ \dots & \dots & \dots & \dots \end{pmatrix} = 0. \quad (1.63)$$

This is, of course, just a special way of writing an algebraic equation for \mathcal{E} which is the sum of a broad of products of all the terms taken in certain ways. These processes will give us the picture of \mathcal{E} up to S^2 .

So we have an N -order polynomial equal to zero, and there are, in general, N roots. (We must remember, however, that some of them may be multiple roots, meaning that two or more roots are equal.) Let's call the N roots

$$E_1, E_2, E_3, \dots, E_n, \dots, E_N. \quad (1.64)$$

(We might also represent each with Roman numeral, or let n take on the values $1, 2, \dots, N$. It may be that some of these energies are equal, say $E_1 = E_{n'}$, but we will still choose to call them different names.

The equations in Eq. (1.64) are one equation for each value of k . It can contain one of the E 's, say E_1 , and (1.64) will solve for the n , from which belongs to the energy E_1 . We will call this set $\{\alpha\}$.

Using these α 's in Eq. (1.64), we have the complete solution, but the other $N-1$ equations remain to be solved. In taking n values for the remaining $N-1$ of the N energy states at $k=0$, we are using

$$C(n) = b_n n! e^{-\beta E_n},$$

and

$$C(0) = c(0). \quad (1.65)$$

The complete definite energy state $|E_n\rangle$ can then be written as

$$|\psi_n(k)\rangle = \sum_{\alpha} \text{coeff}_{\alpha} e^{-\beta E_n} |E_n\rangle, \quad (1.66)$$

The state has one, of course, the only exception of the definite energy states, because the time dependence factor is one. Then they are constant vectors which can be used as a new basis as I have thought.

Let's do this using b_n and the α 's, as you can easily see—that when operated on by the Hamiltonian operator \hat{H} it gives just E_n times the same state:

$$\hat{H}|\psi_n\rangle = E_n |\psi_n\rangle. \quad (1.67)$$

The energy E_n is, then, a number which is a characteristic of the Hamiltonian operator \hat{H} . As we have seen, a Hamiltonian is Q^* . In general, one cannot obtain its eigenvalues. In the mathematics world they would be called the "eigenvalues proper" of the Q^* or H_0 . Physicists usually call them the "eigenvalues" of \hat{H} ("Eigen" is the German word for "characteristic" or "proper"). These are eigenvalues of \hat{H} . In other words, for each energy E_n is the state of definite energy, which we have called the "definite energy". Physicists usually call the states of "eigenstates of \hat{H} ". Each eigenstate corresponds to a particular representation.

Now, generally, the states $|\alpha\rangle$ —of which there are N —can't be independent bases. For this to be true, all of the states must be orthogonal, meaning that the overlap of them, say $|\alpha\rangle$ and $|\beta\rangle$,

$$\langle \alpha | \beta \rangle = 0. \quad (1.68)$$

This will be true automatically if all the energies are different. Also, we can multiply all the α 's by a suitable factor so that the states are normalized. So that we need that

$$\langle \alpha | \alpha \rangle = 1 \quad (1.69)$$

for all n .

When it happens that \hat{H} (Eq. 1.67) accidentally has two (or more) roots with the same energy, there are some easier complications. First, there are still two $\langle \alpha | \alpha \rangle$ and $\langle \beta | \beta \rangle$ which go with the two equal energies for the states $|\alpha\rangle$ and $|\beta\rangle$.

now and be orthogonal. Suppose you performed the normal procedure and find two stationary states with equal energies—let's call them $|v\rangle$ and $|w\rangle$. Then it will not necessarily be so that they are orthogonal—“you’re kidding.”

$$\langle v | v \rangle = 1.$$

It is, however, true that you can end up two new states, which we will call $|v'\rangle$ and $|w'\rangle$, that have the same energies and are also orthogonal, so that

$$\langle v' | v' \rangle = 1. \quad (11.69)$$

You can do this by making $|v'\rangle$ and $|w'\rangle$ a suitable linear combination of $|v\rangle$ and $|w\rangle$ with the ~~constraint~~ chosen to make it come out right. Eq. (11.70) is true. It is always convenient to do this. You will probably encounter this situation so that you can always associate two proper energy states $|n\rangle > n$, all orthogonal.

We would like, for fun, to prove the other two of the ordinary states have different energies, they are indeed orthogonal. For the state $|0\rangle$ with the energy E_0 , we have that

$$\hat{H}_0 |0\rangle = E_0 |0\rangle. \quad (11.70)$$

This operator equation really means the $\langle 0 | \hat{H}_0 | 0 \rangle$ is EQUAL TO zero numbers. Finding the missing part $\langle 0 | \hat{H}_0 | 0 \rangle$ means the same as

$$\sum_i \langle 0 | \hat{H}_0 | i \rangle \langle i | 0 \rangle = E_0 \langle 0 | 0 \rangle. \quad (11.71)$$

If we take the complex conjugate of this equation, we get

$$\sum_i \langle 0 | \hat{H}_0 | i \rangle^* \langle i | 0 \rangle^* = E_0^* \langle 0 | 0 \rangle^*. \quad (11.72)$$

Remember that $\langle 0 | \hat{H}_0 | i \rangle^*$ is a complex number. The magnitude of a complex number is the same as its real part, so (11.72) can now be written as

$$\sum_i \langle 0 | \hat{H}_0 | i \rangle^* \langle i | \hat{H}^* | 0 \rangle = E_0^* \langle 0 | 0 \rangle. \quad (11.73)$$

Now, this equation is valid for any i in its “closed form” is

$$\langle 0 | \hat{H}^* | 0 \rangle = E_0^* \langle 0 | 0 \rangle, \quad (11.74)$$

which is just identical to Eq. (11.71).

Now we can easily prove that E_0 is a real number. We multiply Eq. (11.73) by $\langle 0 |$ to get

$$\langle 0 | \hat{H}^* | 0 \rangle = E_0. \quad (11.75)$$

Since $\langle 0 | 0 \rangle = 1$, then we multiply Eq. (11.75) on the left by $| 0 \rangle$ to get

$$\langle 0 | \hat{H} | 0 \rangle = E_0^2. \quad (11.76)$$

Comparing (11.76) with (11.73) it is clear that

$$E_0 = E_0^*, \quad (11.77)$$

which shows that E_0 is real. We can make the same for E_n in Eq. (11.75).

Finally we can easily to show that two different energy states are orthogonal. Let $|m\rangle$ and $|n\rangle$ be any two of the definite energy basis states. Using Eq. (11.75) for the state $|m\rangle$ and multiplying by $\langle m |$, we get that

$$\langle m | \hat{H} | n \rangle = E_{mn} \langle m | n \rangle.$$

But if we multiply (11.71) by $|m\rangle$, we get

$$\langle m | j | n \rangle = E_n |m|n\rangle$$

Since the left sides of these two equations are equal, the right sides are also:

$$E_m |m\rangle |n\rangle = E_n |m\rangle |n\rangle \quad (11.79)$$

If $E_m = E_n$, the equation does not tell us anything. But if the energies of the two states $|m\rangle$ and $|n\rangle$ are different ($E_m \neq E_n$), Eq. (11.79) says that $|m\rangle |n\rangle$ must be zero, as we wanted to prove. The two states are consequently orthogonal so long as E_m and E_n are numerically different.

The Hyperfine Splitting in Hydrogen

12-1 Base states for a system with two spin one-half particles

In this chapter we take up the "hyperfine splitting" of hydrogen. Because it is a physically interesting example of what we can already do with quantum mechanics, it can exemplify a more far-reaching idea, and it will illustrate all the methods of quantum mechanics as applied to slightly more complicated systems. It is enough more complicated that once you see how this one is treated you can perhaps predict the generalization to all kinds of systems.

As you know, the hydrogen atom consists of an electron moving in the neighborhood of the proton, where it can exist in any one of a number of discrete energy levels, in addition to half the pattern of lines of the exact one-electron. The first excited state, for example, lies just at a Rydberg, or about 10 eV above its ground state. But even the so-called excited only one hydrogen carries really a single definite energy state because of the spin of the electron and the proton. These spins are responsible for the hyperfine splitting. The energy levels, while split, all the energy levels are present pretty much here.

The electron can have its spin either "up" or "down" and the proton can also have its spin either "up" or "down." That is, there are four possible spin states for every electronic condition of the atom. That is, when people say "the ground state" of hydrogen they really mean the "true ground state," and the first excited state. The four spin states do not all have exactly the same energy; there are slight shifts from the energies we would expect with no spin. The shifts are, however, much much smaller than the 10 eV shift from the ground state to the next state above. As a consequence, each electronic state has no energy splitting into very many energy levels—the so-called hyperfine splitting.

The energy differences among the four spin states is what we want to calculate in this chapter. The hyperfine splitting is due to the interaction of the magnetic moments of the electron and proton, which gives a slightly different magnetic energy for each spin state. These energy shifts are only about one billionth of an electron volt, and are small compared with 10 eV's. It is because of this tiny gap that we can think about the ground state of hydrogen as a "true state" system, without worrying about the fact that there are really many more states at higher energies. We are going to have something like a theory of the hyperfine structure of the ground state of the hydrogen atom.

For our purposes we cannot introduce any of the details about the structure of the electron and proton because that has all been worked out by the theory of the spin—it has worked itself out by getting to the ground state. We need know only that we have an electron and proton in the neighborhood of each other with some definite spatial relationship. In addition, they can have various different relative orientations of their spins. It is only the effect of the spins that we want to look into.

The first question we may have to answer is: What are the base states for the system? Now the question has been put incorrectly. There is no such thing as "the" base states because, of course, the set of base states you may choose is not unique. You can in always make out of three combinations of the sort. There are always many choices for the base states, and among them, any choice is equally good. So the question is not what is the base set, but what one do you use? Well, when choosing a set we wish for a measure of bases. It is always best to start with a base set which is physically reasonable. It may not be the solution

to any problem, or may not have any direct importance, but it will generally make it easier to understand what is going on.

We choose the following four base states:

State 1: The electron and proton are both spin "up."

State 2: The electron is "up" and the proton is "down."

State 3: The electron is "down" and the proton is "up."

State 4: The electron and proton are both "down."

We need a handy notation for these four states, so we'll represent them this way:

State 1: $|+\rangle$; electron up, proton up

State 2: $+ - \rangle$; electron up, proton down

State 3: $- + \rangle$; electron down, proton up

State 4: $- - \rangle$; electron down, proton down

(C2.1)

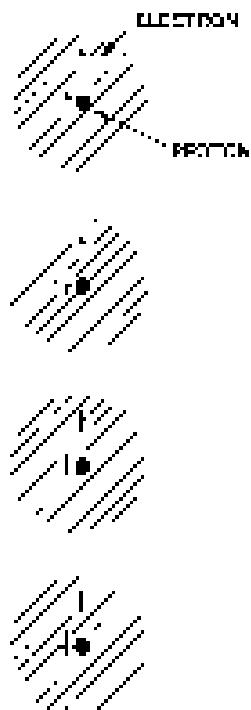

Fig. C2-1. As we see here under the ground state of the hydrogen atom,

You will have in mind either that the first plus sign indicates the electron and the second, is, the proton. For handy reference, we'll also communicate the notation $|+\rangle, |-\rangle, |+\rangle, |-\rangle$. Sometimes, it will also be convenient to use these codes |+, -, +, ->.

You may say, "But the particles interact, and maybe these aren't the right basis states. I propose as though you are considering the two particles independently." Yes, indeed! This is interesting, raises the problem, when is the *interaction* for the system. But the interaction is not involved in the question of how to describe the system. When we choose the base states are according to what other is happening. It may be that the two cannot stay in one of these two states, well, if it is stated this way. That's another question. That's the question: How do the amplitudes change with time in a particular (fixed) case? Describing the two states, we are just choosing our "unit vectors" for our description.

Well, we're in the subject, let's look at the general problem of finding a set of basis states when there is more than one particle. You know the basis states for a single particle. An electron, for example, is completely described in no life—not in our simplified cases, but in real life—by giving the amplitudes (or the coefficients of the following states:

, electron "up" with momentum p_1

$|+$

, electron "down" with momentum p_1

There are really two infinite sets of states, one state for each value of p_1 . There is to say that an electron state $|+\rangle$ is completely described if you know all the amplitudes

$$|+\rangle = |\psi_1^+(p_1)\rangle \quad \text{and} \quad |-\rangle = |\psi_1^-(p_1)\rangle$$

Where the $\psi_1^+(p_1)$ represents the component of angular momentum, along some axis—usually the z axis, and p_1 is its wave-momentum. This means, therefore, the two amplitudes for every possible momentum (a multi-infinite set of cases). That is all there is to describing a single particle.

When there are more than one particle, the base states can be written in a similar way. For instance, if there were an electron and a proton in a more complicated situation (for example, considering the base states of both of the following kind).

|an electron with spin "up" moving with momentum p_1 , and

a proton with spin "down" moving with momentum p_2 ,

And so on, for other spin combinations. If there are more than two particles, so much the same. So you see that the infinite number of base states is really very large. The only problem is, where is the Hamiltionian?

For our study of the ground state of hydrogen we won't need to use the full set of base states for the six spins momenta. We can specialize particular one.

moment shared by the proton and electron when we say "the spin, \vec{s} , is down." The details of the configuration, i.e., computes the all the momentum, how states can be calculated, etc., that is another problem. Now we are concerned only with the effects of the spin, so we will focus only the S_{tot} base states of (12.1). Our next problem is: What is the Hamiltonian for this up of spins?

12-2 The Hamiltonian for the ground state of hydrogen

We'll tell you in a moment when it is that we should remind you of one thing: any state can always be written as a linear combination of the base states. For any state $|\psi\rangle$ we can write

$$|\psi\rangle = \alpha_1 |+\rangle + \alpha_2 |-\rangle + \alpha_3 |+\rangle + \alpha_4 |-\rangle + \alpha_5 |+\rangle + \alpha_6 |-\rangle \quad (12.2)$$

Remember that the complex brackets are just complex numbers, so we can choose them in any way. Let's use C_i, where $i = 1, 2, 3, 4, 5$, and write Eq. (12.2) as

$$|\psi\rangle = \alpha_1 |+\rangle_C_1 + \alpha_2 |-\rangle_C_2 + \alpha_3 |+\rangle_C_3 + \alpha_4 |-\rangle_C_4 + \alpha_5 |+\rangle_C_5 + \alpha_6 |-\rangle_C_6 \quad (12.3)$$

By giving the four amplitudes, C_i , we completely describe the spin state $|\psi\rangle$. If these four amplitudes change with time, i.e., they will, the rate of change in time is given by the operator H . The problem is to find out H .

There is no general rule for writing down the Hamiltonian of an atomic system, and finding the right formula is much more difficult than finding a set of new states. We were able to tell you a general rule for writing a set of base states for my problem of a proton and an electron, but to come to the general Hamiltonian of such a combination is beyond us at this level. Instead, we will find you the Hamiltonian by guess by trial and error—and you will have to accept it as the correct one because the results will agree with the test of experimental measurement.

You will remember that in the last chapter we were able to describe the Hamiltonian of a single, spin-one-half particle by using the sigma operators—the various equivalent sigma operators. The properties of the operators are summarized in Table 12-1. These operators, which has just a momentum shift and stay at keeping track of the spin, is elements of the type $(|+\rangle, \sigma_x, |-\rangle)$ —useful for describing the behaviour of a single-particle of spin one-half. The question is: can we find an analogous device to describe a system with two spins? The answer is yes, very simply, as follows. We are looking which we will call "Sigma electron," which we represent by the sigma operator σ_y^e , and which has two components, σ_{y1}^e and σ_{y2}^e . We now know the condition that when the σ_y^e operator acts upon our six base states of the hydrogen atom, it acts only on the electron spin, and in exactly the same way as if the electric field of itself. Example: What is $\sigma_y^e |+-\rangle$? Since e_2 is an electron, "down" is $-$ times the run-around up state with the electron "up".

$$\sigma_y^e |+-\rangle = -|+\rangle |-\rangle$$

Other, σ_y^e acts on the combined state it will give the electron, but does nothing to the proton and multiplies the result by $-i\hbar$. Operations on the other states, σ_y^e would give

$$\begin{aligned}\sigma_y^e |++\rangle &= i\hbar |++\rangle \\ \sigma_y^e |+-\rangle &= -i\hbar |-\rangle \\ \sigma_y^e |--\rangle &= -i\hbar |--\rangle\end{aligned}$$

You remember that the operators σ_y^e work only on the first spin symbol—that is, on the electron spin.

Next we define the corresponding operator "Sigma proton" for the proton spin. Its three components σ_x^p , σ_y^p , σ_z^p act in the same way as σ_y^e only on the

Table 12-1

$\sigma_x +\rangle =$	$ +\rangle$
$\sigma_x -\rangle =$	$ -\rangle$
$\sigma_z +\rangle =$	$+ +\rangle$
$\sigma_z -\rangle =$	$+ -\rangle$
$\sigma_y +\rangle =$	$ +\rangle$
$\sigma_y -\rangle =$	$- +\rangle$

your spin. For example, if we have σ_z acting on each of the four basis states we get, always using Table 1.1 —

$$\begin{aligned}\sigma_z^1 | + \rangle &= | + \rangle, \\ \sigma_z^2 | + \rangle &= | + \rangle, \\ \sigma_z^3 | + \rangle &= | - \rangle, \\ \sigma_z^4 | - \rangle &= | + \rangle.\end{aligned}$$

As you can see, it's not very hard.

Now in the next general case we would have more complex things. For instance, we could have products of the two operators like $\sigma_x\sigma_y^2$. When we have such a product we do first what the operator on the right says, and then do what the other one does. For example, we would have this

$$\sigma_x\sigma_y^2 = -i(-i\sigma_x) = i(-i\sigma_x)(-i\sigma_y) = -i(-i\sigma_y) = -i\sigma_y.$$

Now, think these operators don't do anything on pure numbers—we have used this fact when we defined $\langle -| = (-D)$. However, that the operator "commutes" with pure numbers, so that a factor "can be moved through" the operator. You can practice by showing that the product $\sigma_x\sigma_y^2$ gives the following result for the four states:

$$\begin{aligned}\sigma_x\sigma_y^1 | + \rangle &= | + \rangle, \\ \sigma_x\sigma_y^2 | + \rangle &= | + \rangle, \\ \sigma_x\sigma_y^3 | + \rangle &= | - \rangle, \\ \sigma_x\sigma_y^4 | - \rangle &= | - \rangle.\end{aligned}$$

If we take τ_{-} the possible operators, using each state as operator only once, there are sixteen possibilities. Using commutativity we include also the "unit operator" 1. First, let's look at the $\sigma_x\sigma_y^2$. This has 16 states, $\tau_1, \tau_2, \dots, \tau_{16}$, which makes six. In addition, there are the 16 possible products of the form $\sigma_x\sigma_y^2$, which makes a total of 16. And then there is the unit operator which just leaves any given state alone. Sixteen in all.

Now, note that for a four-state system, the Hamiltonian matrix has to be a 16x16 matrix of coefficients. It will have zeros entries. It is easily demonstrated that any two $\sigma_x\sigma_y^2$ matrices will, therefore, be commutative. In particular, can be written as a linear combination of the sixteen double-spin operators corresponding to the set of operators we have just made up. Therefore, the commutation between a proton and an electron (i.e. involves only their spins) but you expect that the commutation operation can be written as a linear combination of the same 16 operators. The only question is, how?

Well, first we know that the interaction doesn't depend on our choice of coordinate system at all. If there is no central disturbance like a magnet, the basic interaction is only in direction of space, the Hamiltonian can't depend on the choice of the direction of the x , y , and z axes. That means that the Hamiltonian can't have a term like $\sigma_x\sigma_y^2$. It would be ridiculous, because then somehow with a different coordinate system would go off-center value.

The only possibilities are to come with the unit matrix, say a constant v (from Eq. 1.1), and some combination of the sigma's that does not depend on the coordinates—say, "intrinsic" combination. The only possible invariant combination of the vectors is the dot product, which is zero's to

$$\sigma_x\cdot\sigma_y^2 = \sigma_x\sigma_y^2 = \sigma_x\sigma_y^2 + \sigma_y\sigma_x^2. \quad (1.2.1)$$

This quantity is invariant, will depend to any relabeling of the coordinate system.

[†]For these particular operators you will notice I have got that the sequence of the operators don't matter.

So the only possibility for a Hamiltonian with the proper symmetry to give us a constant term in mutual is plus a constant times the dot product, say,

$$\hat{H} = E_0 + \vec{A} \cdot \vec{\sigma} \cdot \vec{B}_0. \quad (12.2)$$

That's our Hamiltonian. It's the only thing that it can be, by the symmetry of space, no long or short from external field. The constant term doesn't tell us much; it just depends at this level we choose a constant energies from. We must have, as well, $E_0 > 0$. The second term will be all we need to show we find the total binding of the hydrogen.

If you want to, you can think of the Hamiltonian in a different way. If the two are two magnets near each other with magnetic moments μ_1 and μ_2 , the mutual energy will depend on $\mu_1 \cdot \mu_2$, among other things. And, you remember, we found that the classical thing we call the energy is quantum mechanics is $\mu_1 \cdot \mu_2$. Similarly, when you calculate $\mu_1 \cdot \mu_2$ will give you minus in quantum mechanics to be $\mu_1 \cdot \mu_2$ (where μ_2 is the negative moment of the proton, which is about 10.0 times smaller than μ_1 , and has the opposite sign). So Eq. (12.2) says that the interaction energy is like the interaction between two magnets, only not quite, because the interaction of the two magnets depends on the total distance between them. But Eq. (12.2) could represent, in fact, a combination of an average interaction. The electron is moving all around itself, he says, and our theory which gives only the average interaction energy. All it says is the \vec{B}_0 is a vector representing in space for the electron and proton there is an energy proportional to the cosine of their angle between. So the magnetic moment is speaking classically. Such a classical evaluation picture may help you to understand where it comes from, but the important thing is that Eq. (12.2) is the correct quantum mechanical formula.

The order of magnitude of the classical interaction between two magnets would be the product of the two magnetic moments divided by the cube of the distance between them. The reason: he sees the electron and the proton in the hydrogen atom is speaking roughly, one has to stick to each other, or 3.5 separated. It is, therefore, possible to make a crude estimate that the constant should be proportional to the product of the two magnets divided $\mu_1 \cdot \mu_2$, divided by the cube of the separation. Such an estimate gives a number 1.0e-12, perhaps. Then $\vec{B}_0 > 0$ that I can probably estimate once you understand the complete quantum theory of the hydrogen atom—which we are not doing. It has, in fact, been calculated in seconds of about 20 years in one million. So, unlike the dipole constant d of the ammonia molecule, which couldn't be calculated at all well by a classical theory, for the hydrogen can be calculated from complete quantum theory. But never mind, we will for present purposes think of the \vec{B}_0 as a number which needs to be determined by experiment and analyze the physics of the situation.

Taking the Hamiltonian of Eq. (12.2) we can use . with the equation

$$AC = \sum_i B_i C_i \quad (12.3)$$

and out what the spin matrix elements the energy levels. To do that, we need to work in the mixed matrix element $\langle M_i | B_i | M_j \rangle = 0$, B_i is corresponding to each one of the four wave states in (12.1).

We begin by working in what $B|0\rangle$ is the zeroth of the four basis states for $\sigma = \pm \frac{1}{2}$,

$$B = (\vec{\sigma} - \vec{\mu}_1 \cdot \vec{\sigma}_1^0 - \vec{\mu}_2 \cdot \vec{\sigma}_2^0) = \vec{\sigma} = \vec{\sigma}_1^0 + \vec{\sigma}_2^0 = \sigma(\vec{\sigma}). \quad (12.4)$$

Using the method we described a little earlier, it's easy if you have memorized Table 12-1—just find what each pair of σ 's does on $|+\pm\rangle$. The answer is

$$\begin{aligned} \sigma\sigma^0_1 + \sigma^0_2 &= |+\pm\rangle \\ \sigma\sigma^0_2 - |\pm\rangle &= |-\pm\rangle, \\ \sigma\sigma^0_1 - |\pm\rangle &= |+\mp\rangle. \end{aligned} \quad (12.5)$$

be (12.7) becomes

$$\hat{H} = +; \quad A(- -) - - -; + + -) \cdot \mathbf{I} \mid 1 \rangle \lambda = (12.9)$$

Since our basis states are all orthogonal, this gives us immediately that

$$\begin{aligned} (- + \mid H \mid - -) &\sim (0 - + \mid 1 \mid -) = 0, \\ (- - \mid H \mid + +) &\sim A(- - + +) = 0 \quad (12.10) \\ (- + \mid H \mid + +) &\sim A(- + + +) = 0, \\ (- - \mid H \mid + +) &\sim A(- - + +) = 0. \end{aligned}$$

Assimilating each $A(- - + +) / \lambda^2$, we can easily write down the differential equation for the amplitudes C_1 :

$$\begin{aligned} dC_1 - H_{11}C_1 - H_{12}C_2 + H_{13}C_3 - H_{14}C_4 \\ = 0 \\ dC_1 = AC_1. \end{aligned} \quad (12.11)$$

Table 12.2

Spin operators for the hydrogen atom

σ_x^2	$\sim +;$	$- - -;$
σ_y^2	$\sim - +;$	$+ + -;$
σ_z^2	$\sim +;$	$- + -;$
$\sigma_y\sigma_z$	$\sim +;$	$+ + -;$
$\sigma_x\sigma_z$	$\sim +;$	$- - +;$
$\sigma_x\sigma_y$	$\sim + -;$	$- + -;$
$\sigma_y\sigma_x$	$\sim + -;$	$- + -;$
$\sigma_x\sigma_y\sigma_z$	$\sim + - +;$	$- + - +;$
$\sigma_y\sigma_x\sigma_z$	$\sim + - +;$	$- + - +;$
$\sigma_z\sigma_x\sigma_y$	$\sim + - +;$	$- + - +;$
$\sigma_z\sigma_y\sigma_x$	$\sim + - +;$	$- + - +;$

That's all! We get only the one term.

Now, since the rest of the Hamiltonian equations we have to solve through the same procedure for \hat{H} operating on the other states. Then, we will let you proceed by checking out all of the sigma products we have written down in Table 12.2. Then, we can use them to get:

$$\begin{aligned} i(- + -) - A(- + +) &= -C_1, \\ i(- - +) - A(2(+ -) - - +) &= -C_2, \\ i(- - -) - A(- - +) &= C_3. \end{aligned} \quad (12.12)$$

Then, multiplying each one of them on the left by all the other state amplitudes, we get the following Hamiltonian matrix, H_{ij} :

$$H_{ij} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & -4 & 2A & 0 \\ 0 & 2A & -A & 0 \\ 0 & 0 & 0 & A \end{bmatrix}. \quad (12.13)$$

It means, of course, nothing more than that the differential equations for the four amplitudes C_i are

$$\begin{aligned} dC_1 &= AC_1, \\ dC_2 &= -4C_1 - 2AC_3, \\ dC_3 &= 2AC_2 - AC_4, \\ dC_4 &= AC_3. \end{aligned} \quad (12.14)$$

Before solving these equations we can't resist adding one about a clever rule due to Dirac: it will make you feel that you are really advanced although you don't read it for the work. We have seen from the equations (12.9) and (12.12) that

$$\begin{aligned} \sigma_x^2 \cdot \sigma_x^2 &= 1 = + + +, \\ \sigma_y^2 \cdot \sigma_y^2 &= - + - 2(+ -) = -A, \\ \sigma_z^2 \cdot \sigma_z^2 &= + + - 2(+ + -) = + + A, \\ \sigma_x^2 \cdot \sigma_y^2 &= - + - \end{aligned} \quad (12.15)$$

Look, we're doing this also with the first and last equations to

$$\begin{aligned} \sigma^x \cdot \sigma^y |+> &= \frac{i}{\hbar} (1 - 2) |+> + \frac{i}{\hbar} (-1) \\ \sigma^x \cdot \sigma^y |-> &= \frac{i}{\hbar} (-1 - 2) |-> + \frac{i}{\hbar} (-1) \end{aligned}$$

that they are quite similar. Now I invent a new operator, which I will call P_{exchange} , and which I ought to have the following properties:

$$\begin{aligned} P_{\text{exchange}} |+> &= |+> + |> \\ P_{\text{exchange}} |-> &= |-> + |> \\ P_{\text{exchange}} |+> &= |+> + |> \\ P_{\text{exchange}} |-> &= |-> + |>. \end{aligned}$$

All the operator does is interchange the spin directions of the two particles. Then I can write the whole set of equations in (12.13) as a single operator equation:

$$\sigma^x \cdot \sigma^y + 2P_{\text{exchange}} = 0. \quad (12.16)$$

(Don't the terms of $\sigma^x \cdot \sigma^y$ —the "spin exchange operator" gives a handy rule for labeling the states? You see, you can do everything now. The gates are open.)

12-3 The energy levels

Now we are ready to work out the energy levels of the ground state of hydrogen by solving the Hamiltonian equations (12.14). We want to find the energies of the stationary states. This means that we want to find those ψ 's, called ψ 's, for which each equation $H\psi = E\psi$ (ψ belongs to ψ) has the *exact* time dependence—namely, $e^{-iEt/\hbar}$. (I bet the state will have the energy $E = \hbar\omega_0$. So we want to set this, which

$$C_1 = a_1 e^{-iE_1 t/\hbar}, \quad (12.17)$$

where the other coefficients are still independent of time. To see whether we can get such simplitudes, we substitute (12.17) into Eq. (12.14) and see what happens. First multiply in Eq. (12.14) from left to right, and then cancel out the common exponential factor $e^{-iE_1 t/\hbar}$. (Remember why?) we get

$$\begin{aligned} Ee_1 &= Ae_1, \\ Ee_2 &= -Ae_2 - 2Ae_1, \\ Ce_3 &= 2Ce_2 - Ae_1, \\ Ee_4 &= Ae_4. \end{aligned} \quad (12.18)$$

which we have to solve for e_1, e_2, e_3 , and e_4 . Let's notice that the first equation is independent of e_2 too—(that means we can get this solution right away. If we choose $C = A$,

$$e_1 = 1, \quad e_2 = e_3 = e_4 = e_5 = 0$$

gives a solution. (If anyone taking all these's equal to zero gives a solution, but can't be since it all!) Let's call our first solution the state $|+\rangle$ †

$$|+\rangle = |+> + |+>. \quad (12.19)$$

Its energy is

$$E_1 = \hbar\omega_0.$$

† This operator is now called the "Pauli spin exchange operator."

↓ It is *not* really $1/\sqrt{12}$. We just say it's *close* to the state for the convenience of the numbers and $\hbar = 1$.

With two outgoing spin components, another solution from the last eq. is given in (12.18).

$$a_1 = a_2 = a_3 = 0, \quad a_4 = 1.$$

$$E = A$$

We'll see that this leads to $| E\rangle$:

$$| E \rangle = | A \rangle = | + - \rangle, \quad (12.20)$$

$$E_{\text{tot}} = A.$$

Now it gets a little harder. The two equations left in (12.18) are mixed up. But we've done it all before! Adding the two, we get:

$$E(a_1 + a_2) = A(a_1 + a_2). \quad (12.21)$$

Subtracting, we have:

$$(a_1 - a_2) = -A(a_1 - a_2). \quad (12.22)$$

By inspection and remembering symmetry—recall that there are two solutions:

$$\begin{aligned} \text{and} \quad & a_1 = a_2, \quad E = A \\ & a_2 = -a_1, \quad E = -A. \end{aligned} \quad (12.23)$$

They are mirror images of (2) and (3). Getting these states $| A \rangle$ and $| -A \rangle$, and putting in a factor $\sqrt{2}/2$ to make the states properly normalized, we have

$$\begin{aligned} | A \rangle &= \frac{1}{\sqrt{2}} (| + - \rangle + | - + \rangle) = \frac{1}{\sqrt{2}} (| + - \rangle + | - + \rangle), \\ | -A \rangle &= \frac{1}{\sqrt{2}} (| + - \rangle - | - + \rangle). \end{aligned} \quad (12.24)$$

$$E_{\text{tot}} = A$$

and

$$\begin{aligned} | A \rangle &= \frac{1}{\sqrt{2}} (| + - \rangle + | - + \rangle) = \frac{1}{\sqrt{2}} (| + - \rangle - | - + \rangle), \\ | -A \rangle &= -| A \rangle. \end{aligned} \quad (12.25)$$

$$E_{\text{tot}} = -A$$

We have found four stationary states and their energies. Hence, miraculously, that any four states are orthogonal, so they also can be used for basis states if desired. Our problem is completely solved.

Two of the states have the energy A , and the last two the energy $-A$. The average is zero, which means that, when we take $E_1 = 0$ in Eq. (12.5), we were measuring to measure all the energies from the average energy. We can draw the energy-level diagram for the ground state of hydrogen as shown in Fig. 12-2.

Now let's consider the energy between state $| A \rangle$ and any one of the others $\sim 4E$. An atom which happens to be just on the state $| A \rangle$ would fall from there to states $| B \rangle$ and emit light. Not optical light, because the energy is so big—it would emit a microwave quantum. Or, if we shine microwaves on hydrogen gas, we'd find an absorption of energy when an atom is state $| A \rangle$ with energy and we take one of the upper states—say only at the frequency $\omega = 4\pi/3$. The frequency has been measured experimentally; the best result obtained very recently is

$$\omega = \omega/2\pi = 11,430,406.771963 \pm 0.0001 \text{ cycles per second.} \quad (12.26)$$

The error is only one part in 10.5 billion! Probability is basic physical quantity is measured rather than time. It's one of the most remarkable accurate measurements in physics. The Russians were very happy that they could compute the energy to 12 decimal places in 1961, but in the meantime had been measured to 2 parts in 10^{11} —a million times more accurate than the theory. So the experimentalists are

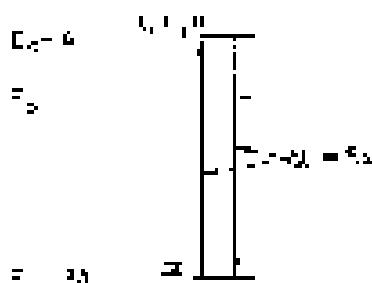

Fig. 12-2. Energy-level diagram for the ground state of atomic hydrogen.

way about 400 femtoseconds. In the theory of the ground state of the hydrogen atom you've seen pretty much everything. You, too, can just take your values out from experiment—that's what everybody does today in general.

You have probably heard before about the "Lyman-alpha" of hydrogen. That's the wavelength of the 121.6 nanometer spectral line between the 1s ground state and the 2s excited state. Radiation of this wavelength is emitted or absorbed by the atom of hydrogen gas in the jet device. So, with radio telescopes (radiation at 21 cm waves (or 1420 megacycles approximately); we can observe the reionization and the local ionization rate of atomic hydrogen gas. By measuring the intensity, we can determine the number of hydrogen. By measuring the frequency shift due to the Doppler effect, we can find out about the motion of the gas in the jet. This is one of the big advances of radio astronomy. So now we're talking about something that's very real—it is an observational program.

13.4 The Zeeman splitting

Although we have treated the problem of finding the energy levels of the hydrogen atom above, we would like to study this interesting system some more. In order to say anything more about it—for instance, in order to calculate the general width the hydrogen atom absorbs at various radio waves at 21 centimeters, we have to know what happens when the atom is disturbed. We have already provided for the atom moving in—say we lower the energy levels we want to find out what happens when the atom moves in a magnetic field. We can't calculate what happens when the atom is held in a radio wave. For the system you see in the magnetic field they're nothing to the levels except to move them off by some constant amount proportional to the square of the field—which is not the right thing because that won't change the energy difference. To do all the calculations that's important. So the next step is to write the Hamiltonian for a free atom in a situation in which the electrons in an external magnetic field.

What is it? Is the Hamiltonian? Well, just tell you the answer, because we can't give you any "secret" except to say that this is the way the atom works.

The Hamiltonian is

$$H = \frac{1}{2}m_e v^2 + p_{\phi}^2 + \mu_0 e \cdot B - \mu_0 \sigma \cdot B. \quad (122)$$

I have written it in three parts. The first term and v^2 represents the magnetic interaction between the electron and the proton. It is the same one that would be used if there were no magnetic field. This is the last term, however; the last and the influence of the magnetic field on the system. A is negligible. The effect of the nuclear magnetic field shows up in the last two terms. The second term, $-\mu_0 \sigma \cdot B$, is the energy the electron would have in the magnetic field if it were there alone.¹ In the same way, the last term, $\mu_0 \sigma^2 \cdot B$, would have been the energy of the proton alone. Classically, the energy of the two electrons together would be the sum of the two, and that works also quantum mechanically. In a magnetic field, the energy of the two electrons being magnetized is not the sum of the energy of interaction of the electron with its external field, since the presence of one field—but has to be expressed in terms of the dipole moments. In quantum mechanics these two don't add really the way they do, but the sum of the classical numbers is the energy. It's a way of doing things for verifying that the Hamiltonian works. Anyways, the current Hamiltonian is Eq. (122).

Now we are going back to the beginning and do the possible null observations. Much of the work is, however, done. We need only an additional term in the new form. Let's take a constant magnetic field B in the z-direction. Then we have to

¹ Remember that there is $-\mu_0 \sigma \cdot B$ to the energy of having when the moment is along the z-axis. The positive part of the magnetic moment is parallel to the spin and the negative part of it is opposite. So in Eq. (122) of the Hamiltonian there is a negative number.

Add to eq. (12.28) the second operator of the two new mass-scales; we call it \tilde{H}^2 :

$$\tilde{H}^2 = -(\mu_2 + \alpha_2)\delta.$$

Using Table 12-1, we get after simplification

$$\begin{aligned}\tilde{H}^2 | + - \rangle &= -(\mu_2 + \alpha_2)\delta, \\ \tilde{H}^2 | + + \rangle &= (\mu_2 + \alpha_2)\delta_1 = -\epsilon, \\ \tilde{H}^2 | - - \rangle &= -(-\alpha_2 + \lambda_2)\delta_1 = \epsilon, \\ \tilde{H}^2 | - + \rangle &= (\mu_2 + \alpha_2)\delta_1 = -\epsilon,\end{aligned}\quad (12.39)$$

thus very convenient! The \tilde{H}^2 operating on each state has given a value from each state. The matrix $(\tilde{H}^2)^{\dagger} \tilde{H}^2$ has, obviously, only diagonal elements; we can now add the coefficients in (12.29) to the corresponding diagonal terms of (12.13), and the Hamiltonian equation of (12.14) becomes

$$\begin{aligned}H(0, \beta) &= \{A + (\mu_2 + \alpha_2)\delta\}C_{11}, \\ H(0, \beta) &= \{A + (\mu_2 + \alpha_2)\delta\}C_2 + 2AC_3, \\ H(0, \beta) &= 2AC_3 + \{A + (\mu_2 + \alpha_2)\delta\}C_{22}, \\ H(0, \beta) &= \{A + (\mu_2 + \alpha_2)\delta\}C.\end{aligned}\quad (12.39)$$

The form of the equations is not quite arbitrary the coefficients. So long as δ doesn't vary with time, we can sum in just as we did before. Substitution, $C_2 = \alpha_2 C_1^{-1} C_{12}$, we get the modification of (12.38):

$$\begin{aligned}C_{11} &= A + (\mu_2 + \alpha_2)\delta\alpha_1, \\ E_{11} &= \{A + (\mu_2 + \alpha_2)\delta\}\alpha_2 = 2.1\alpha_2, \\ E_{22} &= 2\alpha_2 = \{A + (\mu_2 + \alpha_2)\delta\}\alpha_1, \\ E_C &= \{A + (\mu_2 + \alpha_2)\delta\}C.\end{aligned}\quad (12.40)$$

Equations (12.39) and fourth equations are β -independent of course so the same technique works again.

One solution to the above (12.40) when $\alpha_1 = 1, \alpha_2 = \alpha_3 = \alpha_4 = 0, \beta$

$$E = \{A + \beta\} | + + \rangle, \quad (12.41)$$

with

$$A = \beta = (\mu_2 + \alpha_2)\delta.$$

An other is

$$| D \rangle = | 0 \rangle = | + - \rangle,$$

with

$$E_D = A + (\mu_2 + \alpha_2)\delta. \quad (12.41)$$

A little more work is involved for the remaining two solutions because the coefficients of α_1 and α_2 are not proportional. But they are just like the previous case for the original α_1 and α_2 . Looking back at (12.30), we can make the following analogy (remembering that the levels I and II the α 's correspond to λ and β respectively):

$$\begin{aligned}H_{11} &= \beta + A = (\mu_2 + \alpha_2)\delta, \\ H_{12} &= 2\alpha_1, \\ H_{21} &= 2\alpha_1, \\ H_{22} &= \beta + A = (\mu_2 + \alpha_2)\delta.\end{aligned}\quad (12.42)$$

The energies are given by (12.27), which was

$$\epsilon_1 = \frac{H_{11}}{2} = \theta_{12} = \sqrt{\frac{4H_{11}}{3} + \frac{H_{22}(1 + H_{11}H_{22})}{3}}. \quad (12.43)$$

Making the substitutions from (12.7), the energy formula becomes

$$E = -A = \alpha(\mu_0 - \mu_0)B^2 + 4\mu_0.$$

Although the letters α are used to call the energies E_1 and E_{21} , and so on, in the problem calling them E_1 and E_{21} ,

$$\begin{aligned} E_{21} &= \alpha(1 + 2\sqrt{1 - \mu_0/\mu_0})B^2 + 4\mu_0, \\ E_{31} &= \alpha(1 + 2\sqrt{1 - \mu_0/\mu_0})B^2 + 4\mu_0. \end{aligned} \quad (12.8)$$

So we have found the energies of the four sub-energy states of a hydrogen atom in a constant magnetic field. Let's check on this by letting B go to zero, and seeing whether we get the same energies we find in the usual spectrum. You see that we do. For it is E_1 the energies E_1 , E_{21} , and E_{31} go to E_1 and E_{21} become $-4\mu_0$. From the labeling of the states you can see what we called them before. When we put in the magnetic field, though, all of the energy changes in a different way. Let's see how they do.

First, we have to remember that in the situation, μ_0 is negative, and that μ_0 is less negative than μ_0 , which is positive. So $\mu_0 + \mu_0$ and $\mu_0 - \mu_0$ are both negative numbers, and nearly equal. Let's call them μ_0 and $-\mu_0$.

$$a = -\mu_0 - \mu_0, \quad a' = (\mu_0 - \mu_0). \quad (12.9)$$

With a and a' two positive numbers, nearly equal to magnitude, one which is about one Bohr magneton, the energy levels are

$$\begin{aligned} E_1 &= 1 - \mu_0, \\ E_{21} &= 1 - \mu_0, \\ E_{31} &= 1 + 2\sqrt{1 - \mu_0/\mu_0}B^2, \\ E_{32} &= 1 + 2\sqrt{1 - \mu_0/\mu_0}B^2 + 4\mu_0. \end{aligned} \quad (12.17)$$

The energy E_1 starts at 1 and increases linearly with B , with the slope a . The

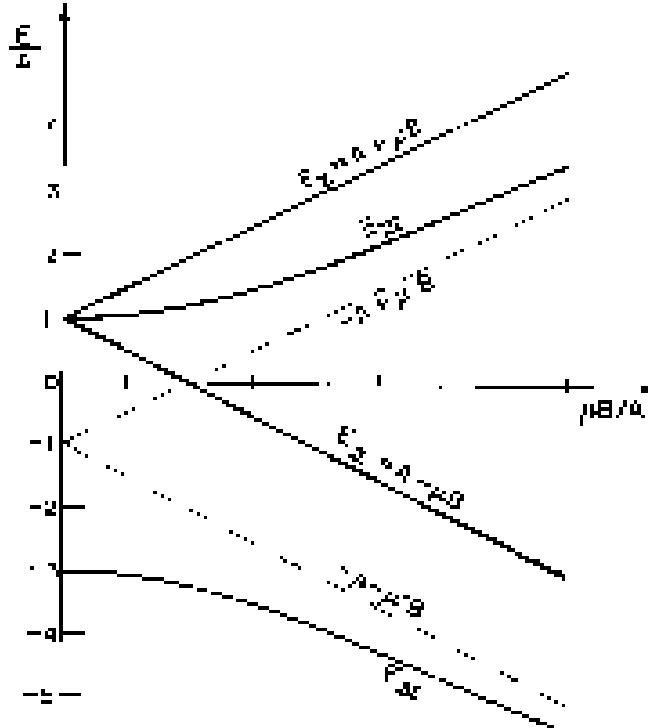

Fig. 12-1. The energy levels of the ground state of hydrogen in a magnetic field B .

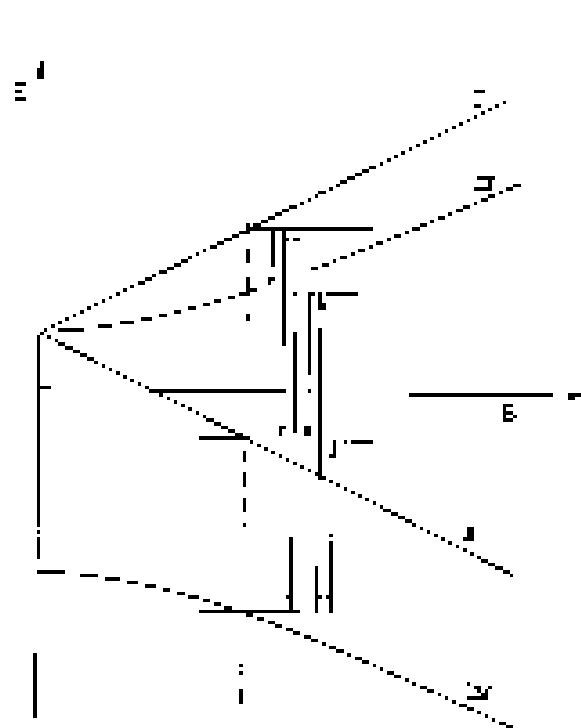

Fig. 12-2. Transitions between the levels of excited state energy levels of oxygen in a magnetic field B .

energy E_1 , which is at the lowest energy with increasing B . Its slope is $-g$. These two levels have with δ as above in Fig. 12-1. We show here in the figure the energies E_1 and E_0 . They have a linear B dependence. The small δ they depend on corresponds to 0 , or very near 0 , which is what we want. Then they begin to curve, and the slopes of the approach straight lines are slopes $-g$, which are exactly the slopes of E_1 and E_0 .

The shift of the energy levels due to a magnetic field is called the Zeeman effect. We can look at it in Fig. 12-1 below the $\psi = 0$ splitting in the ground state of hydrogen. When there is no magnetic field, we get just one ground line from the hyperfine structure of hydrogen. The interaction between spin and field by one of the electrons occurs here the same manner as in case of a photon whose frequency ω_0 is equal to $1/2$ times the energy difference ΔE . When the atom is in a magnetic field, it however has one new line. There are no transitions between only two of the four states, so if we calculate δ in each state, energy can be calculated as follows. It may see of the six transitions shown, by the vertical arrows in Fig. 12-4. Many of these transitions can be forced by the Rabi molecular beam techniques we learned in Section 12-1 (see Appendix).

We can do the transitions $2\psi_1 \rightarrow 1\psi_0$. The perturbing effect of disturbing ψ_1 is field that varies with time proportional to the steady strong field B_0 . Its job is to force a steady electric field on the hydrogen molecule. Only here, it is the magnetic field which couples with the molecular current and does not break. So the theory follows through in the same way that we worked it out for the atom. The ψ_1 is in the situation that a perturbing magnetic field δB comes in the ψ_1 plane. From this he can do oscillating field with δB . When you put this perturbing field as an oscillating term in the fluctuation, you get equations to solve. The amplitudes vary with time—just as it would for the atomic molecule. So you can calculate easily and accurately the probability of a transition from one state to another. And you find that it agrees with experiment.

12-5. The states in a magnetic field

We would like now to consider the energies of the curves in Fig. 12-3. In the first place, the energies in degeneracy are again relativistic and either in constant form or varying through the field. For $\mu_B = 1/2$ we can neglect the form the form of (12-3). This must change because

$$\begin{aligned} E_1 &= A + \mu B, & E_0 &= A - \mu B, \\ E_{0\perp} &= A + \mu' B & E_{1\perp} &= A - \mu' B \end{aligned} \quad (12-3)$$

This somewhat changes the bottom eight lines in Fig. 12-3. We can understand these energies physically in the following way. The nature of the stationary states in zero field is determined completely by the orientation of the two magnetic moments. The numbers of the last states $|+,-\rangle$ and $|-,+\rangle$ in the ordinary scales $|JM\rangle$ are A and $A - \mu B$ in interaction. In large enough field, however, the proton and electron m_e be influenced hardly at all by the effect of the other, and will just sit in one state in the external field. They $\rightarrow \psi_0$. There seem many lines—the plus spin will be down parallel to or opposite to the external magnetic field.

Suppose the electron spin is up— ψ_1 but ψ_0 may be field independent of $\pm \mu B$. The proton can still be either way. If the proton spin is also “up,” its energy is $A - \mu B$. The sum of the two is $A - \mu B - \mu B = A - 2\mu B$. That is just what we find for E_1 , which is the lowest energy occurring because $|+-\rangle = \psi_1$.

There is still the small additional term of $\delta \mu B$ in ψ_1 which represents the interaction energy of the proton and electron if their spins are parallel. We originally took δ as positive because, in ordinary we expect δ to be small, i.e., not too great. It is indeed so! On the other hand, the proton can have its spin down—then its energy is increased. If it is ψ_1 it gets $A - \mu B + \mu B = A$ and the energy $+ \mu B = \mu B^2 = \mu^2 B$. And the intermediate case of ψ_1 has $\delta \mu B$.

The sum neglects energy E_{ext} in (12.38). So the state $|M\rangle$ need not have zero because the state $= -\frac{1}{2}$.

Suppose now the electron spin is "down." Its energy in the external field is $\mu_B B$. If the proton is also "down," the two together have the energy $(m_1 + \mu_B)B = \mu_B$, and the interaction energy α —since their spins are parallel. That makes just the one for E_{int} in (12.38) and corresponds to the state $= + |M\rangle$, which is zero. Finally if the electron is "down" and the proton is "up," we get the energy $m_1 - \mu_B B = -\mu_B B$ for the interaction because the spins are opposite, which is just E_{ext} . And the state corresponds to $= - |M\rangle$.

"But wait a moment!" you are probably saying. "The states $|M\rangle$ and $|M'\rangle$ are NOT basis states $|+\rangle$ and $|-\rangle$; they are mixtures of the two. What's more, B is not $B = 0$, but we have not yet figured out what they are, for large B . When we used the results of (12.38) in the formulas of Chapter 9 to get the energies of the stationary states, we could substitute between the amplitudes that go with them. They come from Eq. (9.29), which is

$$\frac{C_1}{C_2} = \frac{E - E_{\text{ext}}}{\mu_B B}.$$

The ratio C_1/C_2 is of course, just $C_1 C_2^*$. Putting in the analogous quantities from (12.38), we get

$$\frac{C_1}{C_2} = \frac{E + A - (m_1 - \mu_B)B}{\gamma_A},$$

or

$$\frac{C_1}{C_2} = \frac{E + A + \mu_B B}{\gamma_A}. \quad (12.39)$$

What do E and A do to the hyperfine energy levels E_{HF} or E_{HF} ? For instance, for state $|+M\rangle$ we have

$$\left(\frac{C_1}{C_2}\right)_{+M} \sim e^{i\mu_B B} \quad (12.40)$$

So for large B the ground state $|+M\rangle$ (or $|-\rangle$) the atom has almost completely the state $|+M| + +\rangle$. Similarly, if we put E_{HF} zero (12.40) we get $(C_1/C_2)^*_{+M}$. $\propto e^{-i\mu_B B}$ for high-field state $|M'\rangle$ because just the state $|M| + +\rangle$ (you see that the coefficients in the linear combinations of our basis states which make up the stationary states depend on B). The state we call $|M'\rangle$ is a π -pseudostationary $= -\frac{1}{2}$ and $|-\rangle$, at very low fields, but shifts over to $= +\frac{1}{2}$ for large fields. Similarly, the state $|M'\rangle$ where the field is zero is at $\approx 90^\circ$ relative to the opposite energy $\propto |+\rangle$ (and $|-\rangle$), goes over into the state $|-\rangle$ when the spin is unoccupied by a strong external field.

We would also like to tell you about something particularly to what happens to your magnetic fields—there is one energy $= -14$ which does not change when you turn on a small magnetic field. And there is another energy $= -4$ which splits into three different energy levels when you turn on a small magnetic field. These two levels change very with B as shown in Fig. 12.5. Suppose you've somehow selected a bunch of hydrogen atoms which all have the energy $= -14$. If we put them through a Rabi-Clairaut experiment, with fields that are not too strong—you would find them just go straight through. (Since their energy doesn't depend on B , there is—according to the principle of virtual work—the force on them in a magnetic field is zero.) Suppose, on the other hand, we were to select a bunch of atoms with the energy $= -4$, and put the \perp through a Stern-Gerlach apparatus, say in X apparatus. (Again the field in the apparatus should not be so great that they disrupt the bunches of electrons, by which I mean a field going through the atoms that vary linearly with B .) We would find three bands. The states $|+M\rangle$ and $|M'\rangle$ get opposite forces—their energies vary linearly with B with the slopes $= \pm \alpha$. The others are like those of a dipole with $\alpha = 0$. But the state $|M\rangle$ goes straight through. So we are right back ... Chapter 5. A hydrogen atom with an energy $+4$ is a spinless particle. This energy isn't in a "pseudostate" for which $I = 1$, and it can be described with respect to some set of

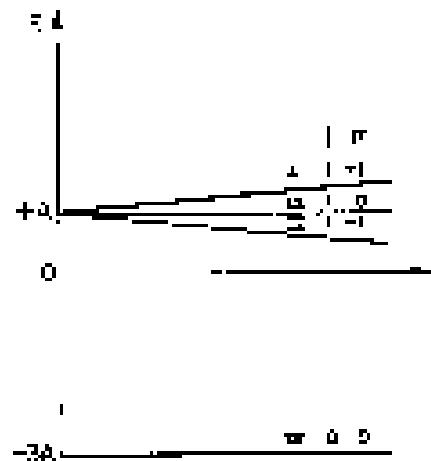

Fig. 12.5. Energy levels of the hydrogen atom for weak magnetic fields.

axes in space— $| +\text{S}\rangle$, $| -\text{S}\rangle$, $| +\text{S}\rangle$ and $| -\text{S}\rangle$ —and in Chapter 10, 3. On the other hand, since the hydrogen atom has the energy $E = \hbar^2/8\pi^2 r^3 m$ it represents a $\frac{1}{2}$ member which when applying $\hat{\mathbf{L}}_z$ will also have to be included in the basis. So we can project the states of hydrogen in zero magnetic field this way:

$$\begin{aligned} |\psi\rangle &= |\psi\rangle_{\text{S}} + |\psi\rangle_{\text{H}} \\ |\psi\rangle &= \left(\frac{1}{2} |\psi\rangle_{\text{S}} + \frac{1}{2} |\psi\rangle_{\text{H}} \right) + \left(\frac{1}{2} |\psi\rangle_{\text{S}} - \frac{1}{2} |\psi\rangle_{\text{H}} \right) \\ |\psi\rangle &= |\psi\rangle_{\text{S}} + \frac{1}{2} (\psi_{+} - \psi_{-}) \end{aligned} \quad (12.41)$$

$$|\psi\rangle = \frac{1}{2} (\psi_{+} + \psi_{-}) + \frac{1}{2} (\psi_{+} - \psi_{-}) \quad (12.42)$$

We have said in Chapter 10 of Vol. 1, II (Section 4) that for any particle its component of angular momentum along any axis can have only certain values, always \hbar apart. The component of angular momentum L_z will be $\hbar/2$ ($j = 1/2$) ($j = 1/2$, ..., $j = j/2$), where j is the spin of the particle (which can be an integer or half-integer). Although we neglected to say so, the same goes for the total angular momentum S .

Table 12.2
Zero-field states of the hydrogen atom

State $ m_S\rangle$	m_s	Orbit quantum no.
$ +\text{S}\rangle$	$+1/2$	1
$ 0\rangle$	0	2
$ -\text{S}\rangle$	$-1/2$	3
$ 0\rangle$	0	4

The m_s columns for one of the numbers $j = 1/2$, $j = 1/2$, ..., $j = j/2$. You will, therefore, see you're likely to find the $|+\text{S}\rangle$ ground state of $|y\rangle$ given by the vector $\hat{\mathbf{L}}_z$ (written below) and its partner called the “orthogonal” one (written vertically in front of it) and “angular momentum coupling” (see 10.4). Then, instead of our wave functions $|\psi_{+}\rangle$, $|\psi_{-}\rangle$ and $|\psi_{0}\rangle$, they will be $|\psi_{+}\rangle$, $|\psi_{-}\rangle$ and $|\psi_{0}\rangle$ which would give one linear superposition in zero field (12.41) and (12.42) as shown in Table 12.2. It's not very precise, it's all just a matter of notation.

12.6 The projecting matrix for spin one

We would like now to use our knowledge of the hydrogen atom in the zero-field case. We discussed in Chapter 5 that the state of the electron which has $j = 1/2$ is one of the two states $|+\text{S}\rangle$, $|-\text{S}\rangle$ with respect to the normalized operator $\hat{\mathbf{L}}_z$ and the $|+\text{S}\rangle$ state $|+\text{S}\rangle$ corresponds to $\hat{\mathbf{L}}_z = \hbar/2$ up to an amplitude. In both cases the $|+\text{S}\rangle$ state will be $|\psi_{+}\rangle$ with respect to the $\hat{\mathbf{L}}_z$ operator in space. There are three such amplitudes $|\psi_{+}\rangle$ which make up the projection matrix. In Section 10.4 we gave the form of this matrix for various orientations of $\hat{\mathbf{L}}$ with respect to $\hat{\mathbf{L}}_z$. Now we will see why, how and they can be derived.

In the hydrogen atom we have found a spin-one system which is made up of two spin-one-half particles. We have already worked out in Chap. 10 how to transform a spin-one-half impurity. Now we use this information to calculate the transformation for both one. The easiest way is worse. We have a system of a hydrogen atom with the energy E_{H} which has spin $j = 1/2$. Suppose we want it enough to transform it. From 5. we see that we know it is in one of the basis states with respect to $\hat{\mathbf{L}}_z$, say $|+\text{S}\rangle$. There is one amplitude a which will be in one of the basis states $|+\text{S}\rangle$ with respect to the $\hat{\mathbf{L}}_z$ operator. If we use the system of the S operator in the $|+\text{S}\rangle$ orientation, the $|+\text{S}\rangle$ state is $|\psi_{+}\rangle$ which we have been calling the state $= +\text{S}$ —the S spin number one, back his head along the axis of $\hat{\mathbf{L}}_z$. He will be selecting his states to whatever will be the S spin number. His “up” are “down” states for S electron and proton would be different from ours. His “parallel” they—which we can write $|+\text{S}\rangle$ —differ in the “up” S sense, i.e. $|+\text{S}\rangle$ state of the spin one particle. What we want is $|+\text{S}\rangle$ which is just another way of writing the amplitude $(|+\text{S}\rangle - |-\text{S}\rangle)$.

*This section does not impress Chapter 10, so I skip this section also.
12.11

We could do the superposition $|+\rangle = |+\rangle + |-\rangle$ in the following way. In our frame, the electron (the $|+\rangle$) state has spin “up”, \uparrow . This means that it has some amplitude $\langle +|+\rangle$ of being “up” in the frame, and some amplitude $\langle +|-\rangle$ of being “down” in the frame. Similarly, the proton $= |\psi_1\rangle + |\psi_2\rangle$ has spin “up” in our frame and the components $= |\psi_1\rangle$, and $= |\psi_2\rangle$ have spin “up” or spin “down” in the “prime” frame. So, as we are talking about the total particle, the amplitudes of each particle will be “up” together in the frame, in the product of the two amplitudes:

$$\langle +|\psi\rangle = \langle +| +\rangle + \langle +| -\rangle = \rho^2. \quad (12.45)$$

You may put the subscripts a and b to the amplitudes $\langle +| \psi_a \rangle$ to make it clear what we were doing – that they are both individual amplitudes for a single final particle, so they are really independent of each other. They are, in fact, just the amplitudes we have calculated $\langle +| \psi_a \rangle$ in Chapter 8, and which we used in the figures at the end of this chapter.

Now, however, we are going to go into much more detail. We have to handle all possible products of amplitudes $\langle +| \psi_a \rangle$, for a spin-one-half particle from which we have also called $= |\psi\rangle$. It is a reasonable idea, if they are completely独立的, that there should be three coefficients, α , β , γ , for the overall amplitude, as well as two for each different $\langle +| \psi_a \rangle$ for the two one-half amplitudes. To help you keep things straight, we can make the new notation in Tab. 12.4. We will continue to use the definition $= |\psi\rangle = |\psi_1\rangle + |\psi_2\rangle$, just as for the standard spin-one-half particles.

With our new notation, Eq. (12.45) looks as simple

$$= \langle +|\psi\rangle = \alpha + \beta + \gamma,$$

and this is just the spin-one amplitude $= |\psi\rangle$. Now, it's apparent, for example, that the other two components of “down” are the β , γ “spin-down” amplitudes, β , γ just related with respect to the α axis by the angle θ ; then from Fig. 6-7

$$\alpha = \langle +| +\rangle = \rho^2 \cos \theta$$

So, from (12.4) we know that the symmetric amplitude is

$$\langle +|T_{+-}|S\rangle = \langle +| +\rangle \langle -| -\rangle = (\rho^2)^2 = \rho^4. \quad (12.46)$$

You can see how it goes.

Now we will work through the general case for all the states. If the proton in our frame had “up” in the frame, the Adjoint, the amplitudes that it must be in my frame (the two possibilities) in another frame (the T4 frame) are

$$\begin{aligned} & \langle +| +\rangle + \langle +| -\rangle = (\rho^2 + \rho^2 \sin^2 \theta) \langle +| +\rangle = \rho^2, \\ & \langle +| +\rangle + \langle -| +\rangle = \langle +| -\rangle = \rho^2 \langle -| -\rangle, \quad \text{etc.} \\ & \langle +| +\rangle = \langle +| -\rangle = \langle -| +\rangle = \langle -| -\rangle = \rho^2, \\ & \langle +| +\rangle = \langle -| -\rangle = \langle +| -\rangle + \langle -| +\rangle = \rho^2. \end{aligned} \quad (12.47)$$

We can, then, write the state $= |\psi\rangle$ as the following linear combination:

$$|+\rangle = \rho^2 |+\rangle + \beta |+\rangle - \gamma |+\rangle + \gamma |-\rangle + \beta |-\rangle - \rho^2 |-\rangle. \quad (12.48)$$

Now we notice that $= |\psi\rangle$ is the state $= |\psi\rangle$ that $= |\psi\rangle = |\psi\rangle$ is just $\sqrt{2}$ times the state $= |\psi\rangle$ (see (12.4)) and that $= |\psi\rangle = |\psi\rangle$. In other words, Eq. (12.48) can be rewritten as

$$|+\psi\rangle = \rho^2 |+\rangle + \sqrt{2} \beta |\psi\rangle + \sqrt{2} \gamma |-\rangle. \quad (12.49)$$

In a similar way we can easily show that

$$|\psi\rangle = \rho^2 |+\rangle + \sqrt{2} \alpha |\psi\rangle + \sqrt{2} \beta |-\rangle. \quad (12.50)$$

Table 12.4

Spin-one-half amplitudes

One-chopper	Composite
$\alpha = \langle + +\rangle$	$= T_{+-} S\rangle$
$\beta = \langle + -\rangle$	$= T_{+-} S\rangle$
$\gamma = \langle - +\rangle$	$= T_{+-} S\rangle$
$\delta = \langle - -\rangle$	$= T_{+-} S\rangle$

for $|+\rangle$ it's a little more complicated, but we

$$|+\rangle_S = \frac{1}{\sqrt{2}}(|+\rangle_1 + |-\rangle_1)$$

But we can express each of the states $|+\rangle_1$, $|\pm\rangle_1$, and $|-\rangle_1$ in terms of the "naïve" states and take the sum. That is,

$$|+\rangle_1 = \omega(|+\rangle^+ - i|\mp\rangle) \quad \text{and} \quad |\pm\rangle_1 = \Re(\omega^{-1} + i\Im(\omega^{-1})) \quad (12.30)$$

and

$$|-\rangle_1 = \omega(|-\rangle^+ - i|\mp\rangle) \quad \text{and} \quad |+\rangle_1 = \Re(\omega^{-1} + i\Im(\omega^{-1})) \quad (12.31)$$

Taking (12.28) times the sum, we get

$$\langle 0|S_1 = \frac{2}{\sqrt{2}}\omega(\omega_1 + \omega_2 - \frac{\omega_1 + i\omega_2}{\sqrt{2}})(|+\rangle^+ - i|\mp\rangle) + \frac{2}{\sqrt{2}}\omega(\omega_1 - \omega_2)$$

It follows that

$$\langle 0|S_1 = \sqrt{2}\omega(\omega_1 + \omega_2 - \omega_1^2 + \omega_2^2) + \sqrt{2}\omega(\omega_1 - \omega_2) \quad (12.32)$$

We have now all of the spin-coordinates wanted. The coefficients of Eqs. (12.28), (12.30), and (12.31) are the matrix elements $\langle Q^a | S_b | 0 \rangle$. Let's put them all together.

$$\langle Q^a | S_b | 0 \rangle = \begin{pmatrix} \omega_1^2 & \omega\sqrt{\omega_1\omega_2} & \omega^2 \\ \sqrt{2}\omega_1 & \omega_1^2 + \omega_2^2 & \sqrt{2}\omega\omega_2 \\ \omega_2^2 & \sqrt{2}\omega\omega_1 & \omega^2 \end{pmatrix} \quad (12.33)$$

We have expressed the spin- a transformation in terms of the spin- b coordinates a , b , c , and d .

The last piece of this S matrix is nothing with respect to b by the angle α , since the result is α . Fig. 5.5. The amplitudes in Table 12.1 are just the matrix elements of $S_a(b)$ in Table 6.2.

$$\begin{aligned} a &= 60^\circ \frac{\pi}{3}, & b &= -60^\circ \frac{\pi}{3}, \\ c &= 30^\circ \frac{\pi}{3}, & d &= -60^\circ \frac{\pi}{3}. \end{aligned} \quad (12.34)$$

Using these in (12.33), we get the form of (12.35), which we give there without proof.

What ever happened to the state $|1222\rangle$? Well, it's a spin-zero system, so it has only one character in the name of all coordinate systems. We can check that everything works out by taking the difference of Eq. (12.30) and (12.31); we get that

$$|+\rangle_1 - |-\rangle_1 = |+\rangle^+ - i|\mp\rangle = (\omega_1^2 - \omega_2^2)|+\rangle + (\omega_1 - \omega_2)|-\rangle.$$

But this is $\omega\omega_1$, the determinant of the spin matrix from (12.28), and so is equal to 1. We see then

$$|\langle 0|S_1 | 1222 \rangle| = |\langle 0|S_1 | 0 \rangle|$$

so the relative orientation of the two coordinate frames.

Propagation in a Crystal Lattice

13-1 States for an Electron in a one-dimensional lattice

You will at first sight think that a low-energy electron would have great difficulty passing through a solid crystal. The atoms are packed together with their outer shells a few angstroms apart, and the distance outside of the outer shell electrons is hardly an angstrom or so. That is, the electrons being bound to their spring, so that you would expect the mean free path between collisions to be of the order of a few angstroms which is practically nothing. You could expect the electron to bump into one atom or another almost immediately. Nevertheless, it is a surprising phenomenon of course that if the lattice is perfect, the electrons are able to travel through. The crystal atoms are easily disturbed; they are in a way like this string which lets me demonstrate electricity so easily; it was also important the development of many practical devices. It is also rather nice that it is possible to manufacture to imitate the lattice also. In a radio tube electrons move freely through a vacuum while in the anode they move freely through a coaxed lattice. The machinery behind the lattice is transistor will be described in this chapter. One day we will describe the application of these principles in various electronic devices.

The conduction of electrons in a crystal is one example of a very common phenomenon. Not only do electrons travel through crystals, but other "things" like current carriers can also travel in a solid medium. So the phenomenon which we are studying appears in many ways in the study of the physics of the solid state.

You will remember that we have discussed many and a lot of discrete vibrations. Let's now think of an electron which can be in either one of two positions in each of which it is in the same kind of environment. Let's also suppose that there is a certain amplitude to go from one position to the other, and of course the same amplitude to go back just as we have discussed for the hydrogen molecule in Section 10-1. The laws of quantum mechanics then give the coupling condition. There are two possible states of definite energy for the electron. But it can be described by the amplitude for the electron to be in each of the two basis functions. In either of the definite-energy states, the magnitudes of these two amplitudes are conserved in time, and the forces vary in time with the same frequency. On the other hand, if we start the electron in a given form, it will have been mixed to another, and so on, so having back again to the first position. This amplitude is analogous to the motion of two coupled pendulums.

Now consider a perfect crystal lattice in which we imagine that an electron can be in one of a kind of "sites" in a regular pattern and with some potential energy. Suppose also that the electron has some amplitude to move into a different potential of the nearby atoms. It's something like the two-sites system, but with an additional complication. When he starts on a site in the neighborhood, he can afterward move on to the nearest position as well as return to his starting point. Now we have a situation analogous not to two coupled pendulums, but to an infinite number of pendulums all coupled together. It's something like what you see in one of those machines—made with a long row of tops mounted on a central wire—that is used in first year physics to demonstrate wave propagation.

If you take a common needle which is coupled to another harmonic oscillator and that one has some initial phase, and if you start in regularity in one place, the regularity will propagate as a wave along the line. The same situation occurs if you place random atoms in one of a long chain of atoms.

13-5 Other states in a lattice

13-6 Scattering by imperfections in the lattice

13-7 Trapping by a lattice imperfection

13-8 Scattering amplitude and bound states

Usually the simplest way of analyzing the technical problem is not to think in terms of what happens if a particle is started at a certain place, but rather in terms of steady-state solutions. There exist certain solutions which propagate through the crystal as a wave of a single fixed frequency. Now the same thing happens with the electron—and for the same reason, because it's described in quantum mechanics by similar equations.

You can appreciate one thing, however. The conditions for the electron to leak a place is unambiguous, not a probability. If the electron were simply falling from one place to another, like water going through a hole, the behavior would be completely different. For example, if we had two levels of state connected by a tube, a general state leakage from one to the other, even the levels would approach each other exponentially. But for the electron, what happens is a definite leakage and not just a plain probability leakage. And it's a characteristic of the quantum theory that it is the differential equation that quantizes the theory—which changes the differential equation to an oscilloscope screen. What happens then is quite different from the leakage between interconnected tanks.

We want now to analyze quantitatively the quantum mechanical situation. Imagine a one-dimensional system made of a long line of atoms as shown in Fig. 13-1(a). (A crystal is of course three-dimensional but the picture is very much the same; just you understand the three-dimensional case; you will be able to understand what happens in three dimensions.) Next, we want to see what happens if we put a single electron on this line of atoms. Of course, in a real crystal there are already millions of electrons. But some of them probably fall far off in insulating crystals, take up positions in some part of the crystal which are bound and everything is quite stationary. However, we are going to this account what happens if we put one extra electron in. We will not consider what the other electrons are doing because we're going to change their motion very little by the addition of energy. We are going to add an electron to 2 to produce one energy bound negative ion. In addition, we'll use extension to 3 to make an approximation which corresponds approximately to the inside workings of the atom.

What does the electron want then to do in another atom, instead of the negative ion it's in its place? We will suppose that just as in the case of an electron jumping between two atoms, the electron can jump from one atom to the neighbor on either side with a certain amplitude.

Now how do we do the nuclei system? What will be reasonably reasonable? If you remember what we did when we had only two possible positions, you can guess how it will go. Suppose that we can put of 2, so the vacancies are all equal, and that we number the atoms in sequence, as shown in Fig. 13-1(b). One of the possibilities is that the electron is at atom number 6, another possibility is that the electron is at atom number 7, or at atom number 8, and so on. We can describe the electron state by saying that the electron is at atom number 6. Let's say that this is the wave state $|6\rangle$. Figure 13-1 shows what we mean by the three basic states

$$|0\rangle = |1\rangle, \quad |5\rangle, \quad \text{and} \quad |4 + 6\rangle.$$

Using these base states, any state $|\psi\rangle$ of our one-dimensional crystal can be described by adding all the amplitude $a_i |\psi\rangle$'s. If the state $|\psi\rangle$ is in one of the two states—which means the amplitude a_i is located at the particular atom. Then we can write the state $|\psi\rangle$ as a superposition of the base states

$$|\psi\rangle = \sum_i a_i |\psi_i\rangle. \quad (13-1)$$

Now, we are going to suppose that when the electron is at one atom, there is some amplitude that it can leak to the atom on either side. And we'll take the simplest case for which it can only leak to the nearest neighbors. Imagine the two nearest neighbors, it has to go in two steps. Well, then if the amplitude for the electron just move next door to the next is a_1 open that means

For the moment we would like to write the amplitude ψ (4) to be on the electron as C_n . Then Eq. (13.1) will be written

$$\psi = \sum_n e^{iE_n t} C_n. \quad (13.2)$$

If we know each of the amplitudes C_n at a given moment, we could take their absolute squares and get the probability that you would find the electron if you looked it up at that time.

Now on the successive readouts from time t by analogy with the parallel system we have studied, we would propose (i.e. the Hamiltonian equations) that the system should be made of equations like this:

$$i\hbar \frac{dC_n(t)}{dt} = E_n C_n(t) - AC_{n-1}(t) - AC_{n+1}(t). \quad (13.3)$$

The last coefficient on the right, A , is, physically, the energy the electron would have if it wouldn't leak away from one of the atoms. (It doesn't matter what we call E_F , as we have seen many times, it represents really nothing but a choice of the zero of energy.) The next term represents the amplitude per unit time that the electron is leaking into the next position (i.e. $n+1$) atom; and the final term is the amplitude for leaking from the $(n-1)$ st atom. As usual, we'll ignore this as a constant (independent of t).

For a full description of the behavior of any state $|n\rangle$, we would have one equation like (13.3) for every one of the amplitudes C_n . But if we want to consider a crystal with a very large number of atoms, we'll assume that there are an indefinitely large number of states (that the atom is going forever in both directions). (For the first case we will have to pay special attention to the exponential terms); if the number N of our wavefunctions is indefinitely large, then obviously the Hamiltonian equations are infinite in number. We'll write down just a sample:

$$\begin{aligned} i\hbar \frac{dC_0}{dt} &= E_0 C_0 - AC_{-1} - AC_1, \\ i\hbar \frac{dC_1}{dt} &= E_1 C_1 - AC_{0,-1} - AC_{2,+1}, \\ i\hbar \frac{dC_2}{dt} &= E_2 C_2 - AC_{1,-1} - AC_{3,+1}. \end{aligned} \quad (13.4)$$

12.2 States of definite charge

We can't say many things about an electron in a lattice but first let's try to find the states of definite energy. As we have seen in earlier chapters this means that we have to find a situation in which the amplitudes all of large at the same frequency if they change at all. We look for such kinds of functions:

$$C_n = c_n e^{-E_n t}. \quad (13.5)$$

The complex numbers c_n will be then the non-time-varying part of the amplitude for the electron in the n th atom. If we put this last solution into the equations (13.4) to test them out, we get the result:

$$c_{n+1} - c_n c_n = -Ac_{n+1} - Ac_{n-1}. \quad (13.6)$$

We have 2.1 infinite number of such equations for the infinite number of unknowns c_n , which is rather gratifying.

All we have to do is take the determinant... but wait! Determinants are the ones that are 2, 3, or n equations. But if there are a lot more than n equations and less than n unknowns, the determinant is not so very meaningful. Well, before you try to prove the equations directly, there are 3 ways to do this:

Similarly, we'll see that the variation is ω_{n+1} if the atom ($n+1$) is at x_{n+1} . If our starting energy is $E_0 = \hbar\omega_0$, we will have that $\omega_{n+1} = \omega_0 + \delta$. By choosing our δ big at about 25%, we can expect now that $\omega_n = \hbar\omega$. We can rewrite Eq. (13.3) to

$$C_n = \alpha(x_n)e^{-iE_n t}, \quad (13.7)$$

and Eq. (13.6) would become

$$\dot{E}_0(x_0) = E_0(x_{n-1}) - i\partial(x_{n-1}) \approx i\partial(x_{n-1}). \quad (13.8)$$

Or, using the fact that $x_0 = \dots = x_n = b$, we might also write

$$\dot{E}_0(x_0) = E_0(x_0) - i\partial(x_0 + \delta) \approx i\partial(x_0 + \delta). \quad (13.9)$$

This equation is somewhat similar to a differential equation. It tells us the ω quantity, $i\partial(x)$, at one point, (x_0) , is related to the same physical quantity at next neighbor inputs, $(x_0 + \delta)$. (A differential equation relates the value of a function at a point to the values at infinitesimally nearby points.) Perhaps, the methods we usually use for solving differential equations will also work here. Let's try.

Linear differential equations with constant coefficients can always be solved in terms of exponential functions. We can try the same thing here to get a CR solution:

$$i\partial(x) = e^{i\omega x}. \quad (13.10)$$

Then Eq. (13.9) becomes

$$E_0e^{i\omega x} = E_0e^{i\omega x} - i\partial e^{i\omega x} \approx -i\partial e^{i\omega x}. \quad (13.11)$$

We can now divide out the common factor $e^{i\omega x}$; we get

$$E_0 - E_0 = i\partial e^{i\omega x} = ie^{i\omega x}. \quad (13.12)$$

The last two terms are just equal to (3.1) or (3.9), so

$$E_0 - E_0 = 2ie^{i\omega x}/\hbar. \quad (13.13)$$

We have found that for any value of ω (or the constant \hbar) there is a solution whose energy is given by this equation. There are various possible constant energy inputs, and each corresponds to a different solution. There are an infinite number of solutions. This is not surprising, since we started our orbit in the middle of base states.

Let's see what these solutions look like. For each ω , the ψ 's are given by Eq. (13.10). The amplitudes C_n are then given by

$$C_n = e^{i\omega x_n} e^{-iE_n t}. \quad (13.14)$$

Since you should remember that the energy E also depends on ω as given in Eq. (13.13), the space dependence of the amplitude is $e^{i\omega x}$. The ω dependence is $e^{-iE_n t}$, which is zero when t is even or the rest.

We might note, in space, the amplitude goes as a complex oscillation—the wavelength is the same at every atom, but the phase at a given site is chosen by its ω and t (odd). You can see this in the next. We can visualize what's going on by placing a vertical line to show just the real part at each atom as we have done in Fig. 13.2. The envelope of these vertical line functions is the broken line called

$I_{\text{Re}(\psi)}$

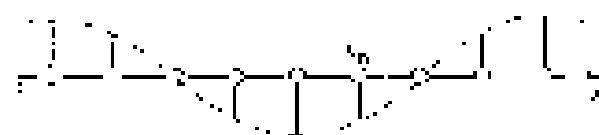

Fig. 13.2. Variation of the real part $\psi(x)$ with x .

is, of course, a cosine curve. The imaginary part of the Naderman oscillating function, however, is shifted 90° in phase so that the absolute square value is the sum of the squares of the real and imaginary parts; this is the state for \pm the C's.

Thus if we pass $\pm k$, we get a stationary state of a particle of energy E . And in any such state, the electron is equally likely to be found at every atom, since there is no preference for location, or the other. Only the phase is different for different atoms. Also, we can pass on the particle wave. From Eq. (13.14) the real and imaginary parts propagate along the crystal as waves—namely, as the real or imaginary parts of

$$\psi(x, t) = e^{iE_0 t} \psi_0(x) \quad (13.25)$$

The wave can travel toward $x < 0$ like a negative k depending on the sign we have picked for k .

Notice that we have been assuming that the number k that we put in our trial solution, Eq. (13.13), was a real number. We can see now why this must be so if we have an infinite line of atoms. Suppose that k were an imaginary number, say iK . Then the amplitude ψ_0 would grow as e^{iKx} , which means that the amplitude would get larger and larger as we go toward large x 's—or toward large negative x 's if K is a negative number. This kind of solution would be O.K. if we were dealing with one or a few atoms, but quickly it would be a physical solution for an infinite chain of atoms. It would give infinite amplitudes—and, therefore, infinite probabilities—which isn't agreement with situation. Later on we will see an example in which the ψ gives it does not do so.

The relation between the energy E and the wave number k is given in Eq. (13.14) & plotted in Fig. 13-3. As you can see from the figure, the energy can go down ($E_1 = -2\pi/\lambda$) & up ($E_2 = 0$) in $(x_0 + \lambda/2)$ at $k = \pi/\lambda$. The graph is plotted for positive k ; if k were negative, the curve would simply be inverted, but the range would be the same. The significant result is that any energy is possible within a certain range or "band" of energies, but no others. According to our assumptions, if an electron in a crystal is in a stationary state, it can have an energy E lower than values in this band.

According to Eq. (13.10), the condition E is not imposed to two-energy states E in (8), (24). As k increases in magnitude (toward either positive or negative k values) the energy at first increases, but then reaches a minimum at $k = -\pi/\lambda$, as shown in Fig. 13-4. For k 's larger than π/λ , the energy would start to increase again. But we do not really need to consider such values of k , because they do not give new states. One just repeat states we already have for smaller k . We can see that in the following way. Consider the lowest energy state for which $k = 0$. The coefficient $a_{k=0}$ is the same for all x_0 . Now we could get the same energy for $k = 2\pi/\lambda$. But then, using Eq. (13.10), we note that

$$a(4,0) = e^{iE_0 x_0},$$

However, taking x_0 to be at the origin, we consider $x_0 = \text{any multiple of } \lambda$, because

$$a(4,0) = e^{iE_0 x_0} = 1$$

The state described by these $a_{k=0}$'s is precisely the same state we got for $k = 0$. It does not represent a different solution.

As another example, suppose that k were real. The real part of $a_{k=0}$ would vary as shown by curve 1 in Fig. 13-4. If k were even times larger ($k = 2\pi/\lambda$), the real part of $a_{k=0}$ would vary as shown by curve 2 in the figure. (The complete

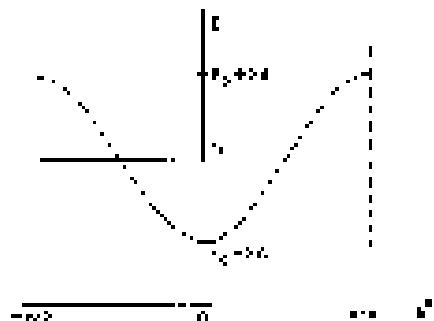

Fig. 13-3. The energy of the stationary wave as a function of the parameter k .

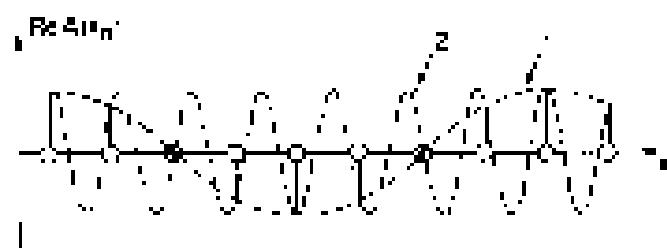

Fig. 13-4. Two values of k which represent the same physical situation, curve 1 is for $k = \pi/\lambda$, curve 2 is for $k = 2\pi/\lambda$.

possible curves don't start anything of course, all that makes ψ the values of the constants. This means we just want to know the energy E_{final} (just). You should note values of E_{final} become symmetric around the E_{initial} 's.

The conclusion that we have an ψ produce what amounts to a problem of calculating E_{final} in a certain limited range. It's not the range between $-E_{\text{initial}}$ and $+E_{\text{initial}}$ —the one shown in Fig. 13-3. In this range, the energy of the stationary states increases linearly with the amplitude L in magnitude of ψ .

One side remark when you're doing your own play with ψ —Suppose that the electron cannot only jump to the nearest neighbor wave amplitude value, but also has the possibility to jump to the next next neighbor with some other amplitudes E_{final} . You will find that the solution of ψ again has written in the form $\psi = \psi_0 + \psi_1 + \psi_2 + \dots$ type of solution, only more complex. You will also find that the stationary states with wave number k have an energy equal to $(E_k - E_{\text{initial}})$ (Prob. 13-1). The solution for the value of the constant E_{final} is no longer unique, it depends upon the particular description of the problem. It is not necessarily the case where E_{final} is not necessarily the same about some individual line. It is true, however, that the new always appears "on" themselves, the interval from $-E_{\text{initial}}$ to $+E_{\text{initial}}$ you never need to worry about other values of ψ .

Let's look a little more closely at what happens for small L , that is when the amplitude of the amplitude from our ψ is the first approximation. Suppose we increase our sum of energies by decreasing E_{initial} . But that is the situation of Fig. 13-2 up to the zero of energy. But just enough, we can write the

$$E_{\text{final}} \approx E_{\text{initial}} + L^2/2,$$

and the energy in Eq. (13-1) becomes

$$E = E_{\text{initial}} + L^2/2. \quad (13-6)$$

We have then the energy of the state is proportional to the square of the wave vector which describes the spatial character of the amplitude L .

13-3 Time-dependent states

In this section we would like to discuss the properties of states in the one-dimensional lattice in more detail. If the amplitude for an electron to be at x is C_x , the probability of finding it there is $|C_x|^2$. For the elementary state described by Eq. (13-1) this probability is very close to 1, and does not change with time. Now let us represent a situation which we would consider as unstable by taking an electron in a binding energy E_0 and then in a certain system ω then it is much likely to be found in one place longer or some other place. We can do that by making a superposition of several solutions like Eq. (13-12) with slightly different values of L and therefore of slightly different energies. Even if $L = 0$ at least the amplitude C_0 will vary with position because of the interference between the various terms, just as the probabilities where there is a mixture of waves of different wave lengths was discussed in Chapter 4E. Very likely some wave mode will have a minimum wave number k_0 , and with various k between this wave number, k_0 is a wave number of stationary states, the amplitudes with different k 's will represent states of slightly different energies, and, the others, of slightly different frequencies. Let's take for convenience of the initial C_0 with the same phase as with $k = k_0$ and $k = k_0 + 1$ (that is, two of them). As we have seen in the writing of column 1, the peaks of the peaks [the peaks where $C(k)$ is largest] will move along in a zig-zag pattern, associated with the quant we have called the "pinning centers." We found that this group of peaks moves with the wave speed c with frequency

$$\omega_{\text{peak}} = \frac{\Delta E}{\hbar}. \quad (13-7)$$

⁴ Provided we do not try to make the period too long.

The same series for would apply equally well here. An electron's energy is a "hump" number one less than for ψ_0 , varying in space just the way ψ_0 does. Fig. 13-5 will show the one-dimensional "transition" with the ψ_0 and ψ_1 in the Ψ , where $\Psi = \psi_0 + \psi_1$. Then if E_0 is for ψ_0 , we get for Ψ

$$\epsilon = \frac{2\pi^2}{\lambda} \psi_0. \quad (13.8)$$

In other words, the ψ_0 terms cancel except at spots where ψ_0 is the right ψ_0 . So since (13.6) tells us that the energy of such an electron is proportional to the square of its velocity, it now looks like a classical particle. So long as we look at things on a scale going enough that we don't see the hump effect, our quantum mechanical picture begins to give results like classical physics. In fact, if we solve Eq. (13.4) by for λ and substitute into (13.6) we can write

$$E = \frac{h^2}{2m} k^2, \quad (13.9)$$

which is equivalent to the extra "kinetic energy" of the electron in a pocket depends on the value k just as for a classical particle. The constant m will be the "effective mass" as given by

$$m^* = \frac{h^2}{2E_0}. \quad (13.10)$$

Also notice that we can write

$$m^* c^2 = E_0. \quad (13.11)$$

If we choose to call m^* the "momentum," it is consistent with our notation, although in the way we have described earlier for a free particle.

Our thought experiment has nothing to do with the real mass of an electron. Energy is quite little time, and the light in real crystals doesn't keep up so long, probably the same order of magnitude, about 1 to 20 times the free space mass of an electron.

We have now established a remarkable property—how an electron in a crystal (or an electron in a vacuum) can move like light through the crystal and flow perfectly freely over the crystal lattice in all the directions. It does so by forming an n -dimensional grid of points in the x -directions x_1, x_2, \dots, x_n , where n is the dimension of the crystal. That is how a solid can conduct electricity.

13-4 An electron in a three-dimensional lattice

Let's look for a moment at how we could apply this same idea to see what happens to an electron in three dimensions. The results turn out to be very similar. Suppose we have a rectangular lattice of atoms with lattice constants a_1, a_2, a_3 in the three directions. (If you've seen a cubic lattice, take the face spacing $a_1 = a_2 = a_3$.) We suppose that the n -component of the wavefunction is ψ_{x_1, x_2, x_3} , where x_1, x_2, x_3 are in the x -directions (x_1, x_2, x_3) and ψ is zero in the x -direction (y_1, y_2, y_3) . Now how shall we describe the basis states? As in the one-dimensional case, the base state is that the electron is at the spot where $x_1 = x_2 = x_3 = 0$, when $\psi(x_1, x_2, x_3)$ is zero at the other points. Choose x_1 with $x_1 = 0$, then there should be a ψ ,

$$\psi = \psi_0, \quad \psi = \psi_1, \quad \psi_0 = 1, \quad \psi_1 = 0,$$

where $\psi_0, \psi_1, \psi_2, \dots$ are any three integers. Using x_1 and x_2 to indicate such points, we will take $x_1 = 0, 1, 2, \dots$ and $x_2 = 0, 1, 2, \dots$ and $x_3 = 0, 1, 2, \dots$ in the lattice points. Thus the base state is represented by the symbol "electron at x_1, x_2, x_3 " and the amplitude for an electron to come into $|1, 1, 1\rangle$ is this function $\psi(x_1, x_2, x_3) = \delta_{(x_1, x_2, x_3), (1, 1, 1)}$.

Fig. 13-5. The real part of $\psi(x)$ as a function of x for a superposition of several states of different energy. The spacing λ is very small on the scale of x shown.

As before, the amplitudes $C(x, y, z)$ may vary with time. With our assumptions, the Helmholtz equation should be like this:

$$\begin{aligned} i\hbar \frac{\partial C(x, y, z)}{\partial t} + E_x C(x, y, z) - A_x C(x + a_x, y, z) - A_x C(x - a_x, y, z) \\ - A_y C(x, y + a_y, z) - A_y C(x, y - a_y, z) \\ = \beta_x C(x, y, z - c) - \beta_x C(x, y, z + c). \quad (13.23) \end{aligned}$$

It looks rather long, but you can see where each term comes from.

Again we can try to find a solution $C(x, y, z)$ in which all the C 's have the same time dependence. Again, the solution is an exponential:

$$C(x, y, z) = e^{-iE_x t/\hbar} e^{ik_x x} e^{ik_y y} e^{ik_z z}. \quad (13.24)$$

If you substitute this into (13.23) you get stuck in worse, provided that the energy E is related to k_x , k_y and k_z in the following way:

$$E = E_0 + \Delta_x k_x a_x + \Delta_y k_y a_y + \Delta_z k_z a_z. \quad (13.25)$$

The total E now depends on the three wave numbers k_x , k_y , k_z , which, recall, are the components of a three-dimensional vector \mathbf{k} . In fact, we can write Eq. (13.25) in vector notation as

$$C(x, y, z) = e^{-iE t/\hbar} e^{i\mathbf{k}\cdot\mathbf{r}}. \quad (13.26)$$

The amplitude varies as a complex plane wave in three dimensions, moving in the direction of \mathbf{k} , and with the wave number $k = (k_x^2 + k_y^2 + k_z^2)^{1/2}$.

The energy associated with this stationary state depends on the three components of \mathbf{k} in the complicated way given in Eq. (13.25). The energy of the vector of E with \mathbf{k} depends on relative signs and magnitudes of A_x , A_y , A_z and β_x . These three numbers are all positive, and, if we are interested in \sin^2 values of k , the dependence is definitely circular.

Expanding the energies we did before to get Eq. (13.16) we can now get this:

$$E = E_{0,0,0} + A_x^2 k_x^2 + A_y^2 k_y^2 + A_z^2 k_z^2. \quad (13.27)$$

For a simple cubic lattice with lattice spacing a we expect that k_x and k_y and k_z would be equal—say $2\pi/a$ for k_x and k_y would be just

$$\begin{aligned} E &= E_{0,0,0} + A_x^2 k_x^2 + k_x^2 + k_x^2 \\ &= E_{0,0,0} + 4A_x^2 k_x^2. \quad (13.28) \end{aligned}$$

This is just like Eq. (13.16). Following the arguments laid down, we could then claim that an electron particle in three dimensions moves by superposing many states with nearly equal energies; also moves like a classical particle with some effective mass.

In a crystal with a lower symmetry, there will be no such symmetry effect so the size of the electron potential term is not symmetric; the three coefficients A_x , A_y and A_z are different. Then the "effective mass" of the electron localized in a small region depends on its direction of motion. It would, for instance, have a different inertia for motion in the x -direction than for motion in the y -direction. (The details of such a situation are consequences described in terms of an "effective mass tensor".)

13.6 Other states in a lattice

According to Eq. (13.24) the electron particles we have been calling now can have energies only in a certain "band" of energies which covers the energy range from the minimum energy

$$E_0 = 2(A_x + A_y + A_z)$$

$$E_1 = \lambda A_1 + A_2 = 4\lambda.$$

Other energies are possible, but they belong to a different class of electron states. For the states we have described, we imagine base states in which an electron is placed on one atom of the crystal in some extended state, say, the lowest energy state.

If you lose a e^- , in empty space, and add an electron to make an ion, the ion can be formed in many ways. The electron can gain enough energy to form the state of lowest energy, or it can go on to form one of another of many possible "excited states" which include with a definite probability all other energy levels. For example, let the energy E_1 be picked above corresponds to base states which are ions of the lowest possible energy. We could also imagine to have set of base states in which the electron is in the other ion in a different way—in one of the excited states of an ion—so that the energy E_1 is now quite a bit higher. As before there is now only one A_1 different from before so that the electron will jump from its excited state in one atom to the same excited state in a neighboring atom. The whole analysis goes as before, we find a band of possible energies centered at a higher energy. There can, in general, be many such bands each corresponding to a different level of excitation.

This is not the only possibility. There may be some amplitude that the electron jumps from one energy condition to another from another neighbor at the next atom. (This is called an interaction between bands.) The mathematical theory is more and more complicated as you take into account more and more neighbors and more and more coefficients for leakage between the possible states. The new ideas are however, however, the equations are set up much as we have done in our simple example.

We should remark that there is a much more elaborate side of the various calculations, such as the amplitude A_1 which appears in the theory. Generally they involve the breakdowns, so in actual cases we hardly know them at all. Only when these are determined, however, can we fully calculate the properties of a real situation.

There are other situations where the physics and mathematics are almost exactly like when we last found for an electron moving in a crystal, but in which the "object" and process is quite different. For instance, suppose that our original crystal is stable, but stable? Not a line of neutral atoms, even with a loosely bound extra electron. Then imagine that we are to remove one electron. Which atom has lost its electron? This is, of course, no important assumption, but the electron is mobile from the atom to atom. There will, in general, be some amplitude with that the electron at a neighboring atom, say the $i - 1$ atom, will jump to be the i leaving the $i - 1$ atom without a contradiction. This is the same as saying that there is an amplitude A for the "wandering electron" to jump from the $i - 1$ atom to the $i - 1$ atom. You can see that the equation ϕ_{i-1} is exactly the same, of course, the value of A need not be the same as we took before. Again we can get the same formulas for the energy levels, the "slopes" of probability which move through the crystal with the ϕ_i 's and ψ_i 's of Eq. (13.1), & the effectiveness, and so on. Only here the waves describe the behavior of the carrier electron. Think of it as called "carrier". That is just what a particle with a 25.00 ± 0.005 m^-1 . You can see that this wave will respond to little local changes. We'll have some more to say about such things in the next chapter.

As another example, we can think of a line of isolated atoms's some one of which has been put into an excited state—that is, with more than its normal ground-state energy. Let C_1 be the amplitude that the atom has the excitation. It can interact with a neighboring atom by leaking out to it and reenergy and returning to the ground state. Call the amplitude for this process λ . You can see that, at the same time, C_1 does something else, too. The C_1 's wave is called an exciton. It behaves like a normal "particle" moving from place to place carrying the excitation energy. Such motion might be involved in certain biological

processes such as vision, or photosynthesis. It has been guessed that the absorption of light in the retina involves an "exciton" which moves through some periodic structure such as the layers in the retina described in Chapter 18. Now, I want Fig. 18-10 to be accumulated at some speed, so that where the energy is used to induce a chemical reaction.

18-6 Straining from imperfections in the lattice

We want now to consider the case of a single electron in a crystal which is not perfect. Our earlier analysis says that perfect crystals have surface energy — that is, energy of a gliding atom through hexagonal close-packed, without friction. One of the most important things that can stop an electron from going on forever is an impurity or irregularity in the crystal. As an example, suppose that somewhere in the crystal there is an atom which is larger than average and has stronger gluons, or one of the gluons here so that things there are different from the other atoms/sites. Say, for example, E_0 is the amplitude it would be different. How would we describe what happens there?

To be specific, we will return to the one-dimensional case and we will assume that our number "zero" is an "impurity" atom and has a different value of E_0 , than any of the other atoms. Take call this energy $(E_0 - E_0)$. What happens? When an electron travels at about "zero" there is some probability that the electron is localized (localized). If a wave packet is moving along and it reaches a place where there is a "hole" or "lump", some of it will cut the wave and some of it will bounce back. It's quite difficult to analyze such a situation using a wave packet, because everything varies in time. It's much easier to work with periodic solutions. So we will work with stationary states, which we will find out. We make up of continuous waves which cover system left and infinite for x . In three dimensions we would call the reflected part the scattered wave, since it would spread out in various directions.

We start our work a set of equations which are just like the ones in Eq. (14-6) except that the constant term = 0 is different, or, in the rest. Use the equations for $a = -\lambda$, 0 , λ , -1 , 0 , 1 , and $-\lambda$ and take the limit:

$$\begin{aligned} E_{a=-\lambda} &= E_{\mu=-\lambda} - Aa_{-\lambda} - Aa_{+\lambda}, \\ E_{a=0} &= E_{\mu=0} = 4a_0 = Aa_{-\lambda}, \\ E_{a=\lambda} &= E_{\mu=\lambda} - Aa_{-\lambda} - Aa_{+\lambda}. \quad (18-8) \\ E_{a=-1} &= E_{\mu=-1} - Aa_{-\lambda} - Aa_{+\lambda}, \\ E_{a=1} &= E_{\mu=1} - Aa_{-\lambda} - Aa_{+\lambda}, \\ &\vdots \qquad \vdots \end{aligned}$$

There are, of course, all the extra equations for a if a is greater than λ . They will look just like Eq. (14-6).

For the general case, we really ought to use a different A for the amplitude that the electron jumps to a from down "zero", but the main features of what goes on will come out of a simplified example which all the A 's are equal.

Equation (18-8) would still work as a solution for all of the equations except the one for atom "zero". Is it right for that one equation? We need a different solution which we can cook up in the following way. Equation (14-6) represents a wave going in the positive x direction. A wave going in the negative x direction would have been an equally good solution. It would be written

$$\phi(x) = e^{-ikx}.$$

The most general solution we could have taken for Eq. (18-8) would be a combination

solution of a forward and a backward wave, namely

$$u_0 = \alpha e^{i k x} + \beta e^{-i k x}, \quad (11.39)$$

This solution represents a complex wave of amplitude α moving in the $+x$ direction and a wave of amplitude β moving in the $-x$ direction.

Now let's look at the set of equations for the new problem. The two in (11.28) together with three for all the other terms. The equations involving u_0 , v_0 , E_0 , ϕ_0 are satisfied by Eq. (11.29) with the condition that β is related to β_0 and the incident spacing h by

$$\beta = E_0 - i k \cos \theta h. \quad (11.40)$$

The physical meaning is an "incident" wave of amplitude α approaching from the left ("extinct" from the left), and a "reflected" wave of amplitude β going back toward the left. We do not care how β behaves if we set the amplitude α of the incident wave equal to 1. Then the amplitude β is, in general, a complex number.

We can see all the same things about the solutions of u_0 for $v \geq 1$. The coefficients α and β are different so we would have for here

$$u_0 = \alpha e^{i k x} - \beta e^{-i k x}, \quad \text{for } v \geq 1. \quad (11.41)$$

From $v > 1$ the amplitude of u_0 wave going to the right and a wave coming from the right, we were to consider the physical situation in which a wave is originally started only from the left, and there is only a "transmitted" wave that continues beyond its source in a pulse form. We will try for a solution in which $\beta = 0$. We can certainly satisfy all of the equations for the u_0 except for the middle three of (11.28) by the following two solutions

$$\begin{aligned} u_0(\text{for } v < 0) &= \alpha e^{i k x} + \beta e^{-i k x}, \\ u_0(\text{for } v > 0) &= -\beta e^{-i k x}. \end{aligned} \quad (11.42)$$

The situation we are setting up is illustrated in Fig. 11-5.

By using the formulae in Eq. (11.22) for $\alpha_{1,0}$ and $\alpha_{0,1}$, the three middle equations of (11.28) will allow us to solve for α and β for the two conditions given. So we have to add a complex solution. Setting $v = 1$ we have found for these solutions

$$\begin{aligned} (\alpha - \beta_0)(e^{i k x} - \beta_0 e^{-i k x}) &= -4(\alpha_1 - \alpha_0 e^{-i k x} - \beta_0 e^{-i k x}), \\ (S - E_0 - i k h) &= -4k^2 e^{i k x} - \beta^2 e^{-i k x} - \beta_0^2 e^{-i k x}, \quad (11.43) \\ (E_0 - S) \alpha e^{i k x} &= -4(\alpha_0 e^{-i k x} - \beta_0). \end{aligned}$$

Remember that S is given in terms of V by Eq. (11.30). If you substitute this value for S into the equations, and remember that $\cos^2 \theta = \frac{1}{2}(e^{i k x} + e^{-i k x})$, you get from the first equation that

$$\alpha e^{i k x} + \beta e^{-i k x} = 0, \quad (11.44)$$

and from the third equation (11.28)

$$\alpha_0 e^{-i k x} = 0. \quad (11.45)$$

These are consistent only if

$$\gamma = 1 - \beta. \quad (11.46)$$

This says that the reflected wave β is just the original incident wave (11.39) with an added wave γ equal to the reflected wave. This is not always true, but happens to be true for a particle impact one atom long. If the ϵ were a lamp of impunity γ and the ϵ were added to the forward wave would not necessarily be the same as the reflected wave.

SCATTERED WAVE

$\theta = 0$	$\theta = \pi/2$	$\theta = \pi$
α_0	$\alpha_{0,1}$	$\alpha_{1,0}$

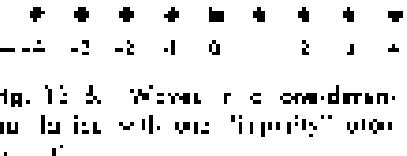

Fig. 11-5. Waves in a one-dimensional barrier with one "impurity" atom ϵ .

We can get the amplitude α of the reflected wave from the middle equation of Eq. (13.33); we find that

$$\alpha = \gamma \frac{-1}{2.0 \sin k_1} \quad (13.34)$$

We have the complete solution for both the wave function and the current.

You may be wondering how the transverse wave can be "brighter" than the incident wave as suggested in Fig. (13.34). Remember though, that β and γ are complex numbers and that the number of electrons (or holes, i.e., probability of finding a particle) in a wave is proportional to the absolute square of the amplitude β ; thus, there will be "transmission of that one" only if

$$|\beta|^2 + |\alpha|^2 = 1. \quad (13.35)$$

You can show that this is true for our solution.

13-7 Trapping by a lattice impurity

There is another interesting situation that can arise if E is a very low number of the energy of the electron is lower at the impurity atom for $k = 0$ than it is anywhere else in the electron gas in the rest of the system. That is, if $E_0 + E_1$ is below the bottom of the band ($E_0 = 0$), then the electron will "trap" itself in a state with $k < k_0$. On such a solution cannot come out of what we have done so far. We cannot, however, if we permit the real solution we look in Eq. (13.15) to have an imaginary number for k , for example, $k = A + iB$, we can have different solutions for $n < 0$ and $n > 0$. A possible solution for $n < 0$ might be

$$\psi_n \text{ for } n < 0 = e^{-kx} \quad (13.36)$$

We have to take a plus sign at the exponent, otherwise the amplitude would get indefinitely large for large negative values of x . Similarly, a possible solution for $n > 0$ might be

$$\psi_n \text{ for } n > 0 = e^{kx} \quad (13.37)$$

If we put these trial solutions into Eq. (13.28) all but the middle three are satisfied provided that

$$E_0 - E_1 = A(e^{k_0} + e^{-k_0}) \quad (13.38)$$

Since the sum of the two exponential terms is always greater than 2, the energy is below the Fermi level and is what we are looking for. Then solving these equations in Eq. (13.38) we find if $e = A$ and $k = B$ is chosen so that

$$A(e^{k_0} - e^{-k_0}) = -E_1 \quad (13.39)$$

Combining this equation with Eq. (13.15) we obtain the energy of the trapped electron, we get

$$E = E_1 - \sqrt{4k^2 + E_1} \quad (13.40)$$

The trapped electron has a binding energy—i.e., it is located below the conduction band.

Note that the amplitudes we have in Eqs. (13.39) and (13.40) do not say that the trapped electron has significant energy above. The probability of finding the electron or nearby atoms is given by the square of these amplitudes. The one particular choice of the parameters it might vary to show: in the k_0 graph of Fig. 13-2, the probability α goes to 0 for finding the electron in the impurity atom. The density denotes the probability that the electron will be far away from the impurity atom. This is another way of "localization" from the point of view of classical physics (the electron doesn't have enough energy to get away from the energy well of the trapping atom). In quantum mechanics it could look out in this way.

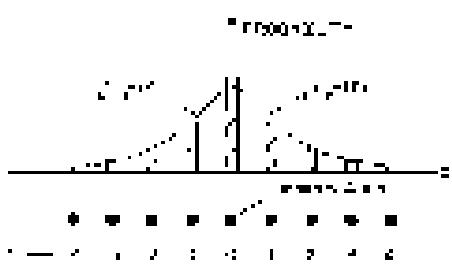

Fig. 13-7. The value of probability of finding a trapped electron at atoms sites near the trapping impurity atom.

13-8 Scattering amplitudes and bound states

Very often examples can be used to illustrate a point which is very useful in the study of the physics of high-energy particles. It has to do with a relationship between scattering amplitudes and bound states. Suppose we have determined strong experimental and theoretical reasons to say that pions can form protons. Then a new particle is discovered and someone wonders whether maybe it is just a combination of a pion and a proton held together in some bound state at $E = 0$? Energy in the way an electron is bound to a proton to make a hydrogen atom. But a bound state we need a combination which has a lower energy than the free propagator.

The π is a "good" theory which says that a bound state will occur if the energy E , where the scattering amplitude becomes infinite, extrapolated algebraically to the mathematical limit is "physically meaningful" to values of E outside of the permitted band.

The physical reason for this is as follows. A bound state is a situation in which there are only waves allowed to be a pion and there's no wave coming in or outgoing, angular momentum and the relative proportion between the so-called "incident" or external wave and the wave being "sent off" is definite. We can test this idea in our example. Let's write an expression Eq. (13.37) for the scattered amplitude directly in terms of the energy P of the particle being scattered from and to a bound state. Since Equation (13.30) can be rewritten as

$$(\Delta \sin \phi) = \sqrt{1/P^2 - (k - k_0)^2}$$

the scattered amplitude is

$$\delta = \frac{-i}{P + \sqrt{1/P^2 - (k_0 - k)^2}}. \quad (13.44)$$

For more satisfaction, this equation should be used only for real states—those with energies in the energy band, i.e., $E_0 < E < E_1$. But suppose we forget this fact and extend the formula into the "unphysical" energy regions where $|E - E_0| > 2.5$. For these unphysical regions we can write

$$\sqrt{1/P^2 - (k_0 - k)^2} = \sqrt{(E - E_0)^2 - 1/P^2}.$$

Then the "scattering" amplitude, whatever it may mean, is

$$\delta = \frac{i}{P - \sqrt{(E - E_0)^2 - 1/P^2}}. \quad (13.45)$$

Now we want to know by energy after which δ becomes infinite (i.e., for which the expression for δ has a "pole"). Yes, so long as E is negative, the denominator of Eq. (13.45) will be zero also

$$(E - E_0)^2 = 1/P^2 - P^2,$$

or when

$$E = E_0 + \sqrt{2 + P^2} = E_1.$$

Term minus sign gives just the energy we found in Eq. (13.43) for the trapped energy.

What about the plus sign? This gives an E larger than the allowed energy band. And, in fact there is another bound state there which we missed when we solved the equations of Eq. (13.25). We leave it as a puzzle for you to find the energy and amplitude δ for this bound state.

The relation between scattering and bound states provides one of the most useful clues in the current search for an understanding of the experimental observations above. The new strange Δ 's are

[†] The sign of the pole to be shown here is a technical point related to the allowed signs of ϵ in Eqs. (13.39) and (13.40). We won't go into it here.

Semiconductors

14.1 Electrons and holes in semiconductors

One of the most valuable contributions developed in recent years has been the application of solid-state electronics to medical diagnosis and electrical devices used in space vehicles. The study of semiconductors led to the discovery of their useful properties and to a large number of important applications. The field is changing so rapidly that what we tell you today may be obsolete next year. It will certainly be incomplete. And it is perfectly clear that with the enormous growth of these electronics many new and more powerful things will be possible as time goes on. You will no doubt continue and go deeper into the subject later in this volume, but you may find it interesting to see that at least something of what you are learning has some relation to the practical world.

There are many numbers of semiconductors. However, however, there are a few that now have the greatest technical importance. These are also the ones that have been studied, and our understanding of them is well advanced. An understanding of most of the others—the semiconductors of interest in this section use today are silicon and germanium. These elements crystallize in the same kind of face-centered cubic lattice as the atoms in the metal, but they bonding with their four nearest neighbors. They are insulators at very low temperatures—near absolute zero—but though they are poor conductors everywhere else, at room temperature. They are *semiconductors*; they are called *nonsolids*.

If we continue our examination of the crystal of silicon or germanium at which is at low temperature, we see no energy regions we expected in the last chapter. The electron will be able to wander around in the crystal, just as our electron did in the last. Actually, we have looked only at the nonconduction electrons in a rectangular lattice, but the situation would be somewhat different in the real lattice, classified as *isotropic*. All of the essential points are, however, shown by the results for the rectangular lattice.

As we saw in Chapter 13, free electrons can have energy only in discrete energy bands called the *conduction bands*. Within this band the energy is allowed to increase in steps of the period of the crystal lattice (see Fig. 13.24); but

$$E = E_0 - 2A_0 \cos k_x - 2A_0 \cos k_y - 2A_0 \cos k_z. \quad (14.1)$$

The A 's are the couplings between the x , y , and z directions, and k 's are the lattice spacing's in the directions.

For energy near the bottom of the band, we can approximate Eq. (14.1) by

$$E = E_{min} - A_0 k^2 + A_0 k^2 = E_0 - \omega^2, \quad (14.2)$$

(see Section 13.4).

Now think of electrons moving, in some particular direction, so that the crystal potentials of A are constant. The state $E_0 - \omega^2$ is the energy of the conduction electrons in the band as we have seen it. The minimum of the electron. We can write

$$E = E_{min} + \omega^2, \quad (14.3)$$

where ω is some constant, and we can take a graph of E versus k as in Fig. 14.1. We call such a graph an "energy diagram." An electron in a particular state of the xy - yz momentum k is indicated by a point such as S in the fig. 14.1.

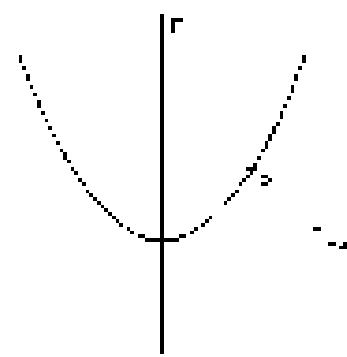

Fig. 14.1. The energy diagram for a lattice system with finite size.

As we also mentioned in Chapter 13, we can have a similar situation if we remove an electron from a neutral atom. The electron can jump over from a nearby atom and fill the hole, thus leaving another hole in the original atom. We can describe this behavior by writing an amplitude to find the hole in any particular atom, and by saying that the hole can jump from one atom to the next. (Clearly, the amplitudes χ that the hole jumps from atom a to the next b [clearly, the amplitudes χ that the hole jumps from atom a to atom b] is just the same as the amplitude that an electron from atom b jumps into the hole in atom a .) The mathematics is just the same [i.e., the form is the same]—electron, and we get again that the energy of the hole is related to its wave number by $E = \hbar c / \lambda$, just like Eq. (14.1) or (14.2), except, of course, with different numerical values for the constants \hbar , c , λ_0 , and A . The hole has an energy relative to the wave numbers of the probability amplitudes. Its energy lies in a discrete band, and near the bottom of the band it increases as its quantification with the wave number—in momentum—just as in Fig. 4-1. Following the arguments of Section 14-3, we would find that the hole also diffuses like a classical particle with a certain effective mass, except that in semiconductors the mass depends on the direction of motion. So the hole behaves like a positive particle moving through the crystal. The charge of the hole particle is positive, because it is caused by the absence of a negative electron; and other "holes" in your mind are temporarily electrons moving in the opposite direction.

If we put several electrons into a neutral crystal, they will move around much like the atoms of a low-pressure gas. If there are no terminals, their interactions will not be very important. If we then put an electric field across the crystal, the electrons will start to move and an electric current will flow. Eventually they would all be driven to one edge of the crystal, and, if there is a metal terminal there, they would be collected, leaving the crystal negative.

Similarly we could put many holes into a crystal. They would roam around at random unless there is an electric field. With a field they would flow toward the negative terminal, and would be "collected"—what actually happens is that they are annihilated by electrons from the metal terminal.

One can also form hole-holes and electrons together. If there are not too many, they will all go their way independently. With an electric field, they will contribute to the current. For convenience, electrons are called the majority carriers and the holes are called the minority carriers.

We have so far considered that electrons are put into the crystal from the outside, or are removed to make a hole. It is also possible to "create" an electron-hole pair by taking a free electron away from one atom's atom and putting it once more away in the same crystal. We then have a free electron and a free hole, and the two can interact, as we have described.

The energy required to put an electron into the S —we say to "create" the state S —is the energy E^+ shown in Fig. 14-2. It is some energy above E_{∞} . The energy required to "create" a hole in the state S is the energy E^- of Fig. 14-3, which is even energy greater than E_{∞}^+ . Now if we create a pair in the states S and S' , the energy required is just $E^+ + E^-$.

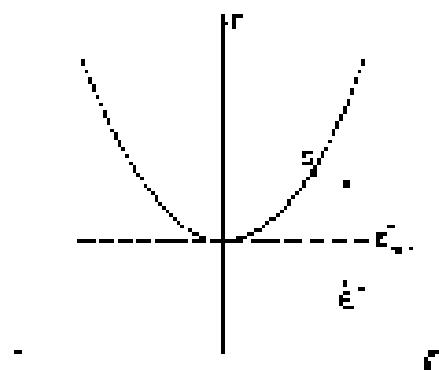

Fig. 14-2. The energy E^+ is required to "create" a free electron.

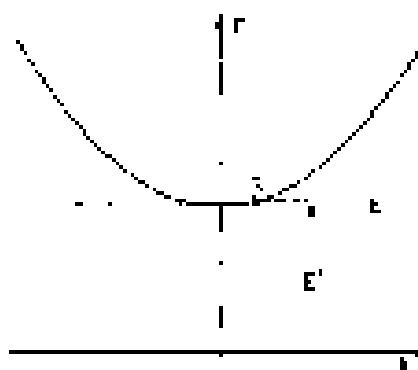

Fig. 14-3. The energy E^- is required to "create" a hole in the state S' .

The creation of pairs in a solid may proceed (as we will see later) so many people like to put Fig. 14-3 and Fig. 14-4 together on the same graph—with the hole energy plotted symmetrically about the zero of carrier energy. We have combined our two graphs in this way in Fig. 14-4. The advantage of this is that a graph of total energy $E_{\text{total}} = E + E'$ is simply a curve of a pair with the electron at S and the hole at S' to set the vertical distance between S and S' as shown in Fig. 14-4. The minimum energy required to break a pair is called the "gap energy" and is equal to $E_{\text{gap}} = E_S + E_{S'}$.

So, when you will see a similar diagram called an energy level diagram which is drawn when people are not interested in backscattering. Such a diagram is shown in Fig. 14-5—just showing the possible energies for the electrons and holes.¹⁴

How can electron-hole pairs be created? There are several ways. For example, photons of light (or x-rays) can be emitted and absorbed. If the photon energy is above the energy of the gap, the rate at which pairs are produced is proportional to the light intensity. If two electrodes are placed on a piece of the crystal and a "bias" voltage is applied, the electrons and holes will be drawn to the electrodes. The current increase is proportional to the intensity of the light. This mechanism is responsible for the phenomenon of photoconduction and the operation of photoconductive cells.

Electron-hole pairs can also be produced by high-energy particles. When a fast-moving charged particle, for instance, a proton or a positron with an energy of tens or hundreds of MeV goes through a crystal, its electric field will knock electrons out of their bound states creating electron-hole pairs. Such events occur hundreds of thousands of times per millimeter of track. After the passage of the particle, the carriers can be collected and measured as a "dissipation electrical pulse." This is the mechanism of "pulsed semiconductor counters" recently popular for experiments in nuclear physics. Such counters do not require semiconductors; they can also be made with crystalline materials. In fact, the best of such counters was made using a diamond crystal, which is at the same time transparent. Very pure crystals (such as diamond) allow holes and electrons to be lost to absorption as the charge carriers without being captured. The semiconductors silicon and germanium are useful because they can be purified with high purity in relatively large sizes (see, i.e., Sec. 14.10).

So far we have been concerned with semiconductors at temperatures near absolute zero. At any finite temperature there is still another mechanism by which electron-hole pairs can be created. The energy can be provided from the thermal energy of the crystal. The thermal energy is released as it transfers its energy to electrons going into "thermionium" emission.

The probability per unit time that the energy of charge is the gas energy E_{gas} will be concentrated around E_{gas} is proportional to $e^{-E_{\text{gas}}/kT}$, where T is the temperature and k is the Boltzmann constant (see Chapter 4), and E_{gas} is the appearance probability, but as the temperature rises there is an increasing probability of producing such pairs. At any finite temperature the generation should continue forever in a random way giving some real mean negative and positive charges. Of course that does not happen because over time the electrons and holes make fully full each state—the electrons drop into the lowest free-carrier energy available to the lattice. When that is the electron and hole "concentration," there is a certain probability per second that a hole meets an electron and the two things annihilate each other.

If the number of electrons per unit volume is N_e and the negative ionized and the density of positive carriers is N_h , the chance per unit time that an electron and a hole will find each other and annihilate is proportional to the product $N_e N_h$. Equilibrium is then found when the rate that pairs are created. You see that

¹⁴ In many books the same energy diagram is also placed in different ways. The carrier μ refers only to electrons. Instead of thinking of the energy of the hole, just think of the energy in case no hole has to be filled to hole. The energy is lower than the backscattered energy—in fact, just the inverse law, just you see in Fig. 14-5. With this interpretation of the energy scale, the gas energy is the minimum energy which must be given to an electron to move it from its bound state to the conduction band.

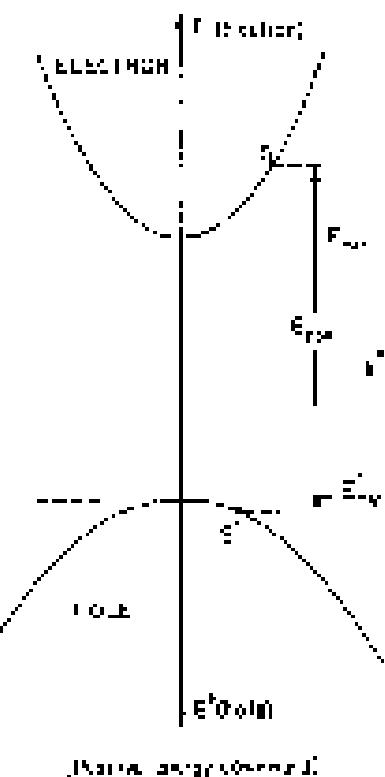

Fig. 14-4. Energy diagram for electron-hole pair creation.

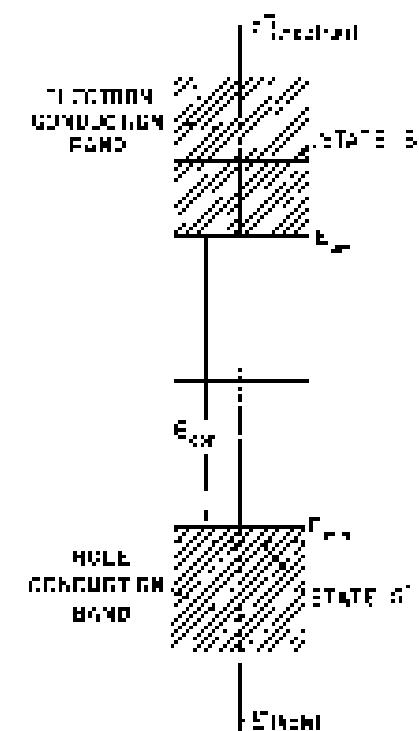

Fig. 14-5. Energy level diagram for electron and hole.

equilibrium the product, $N_e N_h$, should be given by some constant times the "Reitman factor":

$$N_e N_h = \text{constant} \cdot A e^{-E_g/RT}, \quad (14-4)$$

When we say constant, we mean nearly constant. A more complete theory would include more details about how holes and electrons ("fluid" with other) share the band. "Constant" is slightly dependent upon temperature, but the major dependence on temperature is in the exponential.

Let's consider, as an example, a pure material which is originally neutral. At a finite temperature you would expect the number of positive and negative carriers to be equal, $N_e = N_h$. Then each of them should vary with temperature as $e^{-E_g/RT}$. The variation of σ , any of the properties of a superconductor, is "constant" — for example — & mainly determined by the separation E_g between all the other factors very much more slowly with temperature. The gap energy for germanium is about 0.73 eV at the room temperature.

At room temperature (20°C) it is about $1/20$ of an electron volt. At these temperatures there are enough holes and electrons to give a significant conductivity, while at 4°K , 30°K , there is no room temperature. The conductor is then superconducting. The gap energy of germanium is in fact very small — ≈ 0.01 eV at the room temperature.

14-2 Impurity semiconductors

So far we have talked about two ways that electrons can be pulled in a heavily ideally perfect crystal lattice. One way was to let the electrons from an outside source. The other way, was to knock a bound electron out of a donor atom creating simultaneously an electron and a hole. It is possible to produce this in a the conduction band of a crystal in still another way. Suppose we imagine a crystal of germanium in which one of the germanium atoms is replaced by an arsenic atom. The germanium atom is a lone valence of four, the arsenic atom is controlled by the four valence electrons. As it is, in other words, has a valence of 5. It loses part of a single bond atom first at the germanium lattice because it has approximately the largest size, but in doing so it must be to a valence of 4 — using four of its valence electrons to form the crystal bonds and leaving one electron left over. This extra electron is very loosely attached — the binding energy is less than 1/10 of a volt. At room temperature the electron easily picks up sufficient energy from the thermal energy of the crystal, and then dissociates its own — moving away in the lattice as a free electron. An impurity atom such as the arsenic is called a donor site because it can give up a negative charge to the crystal. If it consists of just one atom it is a point source of charge, and instead of the entire face being active, the arsenic atom sites will be distributed throughout the crystal and the crystal will have a certain density of negative charge built in.

You might think that if a high voltage could be applied across the crystal, this will not happen, however, because the arsenic atoms in the body of the crystal will have a positive charge. If the body of the crystal is to remain neutral, the average density of negative ionization must increase in the vicinity of the arsenite. If you put two electrodes on the edges of such a crystal and connect them to a battery, a current will flow, but as the counter-electrons are swept out of one end, new creation of electrons must be introduced from the other end, so that the average density of conduction electrons is left very nearly equal to the density of donor sites.

Since the donor sites are positively charged there will be some tendency to tend to capture some of the conduction electrons as they pass through the crystal. A donor site can therefore act as a trap just as does the discussed in the last section. But if the trapping may be sufficiently small — as is for arsenic — the number of carriers which are trapped in any one site is a small fraction of the total. For a complete understanding of the behavior of semiconductors

one more time introduced to trapping. For the case of no dissipation, however, we see again that the trapping energy is sufficiently low and the temperature is sufficiently high that all of the donor sites have given up their electrons. This is, of course, just an approximation.

It is also possible to work in a germanium crystal with impurity atom whose valence is 2, such as aluminum. The additional atoms are set as a witness & /not/ by adding an extra electron. I can steal an electron from some nearby germanium atom and end up with a negative charge, positive hole or hole carrier. Of course, when it steals the electron from a germanium atom, it leaves a hole there; and this hole can wander around in the crystal as a free hole carrier. An impurity atom which can produce a hole in this way is called an acceptor because it "accepts" an electron. If a portion of a silicon crystal is grown from a melt in which a small amount of aluminum is added, the crystal will have built-in a certain density of holes which can act as positive carriers.

When a donor or an acceptor impurity is added to a semiconductor, we say that the material has been *doped*.

When a portion of a crystal with some built-in impurities is at room temperature, some conduction electrons are compensated by the thermally induced electron hole pairs created as we saw by the donor sites. The electrons from both sources are, usually, equal, $N_{\text{e}} = N_{\text{h}}$, in the total number. N_{e} which comes into play in the statistics processes, lastly, is equilibrium. If the impurity is not too low, the number of negative charges contributed by the donor impurity atoms is roughly equal to the number of its valence atoms added. In equilibrium $N_{\text{e}} \approx N_{\text{h}}$ must still be satisfied at given temperature, T . If $N_{\text{e}} < N_{\text{h}}$, it is determined this means that it is odd to do some trapping which increases N_{h} . The number N_{p} of positive carriers will have to decrease to such an extent that $N_{\text{e}}, N_{\text{p}}$ is unchanged. If the impurity concentration is high enough, the number N_{p} of negative carriers is determined by the number of donors and is mostly independent of temperature. All of the variation in the electrical behavior is supplied by N_{e} , even though it is much less than N_{p} . An alternative picture would be a small concentration of donor impurity with a majority of negative carriers; such a material is called an "n-type" semiconductor.

If the acceptor-type impurity is added to the crystal in the same way, it does not add any net and significant source of free electrons produced by thermal ionization. The process will go on until Eq. (2-4) is satisfied. Under appropriate conditions, the number of positive carriers will be increased and the number of negative carriers will be decreased, leaving the positive a majority. A material with an excess of positive carriers is called a "p-type" semiconductor.

If we put two electrodes on a piece of semiconductor crystal and connect them to a source of potential difference, then we have electric fields inside the crystal. The electric field will cause the positive and the negative carriers to move, and an electric current will flow. Let's consider "n-type" material in an n-type material in which there is a large majority of negative carriers. For such material we can disregard the holes. They can contribute very little to the current because there are so few of them. In addition, if the carriers want to move, without any impurities, in > the crystal at < thin temperature, however, especially in a crystal with some impurities, the electrons do not move completely freely. They are continually making collisions which knock them out of their original trajectories, that is, changing their momentum. These collisions are just exactly the scattering we talked about in the last chapter and occur at ANY frequency in the crystal lattice. In addition, another the main source of scatterings are random thermal sites that are probably present here. Since the conduction electrons have a very slightly different energy at two points here, the probability waves are scattered at all the points. Even in a perfectly pure crystal, however, there are going to be temperature changes, either in the lattice due to thermal vibrations from the classical point of view we can say that the atoms aren't lined up exactly in a regular lattice, but are, at a certain, slightly out of place due to their thermal

currents. The energy loss associated with such current flowing in the resistor as described in Chapter 12 makes it difficult to place so much heat that the losses of resistivity or ohmics are not transmitted perfectly but are scattered in the insulating foreign. At very high temperatures or for very pure materials this scattering may become important, but in most doped substances used in practical devices the impurity atoms contribute more of these losses. We would like now to make an estimate of the electrical conductivity of such a material.

When an electric field is applied to such type semiconductors, that negative carrier will be accelerated in this field, picking up velocity until it is scattered from one of the carrier sites. This means that the carriers which are ordinarily moving occur in a random fashion will have their site, erratic, walk pick up an average drift velocity along the lines of the electric field and give rise to a current through the system. The drift velocity v_d is in general rather slow compared with the typical thermal velocities so that we can estimate the current by assuming that the average time between collisions between scattering is unimportant. Let's say that the negative carrier has an effective positive charge q_e . In an electric field E , the force on the carrier will be $q_e E$. In Recd. 42.5 of Volume 1 we calculated the average drift velocity in units of cm^2/sec and found it to be given by $\frac{q_e E}{\pi \sigma m_e \tau_e}$, where q_e is the charge on one charge, τ_e is the mean free time between collisions, and m_e is the mass. We include the effective mass we mentioned in the last chapter but since we want to do a rough calculation we will suppose that this effective mass is the same as the directions. Then we will call it m_e . With this approximation the average drift velocity will be

$$v_{d,eff} = \frac{q_e E \tau_e}{m_e} \quad (14.1)$$

Knowing the drift velocity we can find the current. Electric current density j is just the number of carriers per unit volume, N_e , multiplied by the average drift velocity, and by the charge on each carrier. The current density is therefore

$$j = N_e v_{d,eff} q_e = \frac{N_e q_e^2 E}{m_e} \tau_e \quad (14.2)$$

We see that the current density is proportional to the electric field, with a semi-conducting constant α says Ohm's law. The coefficient of proportionality between j and E is conductivity σ .

$$\sigma = \frac{N_e q_e^2 \tau_e}{m_e} \quad (14.3)$$

For the n-type material the conductivity is relatively independent of temperature. First, the number of mobile carriers N_e is determined primarily by the density of donors in the crystal (as long as the temperature is not so hot that some of the carriers are suppressed). Second, the mean time between collisions τ_e is mainly controlled by the density of impurity atoms which is, of course, independent of the temperature.

We can apply all the same arguments to p-type materials, changing only the signs of the parameters which appear in Eq. (14.3). If there are comparable numbers of both heavy hole and positive carrier present, then we must add the contributions from each kind of carrier. The total conductivity is then

$$\sigma = \frac{N_h q_e^2 \tau_h + N_p q_e^2 \tau_p}{m_h + m_p} \quad (14.4)$$

For very pure materials, N_h and N_p will be nearly equal. They will be smaller than in a doped material, so the conductivity is "by loss". Also they will vary rapidly with temperature (see $\propto T^{-3/2}$), so the behavior of the conductivity may change extremely fast with temperature.

14.2 The Hall effect

It is certainly a puzzle. Using the circuit resistance where the bulk is relatively free of defects and dislocations, there should be no electrical current carried by holes that behave like positive particles. We would have, therefore, to reverse sign of current. This shows in a rather clear way that the sign of the carrier electric current is again definitely positive. Suppose we have a block made of semiconducting material—again let's make it a metal—and we put an electric field E_x in its x -direction, as shown in Fig. 14.2. Now suppose we put a magnetic field B in the block pointing at a right angle to the current, say along the z -axis of the figure. The moving carriers will feel a magnetic force due to $\mathbf{B} \times \mathbf{v}$, and if v is the carrier velocity, it will be right or left depending on the sign of the charge on the carrier—the average magnetic force on the carriers will be either up or down. Now, that it is right. For the direction we have assumed for the current and the magnetic field the magnetic force on the moving charges will always be up. Positive charges moving in the direction v_x to the right will feel an upward force. If the currents consist of negative charges, they will be moving left (for the same sign of the conductive current) and they will also feel an upward force. Under steady conditions, however, there is an upward motion of the carriers because the current can flow only from left to right. What happens is that a few of the charges, likely 10^6 cm^{-2} per centimeter 2 , have charge density along the upper surface of semiconductor. They are equal and opposite carrier charge density along the bottom surface of the crystal. The charges will do so, the top and bottom surfaces will be electric fields they produce on the moving charges just exactly cancel the magnetic force. For the case $v_x > 0$ the carrier current flows horizontally. The charges on the top and bottom surfaces q_{\pm} produce a potential difference vertically across the crystal, which can be measured with a high-resistance voltmeter, as shown in Fig. 14.3. The sign of the potential difference measured by the voltmeter will depend on the sign of the carrier charges responsible for the current.

Not such experiments were first done. It was expected that the standard potential difference would conjugate signs we could expect for n-type conduction electrons. People were, therefore, quite surprised to find that not some materials the sign of the potential difference was in the opposite direction. It appeared that the carrier current was a positive, not a negative, current. From our discussion of doped semiconductors, it is understandable that an n-type semiconductor should produce the sign of potential difference appropriate to negative carriers, and that a p-type semiconductor should give an opposite positive difference since the current is carried by the positively charged holes.

The original discovery of the anomalous sign of the potential difference in the Hall effect was made in a metal rather than a semiconductor. It has been assumed that in metals the conduction was always by electrons. However, we know our v_x for negative the potential difference had the wrong sign. It is now understood that in metals as well as in semiconductors it is possible, in certain circumstances, that the "holes" responsible for the conductive carriers, i.e., the charge carriers moving in the crystal through the moving, never to least the valence shell of the atom, will have the electric current and the source to external fields, because $v_x > 0$, one would expect for an electric current and the positive carriers.

Let's see if we can make a quantitative estimate of the magnitude of the voltage difference measured from the Hall effect. If the voltage in Fig. 14.3 shows a multiple of e times the charge e , the current must be moving from left to right and the vertical magnetic force must be precisely cancelled by a vertical electric field which we can call E_y , (the "Hall" \rightarrow field, "transverse"). If it is electric field E_y caused the magnetic force we must have

$$E_y = v_x e \times B \quad (14.9)$$

Using the relation between the drift velocity and the electric current density given

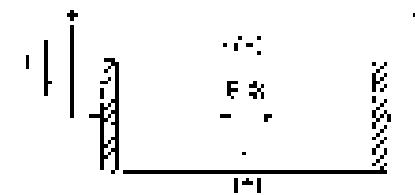

Fig. 14.2. The Hall effect setup from the magnetic forces on the carriers.

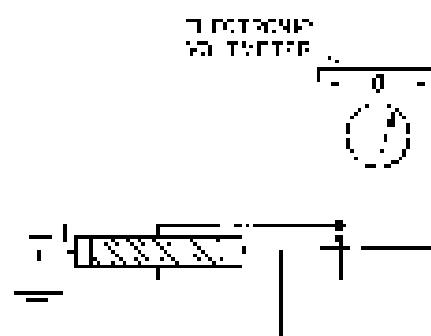

Fig. 14.3. Measuring the Hall effect.

$$V = \frac{q}{\rho A} \cdot \frac{1}{2} B$$

The potential difference between the top and the bottom of the crystal is, of course, the electric field which is supplied by the battery. The electric field strength is proportional to the current density and to the magnetic field strength. The constant of proportionality β_{HJ} is called the Hall coefficient and is usually represented by the symbol R_H . The Hall coefficient depends just on the density of current-carrying carriers of one sign, i.e., on large accuracy. Measurement of the Hall effect is, therefore, one convenient way of determining exactly the density of carriers in a conductor.

14-4 Semiconductor junctions

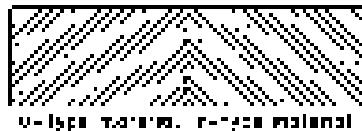

Fig. 14-8. A p-n junction.

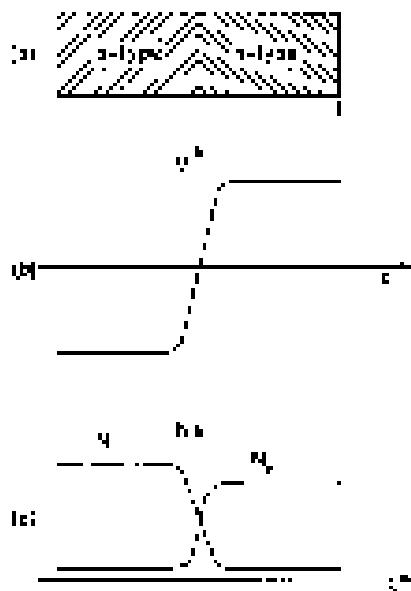

Fig. 14-9. The electric potential and the carrier densities in an idealized semiconductor junction.

We would like to discuss now what happens if we take two pieces of germanium or silicon with different concentrations of dopants, say, one kind of dopants in one piece and another kind in the other. These can be joined together to create a p-n junction, i.e., where we have a type germanium on one side of the boundary, as depicted in Fig. 14-8. Actually, it is not practical to put together two separate pieces of crystal and have them in perfect contact on a microscopic scale. Instead, junctions are made out of a single crystal slice. This was indicated in the two separate regions. One was a small semi-spherical doping impurity in the "n-cell" (the only part of the crystal has grown). Another way is to grow a thin film of a doped element A on the surface of the host. And the crystal contains some impurity atoms to dilute the body of the crystal. In either case, there will always have a sharp boundary through the boundaries can be more or less smooth. A "continuum" of sorts. For example, consider an ideal situation in which each two regions of the crystal with different properties meeting at the boundary.

On the n-type side of the junction there are free electrons which can move about, as well as the fixed donor sites which balance the overall electric charge. On the p-type side there are free holes moving about and an equal number of negative acceptor sites keeping the charge balanced. Actually, last time we saw that in a substitution centre we put the two materials in contact. When they are connected together, the ejection of a charge near the boundary. When the electrons in the n-type material want to be in the p-holes they will not be affected because they would be a free surface, but are able to go right on into the p-type material. Some of the electrons in the n-type material will, therefore, tend to diffuse out into the p-type material where there are fewer electrons. This will cause a build-up because as we lose electrons from the n-side the net positive charge there increases and finally an electric voltage is built up which resists the diffusion of electrons from the p-side. In a similar way, because the carriers of the n-type material can diffuse across the junction into the p-type material, when they do this they leave behind an excess of negative charge. Once equilibrium conditions the net diffusion equals the net recombination. The important about is the electric field which are established in such a way so as to prevent the free electrons from moving the p-type material.

Let us discuss processes we have been describing you in a simple manner and you will notice both act on the diffusion which will charge up the n-type material in positive +ve and the p-type material in a negative sense. Because of the finite conductivity of the semiconductor material, the change in potential from the n-side to the p-side will occur in a relatively narrow region near the boundary; the main bulk of the block of material will have a uniform potential. Let us imagine an electric field direction perpendicular to the boundary surface. Then the electric potential will vary with x , as shown in Fig. 14-9(a). We have a greater concentration of holes in the p-type. The expected variation of the density N_h of holes is $N_h \propto e^{-kx}$ the density N_n of electrons $N_n \propto e^{kx}$ away from the junction. The current densities J_h and J_n should be just the equilibrium density we would expect for individual blocks of the crystal at the same temperature. We have drawn the lines for a

junction at which the p-type material is more heavily doped than the n-type. Because of the potential gradient in the junction, the positive carriers have to climb up a potential hill to get to the n-type side. Thus, there is an equilibrium condition there can be found just below the n-type material that carries no net charge material. Neglecting the way of current, it makes, we expect that the ratio of the carrier densities on the two sides to be given by the "flow equation":

$$\frac{N_{p\text{ in p-side}}}{N_{p\text{ in n-side}}} = e^{-qV/kT} \quad (14.06)$$

The quantity qV is the numerator of the exponential because the energy requires an electric charge qV , through a potential difference V .

We have a parallel similar equation for the density N_n of the negative carriers:

$$\frac{N_{n\text{ in p-side}}}{N_{n\text{ in n-side}}} = e^{-qV/kT} \quad (14.07)$$

With above the equilibrium densities on each of the two extremes, we can use either of the two equations above to determine the potential V across the junction.

Hence that in Eqs. (14.06) and (14.07) you to give the same value for the potential difference V , the product $N_p N_n$ has to be same for the carrier densities on each side. (Remember $N_p = -N_n$.) We have seen earlier, however, that this product depends only on the temperature and the gap energy of the crystal. Provided both sides of the crystal are at the same temperature, the two equations are equivalent with the same values of the potential difference.

Since there is a potential difference from one side of the junction to the other, it induces a drift like a battery. If I hope if we connect a wire from the n-type side to the p-type side we will get an electric current. That would be nice, because then the current would flow forever without using up any material and we would have an infinite source of energy. A violation of the second law of thermodynamics! There is, however, one catch, if you do make a wire from the p-side to the n-side. And the reason is easy to see. Suppose we, in some frequency, turn on a power of induced current. When we connect this wire to the n-type side, we have a junction. There will be a potential difference across this junction. Let's say that there goes one-half the potential difference from the p-type side to the n-type material. When we connect our induced wire to the p-type side of the junction, there is also a potential difference at this junction, so we'll need all the potential difference across the junction. At all other junctions, the potential differences add together themselves so that there is no net current flow in the circuit. Whatever kind of wire you use to connect together the two sides of the crystal, you are producing two new junctions, and in keeping all the junctions at the same temperature, the potential jumps at the junctions to compensate each other and no current will flow in the circuit. It does turn out, however, that if we cut the device so that some of the junctions are at a different temperature than the others, then, perhaps, will flow. Some of the junctions will be heated and others will be cooled by this current and thermal energy will be converted into electrical energy. This effect is known as the Seebeck effect of thermocouples where it is used for measuring temperatures, and of thermoelectric generators. The same effect is also used to cool air by refrigerators.

If we cannot measure the potential difference between the two sides of an *n-p* junction, how can we easily know that the potential gradient shown in Fig. 14-5 really exists? One way is to shine light on the junction. When the light shines on the doped they act as sources or sinks of hole pairs. In the steady state, if a light falls on the junction instead of the edge of the potential barrier of Fig. 14-6 the hole will be driven into the p-type region and the electron will be driven into the n-type region. If the two sides of the junction are now connected to an external circuit, heat and energy will provide a current. The energy of the light is the measured total electrical energy in the junction. The solar cells which generate electrical power for the operation of solar electric satellites operate on this principle.

In our discussion of the operation of a semiconductor junction we have been assuming that the holes and the electrons are moving independently, except that they combine to form a positive ionized equilibrium. When we were describing the current produced by light falling on the junction, we were assuming that all electrons which reached the junction region would get into the metal body of the crystal before being annihilated by a carrier of the opposite polarity. In the intermediate vicinity of the junction, where the density of carriers of both signs is approximately equal, the effect of their mutual annihilation is so small that it is often called "nonradiative recombination." There are, in a crystal and part of a semiconductor junction, must be properly taken into account. We have been assuming that a hole in an electron combined in a junction region has a good chance of getting into the metal body of the crystal before recombining. The typical time for recombination to take place is opposite partner and magnitude is for typical semiconductor junctions about the same between 10^{-1} and 10^{-2} seconds. This time is incidentally much longer than the mean free time τ between collisions with scattering sites in the crystal which we used in the analysis of conduction. In a typical n -type junction, the time for recombination is less formed in the junction region to be negligible over the rest of the crystal is generally much shorter than the recombination time. Most of the pairs will, therefore, contribute to the excess current.

14-5 Rectification at a semiconductor junction

We should like to consider now what happens at a p-n junction under like a rectifier. If we apply a voltage across the junction, a direct current will flow if the polarity is in the direction from the very small current will flow if no voltage is applied in the opposite direction. If an alternating voltage is applied across the junction, a direct current will flow in one direction. The current is "rectified." Let's look again at what is going on in the equilibrium condition represented by the graphs of Fig. 14-4. In the p-type region, there is a large concentration N_p of positive carriers. These carriers are diffusing away and a certain number of them each second approach the junction. The number of positive carriers which approach the junction is proportional to N_p . Most of them, however, are turned back by the high potential hill in the junction and only the fraction $e^{-\frac{qV}{kT}}$ pass through. There is then a current of positive carriers approaching the junction from the p-side. This current is also proportional to the density of positive carriers in the n-type region, but the carrier density here is much smaller than the density in the p-type side. When the positive carriers approach the junction from the n-type side, they find a hill with a negative slope and immediately turn around. In the p-type side of the junction, let's call this current i_0 . Under equilibrium the currents from the two directions are equal. We expect then the following relation:

$$i_0 \sim N_p i_0 e^{-\frac{qV}{kT}} = N_p A_i e^{-\frac{qV}{kT}}, \quad (14-2)$$

You will notice that this equation is really just the same as Eq. (14-10). We have just derived it in a different way.

Suppose, however, that we lower the voltage on one side of the junction by a amount ΔV , which we can do by applying an external potential V to one side of the junction. Now the difference in potential across the junction will be larger by $\Delta V - qV$. The current of positive carriers from the p-side to the n-side will now have this potential difference as its driving factor. Call this current i_1 , we'll get

$$i_1 \sim N_p i_0 e^{-\frac{q(V-\Delta V)}{kT}}.$$

This current is larger than i_0 because the factor $e^{-\frac{qV}{kT}}$ is now less. So we have the following relation between i_1 and i_0 :

$$i_1 = i_0 e^{-\frac{q\Delta V}{kT}}. \quad (14-3)$$

The current from the p-side increases exponentially with the externally applied voltage ΔV . The current of positive carriers from the n-side, however, remains

currents so long as ΔV is not too large. When they approach the barrier, these currents will still be diode currents and will all fall down to the same value if the voltage is less than the natural potential difference V_0 , the x -value would change because other conductors have begun to conduct who are. The maximum of positive current which flows across the junction is then the difference between the currents from the two sides:

$$I_{\text{max}} = I_0 e^{V_0/V} - I_0 \quad (14.14)$$

If the current is a steady flow into the reverse region. Then they have charge the body of the region, where they are eventually annihilated by the majority carriers in the first one. The electrons which are left in the conduction band will be moved by a current of electrons from the source terminal of the negative terminal.

What is done the next instant is Eq. (14.14)'s time. The just as all the other currents rapidly went to negative voltage. But only for A_1 the current increase in size, but the exponential term soon becomes negligible and the negative current never exceeds I_0 . Which makes our assumption is rather valid. That the current I_0 is limited by the rate of recombination current on the side of the junction.

We get through exactly the same analysis for the case of magnetic currents which flows in the junction, first with the potential difference zero, then with a new externally applied voltage, decreased ΔV , yet get again an equation just like (14.14) for the natural conduction. Since the total current is the sum of the current contributed by the two carriers, Eq. (14.14) still applies for the total current provided we identify I_0 as the maximum current which can flow per unit area voltage.

The subexpression of the current of Eq. (14.14) is shown in Fig. 14-10. It shows the typical behavior of small-scale devices such as those used in modern computers. We should remark that Eq. (14.14) is true only for small voltages. For voltage comparable or larger than the natural voltage difference V_0 , there is very little change in the current no longer any exponential equation.

You may remember incidentally that we set exactly the same equation for the law found here in Eq. 14.14 when we discussed the "ideal diode" in Fig. 14-1. In other and probably simpler terms, we might say the same equations in the two situations about the solid-state processes are quite similar.

14-6 The Transistor

Before the discussion can appreciate class characteristics of the transistor, the junction consists of two semiconductor junctions put close together. The junction is usual in part of the same type, but we just described for the semiconductors made the $p-n-p$ junction. Suppose we take a $n-p-n$ type junction. With this diode junctions, a voltage V , a p -type region, and another n -type region, as shown in Fig. 14-11(a). The combination is called a $p-n-p$ transistor. Each of the two junctions in the transistor can never much in the way we have described in the last section. In particular there will be a potential and field at each junction boundary, which prevent the flow from one side region to the other region. If the two junction regions have the same electrical properties, then it will be extended, as we showed in the circuit in (b) shown in the graph of Fig. 14-11(b).

Now let's imagine that we connect each of the two junctions external to the source as shown in part (c) of Fig. 14-12. We will use all voltages to the terminals connected to the left-hand junction as it will be by definition at zero volts. We will call this terminal the emitter. The n -type region is called the base and it is connected to a slightly negative potential. The right-hand p -type region is called the collector, and is connected to a somewhat larger negative potential. Under these circumstances the variation of potential across the crystal will be as shown in the graph of Fig. 14-12(c).

Let's first see what happens to the positive carriers, since it is primarily their behavior which controls the operation of the $p-n-p$ transistor. Since the source is

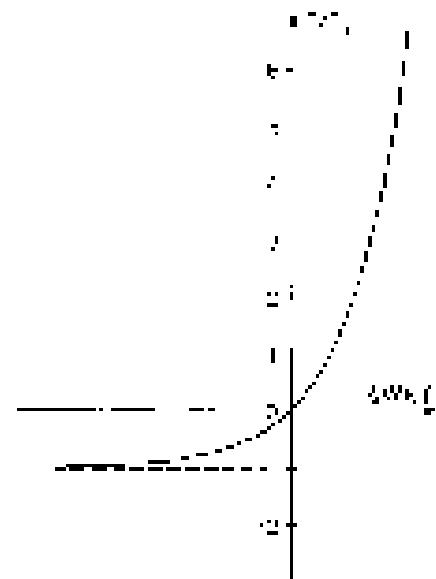

Fig. 14-10. The current density J as a function of the voltage V above V_0 .

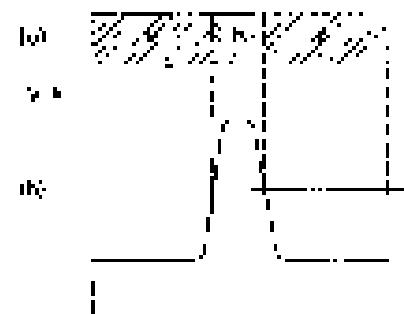

Fig. 14-11. The potential distribution in a diode with no applied voltage.

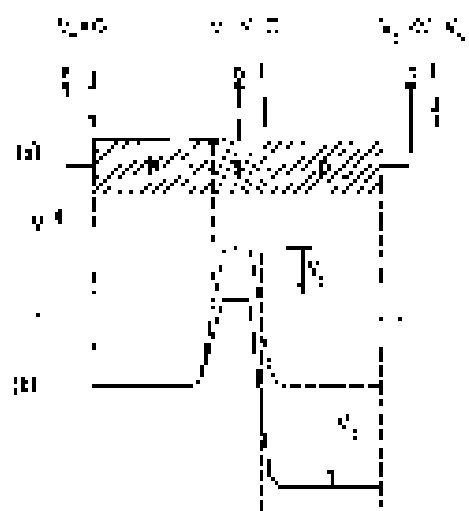

Fig. 14-12. The potential distribution in a $p-n-p$ transistor in operating condition.

at a relatively small positive potential than the base, a current of positive carriers will flow from the emitter region into the base region. A relatively large current flows out between emitter region and collector ("forward voltage") corresponding to the right-hand half of the graph in Fig. 14-11. Now, however, since positive carriers do have to be "brought" from the n -type region into the p -type region, they might think the thickness of the boundary of the n -type region through the base terminal b . Now, however, comes the point of the transistor. The collector region is made very thin, typically 10^{-4} cm or less, much thinner than its base-region dimension. This means that as the holes move toward the region b , there is a very good chance of diffusing across to the other junction because they are annihilated by the electrons in the n -type region. When they get to the uppermost boundary of the n -type region they find a sharp downward potential hill and immediately fall into the right-hand p -type region. This is what the crystal is called the "collector," because it "collects" the holes after they have diffused across the n -type region. In a typical transistor, all but a few tenths of a percent of the hole current which leaves the emitter and enters the base is confined in the collector region, and only the small remainder contributes to the base-emitter current. The sum of the base and collector currents is, of course, equal to the total current.

Now we are ready to see what happens if we apply a negative bias to the base terminal. Since we are at a relatively steady state of the curve of Fig. 14-11, a small variation in the potential V_b will cause a relative percentage change in the collector current I_c . Since the collector voltage V_c is much more negative than the base voltage, these slight variations in potential will not affect appreciably the steep potential hill between the base and the collector. Most of the positive carriers emitted in the negative V_b still reach right by the collector. Thus, as we vary the potential of the base electrode, there will be a corresponding variation in the collector current I_c . The essential point, however, is this: the base current is always zero for a small fraction of the collector current. The resistance is an absolute; a small increase is compensated by the base electrons giving a large current (100 times higher) at the collector electrode.

We return now to the diagram—the way it is when the n -type base has been modulating so far. First, note that we do not expect any significant electron current to flow between the base and the collector. With a large negative voltage on the collector, electrons in the base would have to diffuse over high potential steps, but due to the probability of doing that is very small. There is a very small current of electrons to the collector.

On the other hand, the electrons in the base can drift into the emitter region. In fact, you might expect an electron current in this direction to be proportional to the hole current from the emitter into the base. Since an electron current is useful, and, in fact, working, is bad because it increases the total base current required for a given current of holes in the collector. The transistor is, therefore, designed to minimize the electron current to the emitter. The electron current is proportional to $(N_A/V_b)^{1/2}$, the density of negative carriers in the base region, while the hole current from Amedeo Cesalpino (Noyce et al.), the density of positive carriers in the emitter region. By using relatively thin ribbons—the n -type arsenic N_A (base) can be made much smaller than N_A (emitter). The very thin base region also helps a great deal because the spacing d of the links in this region by the collector increases significantly to average link spacing d from the center into the base, while leaving the electron current unchanged. As a result, if d is the electron current during the intermediate period, it can be made relatively short. In fact, in fact, when the electrons do play a very significant role in operation of the $n-p-n$ transistor, the current is terminated by removal of the holes, and the $n-p-n$ performs as an amplifier as we have described above.

It is also possible to make a transistor by interchanging the p -type and n -type materials in Fig. 14-11. Then we have what is called an $n-p-n$ transistor. In this a p -electrode, the main current is carried by the electrons which flow from the emitter into the base and from there to the collector. Of course, all the arguments we have made for the $p-n-p$ transistor also apply to the $n-p-n$ transistor if the potentials of the electrodes are chosen with the opposite signs.

The Independent Particle Approximation

15-1 Spin waves

In Chapter 10 we worked out the theory for the propagation of an electron or of some other "particle" such as a atomic excitation. In Chap. 11 crystal lattices. In the last chapter we applied the theory to ferromagnets. But when we talked about interactions in which there are many electrons we disregarded any interaction between them. To do this is of course only an approximation. In this chapter we will extend further the idea that you can disregard the interaction between the electrons. We will also see the opportunity to show you some more applications of the theory of the propagation of particles, since we will generally continue to disregard the interactions between particles, this is not unlike what we did in this chapter except for one new application. The first example we'll consider is, however, one in which it is possible to write down quite exactly the exact equations whose case is more than one "particle" present. From them we'll be able to see how the approximation of disregarding the interactions is made. We will, though, analyze the problem carefully.

As our first example we'll consider a "spin wave" in ferromagnetics a solid. We have discussed the theory of paramagnetism in Chapter 9 of Volume II. At zero temperature all the electron spins that contribute to the magnetism in the body are ferromagnetic and are parallel. There is an interaction energy between the spins, which is lower when all the spins are parallel. At any nonzero temperature, however, there is a chance that some of the spins are randomized. We calculate the probability in a approximate manner in Chapter 26. This time we will describe the quantum-mechanical theory—so you will see what you would have to do if you wanted to solve the problem more exactly. We will still make some idealizations by assuming the electron moves fast and far enough that the spin is always anti-parallel to neighboring spins.

The condition in which the electrons at each atom are all paired except one, so that all of the magnetic effects come from one soliton than one atom. Further, we imagine that these electrons are localized in small boxes in the lattice. The model can easily be thought of as a jello.

We also assume that there is an interaction between the two adjacent atoms; electrons which move in the energy of hexagons:

$$E = - \sum_{\langle i,j \rangle} \delta \sigma_i \cdot \sigma_j \quad (15.1)$$

where σ 's represent the spins and the summation is over all adjacent pairs of electrons. We have already discussed this kind of interaction energy when we considered the hyperfine splitting of the magnetism of the nucleus of the hydrogen atom and proton in a hydrogen atom. We represent it then as $\delta \sigma_i \cdot \sigma_j$. Now, for a given pair, say the electrons at atom 1 and atom 3, the Hamiltonian would be $-K \sigma_1 \cdot \sigma_3$. We have σ to indicate pair, and the Hamiltonian is the sum of the energies of each pair of these terms for each interacting pair. The energy is written with the factor $-K$ so that a positive K will correspond to ferromagnetism, that is, the lowest energy results when opposite spins are parallel. In a real crystal, there may be other terms which are the interactions of two nearest neighbors, and so on, but we don't need to consider such complications in this stage.

With the Hamiltonian of Eq. (1), we have a complete description of the system. With our approximation—the properties of the magnetization

15-2 Spin waves

15-3 Independent particle

15-4 The benzene molecule

15-5 More magnetic chemistry

15-6 Other uses of the approximation

should do next. We would also be able to calculate the thermodynamic properties due to the magnetization. If we can find all the energy levels, the probability of the system at temperature T can be found from the principle that the probability that a system will be found in a given state of energy E is proportional to $e^{-E/T}$. This problem has never been completely solved.

We will solve some of the problems by using a simple example in which all three electrons are in a line—a one-dimensional lattice. You can easily extend the idea to three dimensions. At each atomic location there is an electron which has two possible states, either spin up or spin down, and the whole system is described by “flipping over” of the spins as it moves. We take the Hamiltonian of the system to be the operator of the interaction energy. The picture of the spin sectors of Eq. (15.1) is the sign consideration for the signs in the two-electron Heisenberg \hat{H} :

$$\hat{H} = \sum_{i,j} -\frac{A}{2} \hat{\sigma}_i \cdot \hat{\sigma}_j, \quad (15.2)$$

In this equation we have written the constant as $A/2$ for convenience so that some of the later equations will be exactly the same as the ones in Chapter 11.

Now what is the lowest state of this system? The state of lowest energy is the one in which all the spins are parallel, let's say, all up. We can make this state $\psi_0 = |\uparrow\uparrow\uparrow\rangle$, where the “up” symbol is repeated three times. It is easy to figure out the energy for this state. One way is to write out all the cubic terms in terms of $\hat{\sigma}_x$, $\hat{\sigma}_y$, and $\hat{\sigma}_z$, and work through carefully what each term of the Hamiltonian does to the ground state, and then add the results. We can, however, also use a quicker method. We saw in Section 14-2 that $\hat{\sigma}_x$, $\hat{\sigma}_y$, and $\hat{\sigma}_z$ could be written in terms of the Pauli spin exchange operator, like this:

$$\hat{\sigma}_i \cdot \hat{\sigma}_j = i \hat{\sigma}_{ij}^{(1/2)} - 1, \quad (15.3)$$

where the operator $i \hat{\sigma}_{ij}^{(1/2)}$ interchanges the spins of the i th and j th electrons. With this substitution, the Hamiltonian becomes

$$\hat{H} = -A \sum_{i,j} (\hat{\sigma}_{ij}^{(1/2)})^2 - \beta. \quad (15.4)$$

It is now easy to work out what happens in different states. For instance if i and j are both up, then exchanging the spins leaves everything unchanged on $\hat{\sigma}_{ij}^{(1/2)}$, acting on the state just gives the same state back, and is equivalent to multiplying by -1 . The expression $(\hat{\sigma}_{ij}^{(1/2)})^2 = 1$ is just right. In one-half, i there are no we will leave off the recursive superscripts on the $\hat{\sigma}$'s.

For the ground state of spins one and so if you exchange a particular pair of spins you get back the original state. For you get zero in this energy case. If you operate on α with the Hamiltonian you get the state α again multiplied by a sum of terms, $-(A/2)$, for each pair of spins. That is, the energy of the system in the ground state is $-A/2$ per atom.

Next we should like to look at the energies of some of the excited states. It will be convenient to measure the energies with respect to the ground state—the reference ground state has zero energy. We can do this by adding the energy $1/2$ to each term in the Hamiltonian. Each just changes the “ β ” in Eq. (15.4) to “ β_+ .” Our new Hamiltonian is

$$\hat{H}' = -A \sum_{i,j} \hat{\sigma}_{ij}^{(1/2)} + \beta_+. \quad (15.5)$$

With this Hamiltonian the energy of the lowest state is zero. The spin exchange operator is now taken by multiplying by a unity $(1 - \hat{\sigma}_{ij}^{(1/2)})$, and this is canceled by the “ $\hat{\sigma}_{ij}^{(1/2)}$ ” each term.

The ground state here is not “degenerate”; there are no two states with the same energy—for example, all spins down, or all three other directions. The original reference level is the excited state with all up, and the excited state with all down are the only other two energy possibilities.

For decreasing states other than the ground state you will need a subspace $\mathcal{H}_{\text{down}}$. One convenient approach is to group the states according to whether the electron has spin down, or has two down spins, or up, and so on. There are, of course, many states with one spin down. The down spin could be at atom "A," or at atom "B," or at atom "C." We can, in fact, choose just such states for our basis states. We could write them as $|x_1\rangle \otimes |S_1\rangle \otimes |S_2\rangle \dots$ It will, however, be more cumbersome later on to put the total quantum number with the downspinning electron by its coordinate x_i . That is, we'll define the state $|x_1\rangle$ to be one with all the atoms nonspinning up except for the one at A , atom x_1 , which has a downspinning electron (see Fig. 15-1). In general, $|x\rangle$ is the state with one down spin that is located at the coordinate x_1 , x_2 , etc.

Next, let's act on one of the basis function $|S_1\rangle$ on the state $|x\rangle$? One term of the Hamiltonian is say $= A(S_{1,A} - 1)$. The operator $S_{1,A}$ exchanges the two spins of the adjacent atoms 1, 2. But, if the state $|x\rangle$ has $x_1 = 1$, nothing happens; $S_{1,A}$ is equivalent to multiplying by 1:

$$S_{1,A}|x\rangle = |x\rangle$$

It follows that

$$(S_{1,A} - 1)|x\rangle = 0$$

Thus all the terms of the Hamiltonian give zero—except those involving $x_1 = 1$, of course. On the state $|x\rangle$, the operation $S_{1,A}$ exchanges the spin of atom 1 (up) and atom 2 (down). The result is the state with all spins up except the atom at 1, that is

$$S_{1,A}|x\rangle = |x_1\rangle$$

In the same way

$$S_{2,A}|x\rangle = |x_2\rangle$$

Hence, the only terms of the Hamiltonian which survive are $= A(S_{1,A} - 1)$ and $= A(S_{2,A} - 1)$. Acting on $|x\rangle$, they produce $= A|x_1\rangle + A|x_2\rangle$ and $= A|x_1 + 1\rangle + A|x_2\rangle$, respectively. The result is

$$\hat{H}|x\rangle = -A \sum_i (S_{i,A} - 1)|x\rangle = -A(x_1 + x_2 - 2)|x\rangle. \quad (15.6)$$

When the Hamiltonian acts on $|x\rangle$, it gives me the same amplitude to be in states $|x_1\rangle$ and $|x_2\rangle$. That just means that there is a central coupling to have the down spin flip over to the next atom. So because of the interaction between spins, if we begin with one spin down, there must be some probability that an electron whose one will be down instead. Operating on the general state $|x\rangle$, the Hamiltonian gives

$$\hat{H}|x\rangle = -A(|x_1\rangle - |x_2\rangle) - 2|x\rangle. \quad (15.7)$$

Notice particularly that if we take a complete set of atoms with only one spin down, they will only be mixed among themselves. The Hamiltonian will never mix these states with others that have more spins down. So long as you only exchange spins, you never change the total number of down spins.

If we're going to use the matrix equation for the Hamiltonian, we find $(x_1, H|x\rangle, x_2)$ (Eq. 15.7) is equivalent to

$$\begin{aligned} H_{1,1} &= A; \\ H_{1,2} &= H_{2,1} = -A; \\ H_{2,2} &= 0, \quad \text{for } |x_1 - x_2| > 1. \end{aligned} \quad (15.8)$$

Now what are the energy levels for states with one spin down? As usual we let C_x be the amplitude that some state $|p\rangle$ is in the basis $|x\rangle$. If $|p\rangle$ is to be a definite energy state, all the C_x 's must vary with time in the same way, namely,

$$C_x = S_x e^{iE_p t/\hbar}. \quad (15.9)$$

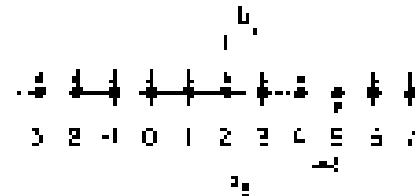

Fig. 15-1. The basis state $|x_1\rangle$ of a chain of three atoms. All the spins are up except the one at x_1 , which is down.

We can put the field ψ on into one- and two-millimeter regions:

$$\psi \left(\frac{2\pi}{3} \right) = \sum_{k=1}^{\infty} (L_k C_k) e^{ikx_1} \quad (15.1)$$

Using Eq. (15.1), we can multiply elements. Of course we get an infinite number of terms, but they cancel by symmetry:

$$C_{k+1} = C_{k+2} = \dots = C_{k+L} = 0 \quad (15.2)$$

We know again exactly what some particular set of coefficients in the wave function ψ tell us because C_k are the wave functions of the k -th mode, which propagates along the lattice with a propagation constant L_k and an energy

$$E_k = L_k C_k = \cos(kL) \quad (15.3)$$

where L is the lattice constant.

The different energy stations correspond to "waves" of even spin ("odd spin waves") and for each such mode there is a constant power. For large scattering by (and thus) inelasticity comes in:

$$E = \omega / 2 \pi \quad (15.4)$$

In this section we can consider a localized wave packet (frontaining, however, only long wavelength) which represents a single mode of motion in one part of the lattice. This domain will behave like a "particle." Because its energy is related to λ via (15.3) this "particle" will have in all directions:

$$m_\lambda = \frac{\lambda^2}{2\pi c} \quad (15.5)$$

15-2 Two-spin waves

Fig. 15-2. A wave with two spins

Note that work must be done prior to parts of these two sections (part A against the previous two parts). We'll discuss states in which there are two spin- $\frac{1}{2}$ fermionic particles, such as the state shown in Fig. 15-2. We can label such a state by the wavefunction in the two spin-wave directions. The two shown can be called $| \psi_1, \psi_2 \rangle$. In general the basis states are $| \psi_1, \psi_2, \psi_3 \rangle$, etc., fully defined with the direction of the spin. If the state is $|\psi_1, \psi_2, \dots, \psi_n\rangle$ it is very likely to be made up of several components of different spin up and down at different sites according to the order. Furthermore, the state $|\psi_1, \psi_2, \dots, \psi_n\rangle$ has no meaning, there isn't such a thing. We can do better by writing $|\psi_1, \psi_2, \dots, \psi_n\rangle$ as a superposition of basis states, $|\psi_1, \psi_2, \dots, \psi_n\rangle = |\psi_1\rangle \otimes |\psi_2\rangle \otimes \dots \otimes |\psi_n\rangle$. Now means the amplitude for a given state ψ_i to be in a certain place depends both on the spin and with atoms have a dual spin. The wavefunctions below show two nice examples of ideas. They are much simpler than in mechanics. (Remember the completeness of quantum mechanics is just one weak point. Here there are more degrees of freedom, the condition becomes more and more delicate with lots of other and the equal ones always look very similar, p. but the ideas are not necessarily more complicated than in the simplified case.)

The equations of motion of this spin system are the differential equations for the $C_{\mu k}$. That is,

$$i\hbar \frac{dC_{\mu k}}{dt} = \sum_{\nu} (H_{\mu\nu} - \mu \delta_{\mu\nu}) C_{\nu k} \quad (15.6)$$

Suppose we want to find the stationary states. As usual, we begin here with no motion; time becomes & time the spin angles $\theta_{\mu k}$ and $\phi_{\mu k}$ will be replaced by $\theta_{\mu k}$ and $\phi_{\mu k}$.

coefficients $\alpha_{\pm k}$. And we have to work out carefully the effect of H on a state with spins σ_1 and σ_2 , since H is not linear to figure out. Suppose for a moment that spins σ_1 & σ_2 are strong enough that we don't need to worry about the other constituents. The operator of exchange in the hamiltonian σ_z , will move the down spin either to the $k=+1$ or $k=-1$ room, and so there's an amplitude that the present coefficients come from the state $|\downarrow\downarrow\rangle$, right? And also an amplitude that it has come from the state $|\uparrow\uparrow\rangle$? It may have been the upper spin that moved, so there's a certain amplitude that $C_{\sigma_1\sigma_2}$ is fed from $C_{\downarrow\downarrow}$ or from $C_{\uparrow\uparrow}$. These effects should all be equal. The final result for the Heisenberg equation is Eq. 5.5

$$\dot{C}_{\sigma_1\sigma_2} = -iA(\alpha_{k=+1} + \alpha_{k=-1} + \alpha_{k=+2} + \alpha_{k=-2}) + i\epsilon C_{\sigma_1\sigma_2} \quad (5.16)$$

This equation is *exactly* correct in our situation. If $\sigma_1 = \sigma_2$ there is no spin flip, and if $\sigma_1 = \sigma_2 = 1$, then two of the terms in Eq. (5.16) should be missing. If we are going to diagonalize this equation, we simply ignore the last two terms of these equations & slightly alter A so that C is supposed to be infinite, and we have an infinite number of terms; neglecting a few might not matter much. So for a first rough approximation let's forget about the dotted equation. In other words, we assume that \tilde{T}_1 (Eq. 5.6) is true for σ_1 and σ_2 , even if M and N are next to each other. This is the condition given of our approximations.

Then the equation is not hard to find. We get immediately

$$C_{\sigma_1\sigma_2} = e^{-iE_{\sigma_1\sigma_2}t/\hbar} \quad (5.17)$$

with

$$\epsilon_{\sigma_1\sigma_2} = (\text{polar } \sigma_1)^{\frac{1}{2}} \text{polar } \sigma_2^{\frac{1}{2}} \quad (5.18)$$

where

$$E = 4M + 24 \cos(k_M) - 24 \cos(k_N) \quad (5.19)$$

think for a moment what would happen if we had two independent single spin waves like in the previous section corresponding to $\sigma_1 = \sigma_2$ and $\sigma_1 = -\sigma_2$; they would have merged. From Eq. (5.12), of

$$E_1 = (3M + 24 \cos(k_M))$$

and

$$E_2 = (3M - 24 \cos(k_M))$$

Notice that the energy E in Eq. (5.19) is just $E_1 + E_2$.

$$E = 6M + 24 \cos(k_M) \quad (5.20)$$

In other words we can think of our solution in this way: objects are two particles (that is, two spin waves). One of them has a momentum described by k_M , the other by k_N and the energy of the system is the sum of the energies of the two objects. The two particles are completely independent — that's all there is to it.

Of course we have to assume some approximations, but we do not wish to discuss the precision of our answer at this point. However, you might guess that it is reasonable to expect with billiards or something-and, therefore, by force of mass in the Hamiltonian, keeping out a ΔE to not wouldn't make much of an issue. If we are ϵ -energy downspins, then there was an appropriate constant ϵ , then we would certainly have to worry about the perturbations.

Interestingly enough, an exact solution can be written down if there are just the two down spins. The result is not particularly impressive. But it is interesting that an exact form can be solved exactly for this case. The solution is

$$C_{\sigma_1\sigma_2} = \exp(iE_{\sigma_1\sigma_2}t/\hbar) \delta_{\sigma_1\sigma_2} - \delta_{\sigma_1\sigma_2} \quad (5.21)$$

with the energy

$$E = 4M - 24 \cos(k_M) - 24 \cos(k_N)$$

and with the wave numbers k_1 and k_2 related to k_x and k_y by

$$k_1 = k_x + k_y, \quad k_2 = k_y - k_x = 0. \quad (15.22)$$

This section includes the “interaction” of the two spins. It describes the fact that when the spins come together there is a certain chance of scattering. The spins act very much like particles with an interaction. But the detailed theory of their scattering goes beyond what we want to talk about now.

15.9 Independent particles

In the last section we wrote down a homogeneous eq. (15.9), for a two-particle system. Then, using an approximation which is equivalent to neglecting any “interaction” of the two particles, we found the following state, described by Eqs. (15.17) and (15.18). This state is just the product of two single-particle states—the solution we have given for $\psi_{\alpha_1, \alpha_2}$ in Eq. (15.19) is, however, really not satisfactory. We have very carefully pointed out earlier that the state $\psi_{\alpha_1, \alpha_2}$ is not a different state from $\psi_{\alpha_2, \alpha_1}$; the order of α_1 and α_2 has no significance. In general, the physical interpretation for the amplitude C_{α_1, α_2} must be unchanged if we interchange the values of α_1 and α_2 , and this does not happen with $\psi_{\alpha_1, \alpha_2}$. Either very foolishly represent the amplitude to find a down-spin up-spin and an up-spin down-spin, or else make it symmetric in α_1 and α_2 . Since k_1 and k_2 can in general be different,

The trouble is that we have not solved our equation of Eq. (15.17) to satisfy this additional condition. Fortunately it is easy to fix this up. Because the solution of the Dirac equation just as given in § 15.5 is

$$\psi_{\alpha, k} = R e^{i k_x x} e^{i k_y y}, \quad (15.23)$$

it even has the same energy we got for (15.22). Any linear combination of (15.23) and (15.22) is also a good solution and has no energy still given by Eq. (15.19). The solution we should have chosen—because of our symmetry requirement—is just the sum of (15.17) and (15.22),

$$\psi_{\alpha_1, \alpha_2} = R e^{i k_x x_1} e^{i k_y y_1} + R e^{i k_x x_2} e^{i k_y y_2}. \quad (15.24)$$

Now, given any k_1 and k_2 the amplitude C_{α_1, α_2} is independent of which way we put x_1 and x_2 . If we decide happen to define x_1 and x_2 reversed we get the same amplitude. Our interpretation of (15.24) in terms of “independent” must also be different. We can no longer say that the equation represents one particle with two summed α_1 and a second particle with wave number k_2 . The amplitude (15.24) represents one state with two particles (magnetic). The state is characterized by the two wave numbers k_1 and k_2 . One solution looks like a composite state of one particle with the momentum $p_1 = \hbar k_1$ and another particle with the momentum $p_2 = \hbar k_2$, but... our wave we can't say which particle is which.

By now this discussion should remind you of Chapter 4 and of a story of identical particles. We can just keep crossing out the particles of the spin system the magnetic, because like electrons these particles. A magnetic must be symmetric in the wave numbers of the two particles. What is this same as saying that if we “interchange the two particles” we get back the same amplitude after ± 0 the same sign. But you may be thinking why did we have to add the two terms in making Eq. (15.24). Why not subtract? Well, it might appear that changing x_1 and x_2 would just change the sign of $\psi_{\alpha_1, \alpha_2}$, which doesn't matter. But after changing x_1 and x_2 doesn't change anything—all the elements of the matrix are exactly where they were before, so there is no reason for even the sign of the amplitude to change. The magnetic will be one like these particles!†

† In general, the same particles of one kind won't. Decaying may not like either two fermions or two particles, and as for free particles, the particles will interact with each other while being almost unbound. This “interact” is not the same as the interaction with time. The system is open to it. That means that the entire system is not closed.

The wave pairs of the discussion have been twofold. First we show you something about spin waves, and second we demonstrate a state whose amplitude is a product of two amplitudes, and whose energy is the sum of the energies corresponding to the two amplitudes. For a two-wave packet the amplitude is the product and the energy is the sum. This is exactly what the energy is in the sum. The energy is the sum of the two energy exponentials— $e^{i\omega_1 t}$ plus $e^{i\omega_2 t}$. If two objects are doing something, one of them with the amplitude $e^{i\omega_1 t}$ and the other with the amplitude $e^{i\omega_2 t}$, and if the amplitude for the two things add up together, is the product of the amplitudes? No, even then there is a single frequency in the product which is the sum of the two frequencies. The energy corresponding to the amplitude is proportional to the sum of the two energies.

We have gone through another long-winded argument to tell you a simple thing. When you don't take into account any interaction between particles, you can think of each as being independent. They could potentially exist in two different states; they would then interact, and they will each contribute to energy; they would have had it they were alone. However, suppose we take the ψ . If they are identical particles, they may behave either as bosons or as Fermi particles, depending upon the quantum. Two boson electrons added to a system, for instance, would tend to behave like Fermi particles. When the positions of the electrons are interchanged, the amplitude would reverse sign. In this equivalent situation, a pair of $(1, -1)$ terms would have to be added as sign between the two terms in the total. As a consequence, over there the contribution to energy for one electron will be the same as for the other. The amplitude for this state is zero.

15-4 The benzene molecule

Although quantum mechanics provides the basis from which determine the structures of molecules, there has not yet applied exactly such a detailed description. The chemists have, therefore, worked out various approximate methods for calculating some of the properties of complicated molecules. We would now like to show you how the independent-particle approximation is used to the structures. We begin with the benzene molecule.

We also used the benzene molecule from another point of view in Chapter 12. There we took an s -approaching picture of the molecule at its lowest energy, with the wave functions shown in Fig. 12-3-2. There is a ring of six electrons with a hydrogen attached to the carbon at each head-on. With the conventional picture of valence bonds, it is necessary to use the multiple bonds between half of the carbons, and in the lowest energy conduction bands, we see something like shown in Fig. 12-3. There are also other higher-energy states. When we computed them in Chapter 12, we just took the two states and forgot all the rest. We found that the ground-state energy of the molecule was not the energy of one of the states, the true, but our lower than that by an order proportional to the amplitude of the transition of those states to the rest.

Now we're going to turn to the same molecule from a completely different point of view, and get kind of approximation. The two points of view will give us different answers, but if we include either approximation, it would lead to the true, realistic description of benzene. However, if we don't let in to improve them, which is of course the usual situation, then you can end up as surprised if the two descriptions do not agree exactly. We shall attempt to do this also with our new point-of-view: the lowest energy of the benzene molecule is low, that is, of the three bond structures of Fig. 12-2,

Now we want to use the bonding picture. Suppose we imagine the six electrons of a benzene molecule concerned only by what has done at Fig. 15-1. We have received six electrons— $-\psi_1$ a bond stands for a pair of electrons.

So we have a distance function for this molecule. Now we will consider what happens when we put back the six electrons one at a time, imagining that each one can run freely around the ring. We assume also that all the bonds shown in Fig. 15-4 are satisfied, and don't need to be established further.

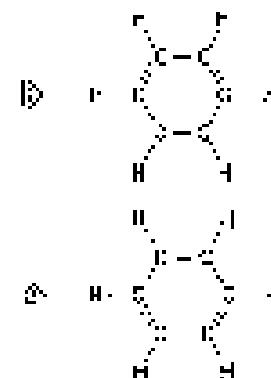

Fig. 15-3. The two base states for the benzene molecule. (1) unpaired

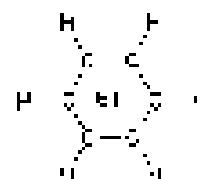

Fig. 15-4. A benzene ring with six electrons removed.

Fig. 15-5. The ethylene molecule.

What happens when we put one electron back into the molecule, and the other, of course, be located in just one of the six positions around the ring—corresponding to the lone states. It would also have a certain amplitude, say ψ_1 , to go from one position to the next. If we analyze the stationary states, it's possible to obtain possible energy levels. That's what we're going to do.

Next put a second electron in. And now we make the most ridiculous approximation that you can think of—that the electrons don't affect each other. Well, we know it's false. Of course they really will interact; they repel each other through the Coulomb force, and furthermore when they are both in the same spot, they must have considerably different energy than twice the energy for one electron. Certainly the expectation value of $\psi_1 \psi_2$ is not zero, because when there are only six sites, particularly when we want to put in an electron. Nevertheless, the approximate have been able to learn a lot by taking this kind of an approximation.

Before we work out the harmonic oscillator, let's consider a simpler example—the ethylene molecule which contains just two carbon atoms with two hydrogen atoms on either side as shown in Fig. 15-5. This molecule has four valence orbitals involving two electrons in each of the two carbon atoms. Now remove one of these electrons. What do we have? We still have just a two-state system, the remaining electron can be at the carbon or the other. We can analyze this as a two-state system. The possible energies for the single electron are either $E_0 = -4$ or $(E_0 + 4)$ as shown in Fig. 15-6.

Now add the second electron. Good, if we have two electrons, we can put the first one in the lower state and the second one in the upper. Not quite we forgot something. Each one of the values is really double. When we say there's a possible state with the energy E_0 , -4 , there are really two. Two electrons can go into the same state if one has to spin up and the other, spin down. This cannot be put in because of the exclusion principle. So there really are two possible states of energy $(E_0 - 4)$. We can draw a diagram as in Fig. 15-7, which indicates both the energy levels and their occupancy. In the condition of lowest energy both electrons will go in the lowest state with their spins opposite. The energy of the extra bond in the ethylene molecule is then is $2E_0$. Why? We neglect the distance between the two electrons.

Let's get back to the harmonic. Now we are two states of Fig. 15-6 has three contributions. Just as there is just one bond in ethylene, and contributes $2(\delta_1 - 4)$ to the energy if E_0 is now the energy is just one electron on one in the one and it is the amplitude to flip it. In this case, the energy due to it is roughly $2(E_0 - 4)$. When we studied benzene before, we got that the energy was lower than the energy of the structure with three extra bonds. That's all the energy the benzene excess is known. But this comes from a new point of view.

We shall now do the six times reduced harmonic, and add one electron. Now we have a benzene system. We haven't drawn one yet, but we know what it is. We can write six electrons in the six napoleons, and so on. Let's save some work by realizing that we've already solved the problem, when we worked out the problem of finding the six ψ 's in the first line of terms. Of course, the second line is an ψ in ψ , it has a nature very similar. But imagine, if I took an ψ and the ψ to a line, and summed the ψ 's along the line from 1 to 6, it is an ψ in the next ψ would be ψ in ψ in ψ etc., which is the same as the original ψ . One reason the situation will be very like the benzene ring. In other words, we can take the solution for ψ , infinite line set in addition to the solution must be periodic with a cycle of six along. From Chapter 13 the idea being, in fact, that ψ is of finite energy when the amplitude at each site is finite. And each ψ the energy is

$$E = E_0 - 2A \cos \frac{\pi k}{6} \quad (15-2)$$

We want to end now with the law of sums which repeat every 6 atoms. Let's find the general case for a ring of N atoms. If the solution is to have a period 12-4

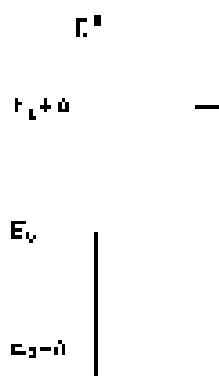

Fig. 15-6. The possible energy levels for the "extra" electrons in the ethylene molecule.

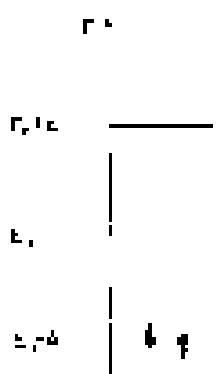

Fig. 15-7. In the extra bond of the ethylene molecule two electrons, one spin up, one spin down, can occupy the lowest energy level.

of N atomic species, each may be unity or it may be a multiple of $\frac{1}{2}$. Taking $\psi = \pm \sqrt{\lambda}$ instead, the conclusion is that

$$\langle \psi | \psi \rangle = N_{\text{sp}} \quad (15.26)$$

We have seen before that there is no meaning to taking ψ 's outside the square root. This means that we get all possible states by taking values of ψ in the range $= \pm \sqrt{\lambda}$.

We find also that N_{sp} in Nalor's case there are six degenerate energy states and they have wave numbers k_x given by

$$k_x = \frac{2\pi}{N_{\text{sp}} a} \quad (15.27)$$

Each state has the energy (15.25). We have a fine spectrum of possible energy levels. The seven numbers $(N_{\text{sp}} = 4)$ is shown in Fig. 15.8(b); the numbers in parentheses indicate the number of different states with the same energy.

There's a nice way to visualize the six energy levels we've been discussing (Fig. 15.8c). Imagine a molecule centered on a level with E_1 , and with a radius of $a/2$. If we start at the bottom and work our way up to a point just below the vertical height of $2\pi/a$ from the center, we'll end up at E_2 (Fig. 15.8c). The six points represent the six possible states. The lowest-energy level is at $(E_1 - 24)$; there are two states with the same energy ($E_1 - 12$), and so on. These are possible energy states for one electron. If we have more than one electron, two with opposite spins can go into each one.

For the benzene molecule we have to put in six electrons. For the ground state they will go into the lowest possible energy states: one at $\epsilon = 0$, two at $\epsilon = -12$, and two at $\epsilon = -24$. According to the independent-particle approximation the energy of the ground state is

$$E_{\text{total}} = N(E_1 - 24) + 2(E_1 - 12) + 2(E_1 - 0) \\ = 6E_1 - 84 \quad (15.28)$$

The energy is increased less than that of three separate double bonds—by the account of 24.

By comparing the energy of benzene to the energy of ethylene it is possible to determine A . It comes out to be 0.4 electron volt, or, in old units the chevalier libri, 14 kilocalories per mole.

We can use this description to calculate or understand other properties of benzene. For example, using Fig. 15.8b we can discuss the excitation of benzene by light. What would happen if we tried to excite one of the electrons? It could move up to one of the empty higher states. The lowest energy of excitation would be a transition from the highest-filled level to the lowest-empty level. That is at the energy 24. Benzene will absorb light of frequency ν when $\hbar\nu = 24$. Light will also be absorbed with the energies 12 and 4. (Indeed, in one of the absorption spectra of benzene has been measured and the pattern of spectral lines is more or less constant except that the lowest transition occurs in the ultraviolet and its frequency would have a definite value of 4 between 12 and 24 electron volts.) That is, the numerical value of A is two or three times larger than is predicted from the theory of bonding energy.

When we calculate these quantities like this it is usually more convenient of a simpler form and you won't remember much. In fact, for example, for calculating bonding energy use such and such a value of A , but for getting the absorption spectrum upon relatively light use another value of A . You may feel

[†] You might think that $2\pi/N$ is even number. Here are $N = 1$ states. That is not so because $\psi = \pm \sqrt{\lambda}$ give the same ψ .

[‡] When there are two states (which will have different amplitude of overlap) with the same energy, we say that the two states are "degenerate." Notice that your electrons can have the same $E_1 - A$.

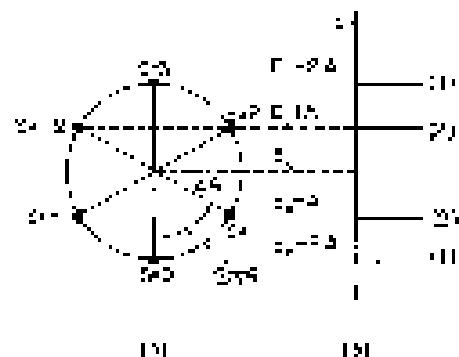

Fig. 15.8. The energy levels belonging to the molecule of benzene. (a) The hexagonal ring with six vertices (levels). (b) The energy levels belonging to the molecule of benzene. (c) The circle with radius $a/2$ centered at E_1 .

But this seems a little absurd. It is not easy to justify from the point of view of a physicist who is trying to understand the world from first principles. But the problem of the chemist is different. He must try to predict what will happen when he is going to heat up a substance so that it may decompose, or in which order various substances will decompose. Now he needs to know of several types of reaction. It doesn't make much difference where they come from. So we use the theory in a site... To satisfy them the physicist. He likes to have theories as abstractions of the facts in them, but then he must always be concrete in them - making experiments.

In the case of human life the "principles" used in the interventionary is not the simpler theory that all elements are independent—the theory we started with is really not legitimate. Nevertheless, it has some shadow of the truth because it results in more or less action in the right direction. We know approximate place where organized sub-environment varies (especially the *organic* climate) takes us way through the rounds of complicated things it cannot be easy. (Dunlop says that the reason a physician can easily calculate from his principles is that he chooses only simple problems. He never comes to a situation with 40 or even 50 variables in it. So far he has been able to calculate reasonably accurately only the 10 or 12 or 15 or 20 minimum items.)

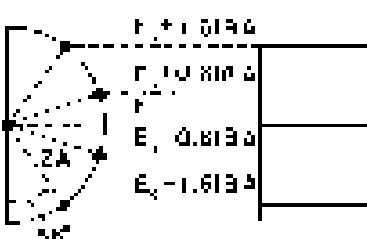

Fig. 15-11. The energy level diagram for the hydrogen atom.

We can play the same game with the wave function except along the two center lines. If we move from left to right, the center is on a line that already corresponds to index 1, Eq. (2), (which I only asked you to solve for infinite λ). But the solution is not unique, we can include the one from Eq. (1). Watch! Now, let me add a few terms on the line and remove them from the basis shown in Fig. 15-10. In writing the equations for the magnitude of position 1 you would not have to be in trouble, but in trouble? Similarly, the equation for position 2 would differ from before, but we need not be in trouble, the rest of time would be nothing new if position 2 is 1, but suppose that we can't get it to zero. In the infinite case we have following procedure, the sum should go to zero even if it is not zero, the sum of the absolute value of the coefficients from the equations from Eqs. 9 or the finite lines 1, 2 to avoided. You might think no such solution exists for a finite line because all the terms all looked like $\lambda^{\pm n}$ which has the same absolute value of the amplitude everywhere. But you are wrong because the energy depends only on the absolute value of λ , so the other solution, which is exactly legitimate in the continuity, would be $\lambda^{\pm n}$. And the same argument applies to a superposition of two such solutions. By superposing them we can set the amplitude equal to zero, which requires the requirement that the amplitude be zero at $\lambda = 0$. It will correspond to the energy $E_0 = -24 \text{ meV}$. Now my question is what the value of λ we can choose to get amplitude zero at $\lambda = 0$? This requires that $\psi_0 = -\psi_1$ as a multiple of ψ_0 or that

$$B = \frac{c}{(q-1)} \cdot S \quad (1^{\text{st}} \text{ eq})$$

where i is an integer from 1 to M . (We take only positive N 's because each solution contains a term $-k$; changing the sign of k gives the same set of all even N 's.) Then, the solution involves $\psi = \phi \times \text{Bessel}(kx) \times \text{cos}(k\theta)$.

$$M_{\rm min} = 1.5 \cdot 10^{-3} M_{\odot}, \quad M_{\rm max} = 10 M_{\odot}, \quad M_{\rm crit} = 5 \cdot 10^{-3} M_{\odot}. \quad (15.1)$$

We can repeat the same procedure as above, however since α is now fixed we do not have to. This time we use a semi-infinite interval for input parameter x , shown in Fig. 12-1. The point at the bottom corresponds to $x = 0$. While you can see $\mu(x)$

case is one of the points at the top, which corresponds to $\delta = 1$, the resonance dipole giving us four allowed curves. These are four valence states, such as what we expect having started with a π -electron with the double bond on the angular interval, and $\pi/3$ to $2\pi/3$ degrees. The lowest energy comes from $\delta_1 = -81.46$ eV, while gradually increasing higher, the golden mean of the Chebnet gives us the lowest energy state of the butadiene molecule according to his theory.¹

Now we can calculating the energy of the excited molecule when θ_2 put in two electrons. With θ_2 next time we will try the lowest π -levels each with two electrons of opposite sign. The total energy is

$$E = 3(E_1) + 1(E_2) + 0(E_3) + 0(E_4) = 0 = 0.407 \text{ eV}$$

This result seems reasonable. The energy is much lower than for two single double bonds, but the π -bond is not so strong as in benzene. Anyway, let's fix now the electron density around this molecule.

The chemist can do not only the energies but the probability amplitudes as well. Knowing the amplitudes in each state, one should either are occupied, he can tell the probability of for any π -electron anywhere in the molecule. These states where the electrons are most likely to be found. In the next we investigate substitutions, which explain the π -electrons are shared with some other group of atoms. The reaction rates increase if there is some in these substitutions effect. It's equivalent to yield an extra electron to the system.

The same here we have one π -ring and give us some unpaired energy of a molecule with two π -systems as in dimethyl-pheophytin shown in Fig. 15-12. Now we can see double and single bonds as well as three methyl groups from a large clockwise ring with twenty electrons. Let's to the electrons of the double bonds remain around this ring. Using the π -dependent basis & method we can see a whole set of energy levels. There is a strong absorption band transition between these levels which is in the visible part of the spectrum and give this molecule its coloring role. Similar compounds molecules such as the methoxygiant, which we've discussed, can be studied.² (see p. 300).

There is one more law which emerges from the application of the kind of theory in organic chemistry. It is probably the most accessible of all laws in a certain sense. The most occurs in the first case with the question: In what substances does a particular strong chemical binding? The answer is very interesting. Take the same π -calculus basis and compare the sequence of curves that occurs now, even with the connection of molecules and adiabatic and photo-electron. We would start by bringing all electrons toward the origin as positive. But since we put the charge of the molecule to zero, takes the number of the number of electrons. First, like $\delta_1 = 0$ since we don't know what it is, we get the curve shown in Fig. 15-13. For the first we calculate the slope of the Coulombic potential V . For each successive group of electrons, increases and decreases exponentially in slope between the groups of electrons. The slope changes when one has just finished filling a set of molecules after these electrons and then goes up to the next higher set of levels for the next electrons.

The second change of the behavior looks very quite different from the curve of Fig. 15-13 because of the interaction of the electrons and because of excited states electrons we have two competing. These corrections will however not with error in the seventh view. For if we scale the values of these corrections, the resulting energy of the molecule still have only a few values in which not happen a Coulomb energy level.

Now consider a new seventh curve due to the points of the average for the one drawn in Fig. 15-14. We clearly see that the points above this curve have "quantum" character, and the points below the curve have "classical character".

¹ The role of resonance of existing interest in molecular mechanics and a similar reference.

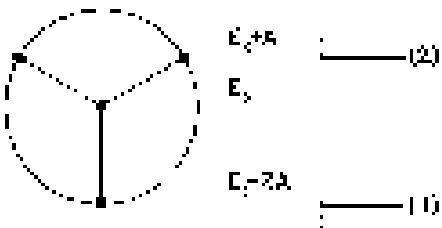

Fig. 15-15. Energy diagram for a ring of three.

example. We would, however, expect that the configurations with a fewer than normal energy would have an above average such hyperactivity-sparking. Notice that the configurations further below the curve always occur at the end of one of the levels. This again is, namely when there are enough electrons left up on "empty shells" so it's willing. This is the very basis of the whole of the theory. Molecules or ions are only really stable (in comparison with other similar configurations) when the available electrons just fit in one empty shell.

This theory has experiment and prediction some very peculiar chemical facts. To take a very simple example, consider a ring of three. It's almost unbelievable that the electrons can make a ring of three and four. You might think that it has been done. The energy diagram for three electrons is shown in Fig. 15-15. Now if you put two electrons in the lower state, you have only two of the three electrons that you require. The third electron must be put in at a much higher level. By our argument this molecule should not be particularly stable, whereas the four-electron state is a scutti-be stable. It does turn out, in fact, that the neutral molecule of triphenyl cyclopropenyl is very hard to make but at the first ionization in Fig. 15-16 is relatively easy to make. Making of them is more really easy because there is always a large stress when the bonds in an organic molecule make an equilateral triangle. To make a stable one would not do, the structure must be stabilized in some way. Anyway if you add three benzene rings on the corners, the positive ion can be made. (The reason for this requirement of odd-benzene rings is not really understood.)

In a similar way the five-membered ring can also be analyzed. If you draw the energy diagram, you can see in a qualitative way that the five-electron system should be the especially stable structure so that each molecule should be most stable as a negative ion. Now the five-ring is well known and does not make and always makes a negative ion. Surprisingly, you can only get a ring of four & is not very interesting, but that a ring of five in IC base along with should be especially stable as a neutral object.

15-6 Other uses of the approximation

There are now other similar situations which we will describe only briefly. In considering the structure of an atom, we can consider that the electrons fill successive shells. The Schrödinger theory of electron motion can be worked out easily only for an electron moving in a "circular" field—one which varies only with the distance from a point. We can then understand what goes on in an atom which has 12 electrons! One way is to use a kind of independent-particle approximation. First you calculate what happens with one electron. You get a number of energy levels. You put an oxygen into its usual energy shell. You can, for a rough model, continue to ignore the electron interactions and go on filling successive shells. In there is a way to get both electrons by taking the account—an approximate way of saying the effect of one extra charge carried by one electron. Each time you add an electron you compute its amplitude to be at various places and then see this amplitude is actually a kind of spherically symmetric charge distribution. You see the field of the distribution—regular with respect to the positive nucleus and all the previous electrons—to calculate the states available to the next electron. In this way you can get reasonably accurate estimates for the energies for the central atom and the outer occupied shells. You find that there are energy wells, just as we saw for one electron in a ring molecule. With a partially filled shell, the atom will seek a preference for having one or more electrons in the lowest state that has to go into the next shell outside of a full shell.

The theory explains the oddities behind the fundamental chemical properties which show up in the periodic table of the elements. The last group of these elements in which a single valence electron is present, and it is especially difficult to make them react. (Some of them do react of course—such as carbon and oxygen, for example, but such compounds are very weakly bound, the associated interaction is nearly zero.) An atom which has one valence electron has less

the α has got off easily losing just one electron to set into the excited state); low-energy excitation which comes from here to a completely filled shell—they are the very noble chemical elements of valence = 0 or $-$.

The other situation is found in nuclear physics. In nuclei, nucleons—protons and neutrons interact with each other quite strongly. From the independent particle model can again be well-defined a shell structure. Twisted discoveries eventually in nuclei were reported shortly after they calculated certain magic numbers by Gurney (1932, 1933, 1934, 1935, 1936). Since there was literally no explanation for these numbers they were called "magic numbers" at nuclear physics. It is well known that nucleons don't interact strongly with each other—people were therefore quite surprised when it was discovered that an independent particle model predicted a shell structure which came out with the first few magic numbers. The model assumed that each nucleon (proton or neutron) remained in a central potential which was created by the exchange effects of all the other nucleons. This model failed, however, to give the correct values for the magic numbers. Then it was discovered by Maria Goeppert Mayer, and independently by Jensen and his collaborator, that by taking the independent particle model and adding only a correction for what is called the "spin-orbit interaction," one could calculate an improved model which gave all of the magic numbers. (The spin-orbit interaction states the energy of a nucleon to be lower if its spin has the same direction as its orbit's angular momentum from motion in the nucleus.) The "spin-orbit correction" is also called "the so-called 'shell structure'" of the nuclei, though it is not related with the necessities of nuclei and their interactions.

"An independent particle approximation has been...a valuable range of subjects: from solid-state physics, to chemistry, to biology, to nuclear physics. It is often only a crude approximation, but it is very useful in understanding why there are especially stable configurations of shells. Since it is all of the complexity of the interactions between the individual particles, we thank you for accepting that a student's opportunity to grow correctly many important details."

The Dependence of Amplitudes on Position

16-1 Amplitudes on a Line

We are now going to discuss how the probability amplitude of a atom is related to ψ_{1s} in space. In some of the earlier chapters you may have had a prior impression that all of the wave function was being cut off. This is only what we are talking about here, in principle, you do not do this in the theory of quantum theory. But one has to say which the situation in which it is necessary, since we "lived" in the plane of the three oxygen atoms, and for the other two ways we took on the condition is set that one oxygen atom was "below" the plane of the three oxygen atoms. Very likely we pick just these two sites.¹ Why is it not possible that the oxygen atom could be at a hydrogen above the plane? C_6H_6 ? In there are many positions that the hydrogen atom is allowed. Again we see we take along the hydrogen molecular bond, in which there is one site surrounded by two hydrogens, we know well, we have shown, and so the electron in the hydrogen bond of C_6H_6 jumps from and the other for the electron in the oxygen, enclosed of proton number two. Clearly we were being very many details. The electron is not necessarily at proton number two, but is only to the neighborhood it could be somewhere there or perhaps even when below the proton, or maybe even to the left of the proton or somewhere to the right of the proton.

We fundamentally assumed wavefunction Little details. We said that we were interested in only certain features of the position so we were imagining that with the electron we in the vicinity of proton number two, it would take up a certain energy definite state. In that condition the probability to find the electron would have come to be definitely restricted around the proton, and we were not interested in the details.

We can also put another way. An electron in a hydrogen molecule has got to move in approximately a region where we described the situation in terms of two base states. Interacting there are four kinds of the states. And then one has to be up essentially around 2.3732 ± 0.00007 , or greater than one, but there are many excited states. For each excited state the distribution of the electron around the proton is different. We ignore all these excited states, saying that we were interested in only the components of free energy. But it is not these other excited states which give the possibility of various distributions of the electron around the proton. If we want to do this, to recall the oxygen negative ion, we have to take into account these other possible base states. We could do this in several ways, one one way is to consider the orbital paths in which the motion of the electron in space is more or less described.

We are now ready to consider a more detailed discussion where we allow us to talk in detail about the position of the electron by giving a probability amplitude of five. In fact in most books you will see everywhere the given as six. This more complete theory provides the model fitting for the calculations we have been making in our earlier discussions. The same number of equations can be derived as a kind of generalization to the more complete theory.

You may be wondering why we did not learn such the more complete theory and make the approximations as we want doing. We have said that it would be much easier for you to gain an understanding of the basic mechanics of quantum mechanics by beginning with the two-state approximation and working gradually up to the more complex theory than to approach the subject in the usual way. It is good. For this reason the approach to the subject requires to be in the reverse order to the one you will find in many books.

16-1 Amplitudes on a line

16-2 The ψ_{1s} function

16-3 States of definite momentum

16-4 Normalization of the states in L^2

16-5 The Schrödinger equation

16-6 Quantized energy levels

As we go into the subject of this chapter you will realize that we are breaking a rule we have always followed in the past. Whenever we have taken up any subject, we have always tried to give a more or less complete description of the theory—showing you as much as we could about it. Since the idea has been “We have tried to describe the general consequences of a theory as well as describing some specific detail—but you can see where the theory would lead.” We are now going to break that rule because we are trying to describe how one can fit the probability amplitudes in space and show you the different equations which they satisfy. We will not have time to go into all the details of the various implications which come out of the theory. Instead we will just have to go far enough to relate this theory to some of the approximations which we have used earlier. For example, to the hydrogen molecule or to the diatomic molecule. Perhaps you might have a hunch—uninformed and unprepared. We are approaching the end of our course, and we must surely confess with trying to give you an induction to the general ideas and start indicating the connections between what we have been describing and some of the other ways of approximating the subject of quantum mechanics. We have to give you enough opportunity that you can go off by yourself and by reading books here about some of the implications of the equations that we are going to describe. We must after all leave something to the future.

Let's review once more what we have found out about how an electron can move along a line of atoms. When an electron has an amplitude to jump from one atom to the next, there are definite energy states in which the probability amplitude to find the electron at a distance along the lattice is the form of a travelling wave. For long wavelength, i.e., small values of the wave number k , the energy of the state is proportional to the square of the wave number. For a typical state with the spacing Δx at which the amplitude per unit size for the electron to jump from one atom to the next is a_0 , the energy of the state is related to k (per atom) by

$$E = \frac{e^2}{4\pi\epsilon_0} k^2 \quad (16.1)$$

(see Section 13.3). We also saw that groups of such waves with similar energies would make up a wave packet which would behave like a classical particle with a mass m_e given by

$$m_e = \frac{\hbar^2}{2\Delta x} \quad (16.2)$$

Since waves of probability amplitude a cannot behave like a particle, one might well expect that the general quantum mechanical description of a particle would show the same kind of wave behavior we observed for the lattice. Suppose we were to think of a lattice on a line and imagine that the lattice spacing Δx were to be very small and smaller. In that limit we would be thinking of a state in which the electron could be anywhere along the line. We would have just one continuous distribution of probability amplitudes. We would have no amplitude to find an electron anywhere along the line. This would be one way to describe the motion of an electron in a vacuum. In a framework like this, space can be labeled by an infinity of points all very close together and we can work out the equations that relate the amplitudes at one point to the amplitudes at neighboring points. we will have the continuum mechanics laws of motion of an electron in space.

Let's begin by reviewing some of the general principles of quantum mechanics. Suppose we have a particle which can exist in various conditions in a system in a mechanical space. Any particular condition or state can be found in, we call it, “space,” which we label with a state vector, say $| \psi \rangle$. Some other condition would be labeled with another state vector, say $| \phi \rangle$. We then introduce the idea of base states. We can then choose a set of states $| 1 \rangle, | 2 \rangle, | 3 \rangle, \dots$, and so on, which have the following properties. First, all of these states are quite distinct—we say they are orthogonal. By this we mean that for any two of the base states, $| \beta \rangle$ and $| \gamma \rangle$, the amplitude $\langle \beta | \gamma \rangle$ that a electron, known to be in the state $| \beta \rangle$ is also in the

state $|j\rangle$ is equal to zero—unless, of course, $j = 0$ and ψ is odd for the wave function. We represent this symbolically by

$$\langle j | \hat{j} | \psi \rangle = \delta_{j0}. \quad (16.1)$$

You will remember that $\delta_{j0} = 0$ if j and j_0 differ, and $\delta_{j0} = 1$ if j and j_0 are the same numbers.

Second, the base state $|\psi\rangle$ must be a complex wave so that any state or field can be described in terms of them. That is, any wave, $\psi(x)$, can be described completely by giving all of the amplitudes of $|\psi\rangle$ that a particle in the state $|\psi\rangle$ will also be found in the state $|j\rangle$. In fact, the wave function $\psi(x)$ is equal to the sum of the wave functions each multiplied by a coefficient which is the amplitude of the state $|j\rangle$ in the wave $|\psi\rangle$.

$$|\psi\rangle = \sum_j c_j |j\rangle, \quad (16.2)$$

Finally, if we consider any wave state $|\phi\rangle$ and $|\psi\rangle$ the amplitudes that we gave $|\phi\rangle$ will also be in the state $|\psi\rangle$ can be found by first preparing the state $|\phi\rangle$ in the base states and then projecting back each one into the state $|\psi\rangle$. We write that in the following way:

$$\langle \phi | \psi \rangle = \sum_j \langle \phi | |j\rangle \langle j | \psi \rangle. \quad (16.3)$$

For summation j , of course, to determine c_j over the whole set of base states $|j\rangle$.

In Chapter 11 when we were working out what goes on in an unoccupied or a linear array of atoms, we chose a set of base states $|j\rangle$ which the electron was localized at one or either of the atoms in the line. The base state $|j\rangle$ represented the atom in which the electron was localized at atom number “ j .” (There is, of course, no significance in the fact that we called our base states $|j\rangle$ instead of $|0\rangle$.) At this time, we found it convenient to label the base states by the coordinate x_j of the atom rather than by the number of atom j in the array. The state $|x_j\rangle$ is either way of writing the state $|j\rangle$. Then, following the general rules, any state in QM, $|\psi\rangle$, is described by giving the amplitudes and that an electron in the state $|\psi\rangle$ is also in one of the states $|x_j\rangle$. Thus, whenever we have to refer to symbols, we want to choose amplitudes,

$$c_j = \langle \psi | x_j \rangle. \quad (16.4)$$

Since each base state associated with a location along the line, we expect each of the amplitudes c_j as a function of the coordinate x and write it as $C(x_j)$. The amplitude $C(x_j)$ will, in general, vary with x and j ; there is also the factor of i . We will generally bother to show explicitly the dependence.

In Chapter 11 we had proposed that the amplitudes $C(x_j)$ should vary with x in a way described by the Hamiltonian equation (Eq. 16.2). In the new notation this equation is

$$i\hbar \frac{dC(x_j)}{dx} = E_j C(x_j) = -4C(x_j + \Delta) + 4C(x_j - \Delta), \quad (16.5)$$

The last two terms on the right-hand side represent the process in which an electron travels from atom j to atom $j + \Delta$ and back again.

We found that Eq. 16.5 has solutions corresponding to relative energy states, which we wrote as

$$C(x_j) = e^{iE_j x_j / \hbar}, \quad (16.6)$$

For the low-energy states the wavelengths are large (k is small), and the energy is related to k by

$$E_j = (E_F - 144) + 2k^2 \hbar^2. \quad (16.7)$$

For electrons near zero of energy we find $(E_F - 144) = 0$ because E_F is given by Eqs. 16.1.

Let's see what might happen if we were to let the lattice spacing Δx go to zero, keeping the wave number k fixed. If ψ_0 is still between x_0 and x_1 , the last term in Eq. (16.9) would just go to zero and there would be no physics. But suppose k and ϵ are varied together so that k goes to zero the product $k\epsilon$ is kept constant. For $k \ll k_0 = \pi/\Delta x$ we will write $k\epsilon^2$ as the constant $M/\Delta x^2$. Then there is no surprise, Eq. (16.8) would not change, but what would happen to the differential equation, Eq. (7.1)?

For ϵ we will use $\epsilon = \epsilon_0 + \delta \epsilon$.

$$i\hbar \frac{\partial \Psi(x)}{\partial t} = (\epsilon_0 - M\chi(x_0) - M\chi(x_1)) + C\epsilon_{x_0} + N + C\epsilon_{x_1} = \psi_0. \quad (16.10)$$

For small values of $\delta \epsilon$, the first term is dominant. Now we can think of a continuous derivative of ϵ that goes smoothly through the point ϵ_0 at x_0 and x_1 . As the amplitude ψ goes to zero, the solution gets close and close together, and (if we keep the variation of ϵ fairly small) the quantity in parentheses is just proportional to the second derivative of $C\chi$. We can write (as you can see by making a Taylor expansion of $\psi(x)$ about the center)

$$\chi(x) = C(x + \delta) = C(x - \delta) \approx -i\hbar \frac{\partial^2 \chi(x)}{\partial x^2}. \quad (16.11)$$

In this limit, then, as δ goes to zero, keeping $\delta^2 \epsilon$ equal to M , Eq. (16.10) goes over into

$$i\hbar \frac{\partial \Psi(x)}{\partial t} = -\frac{C^2}{\Delta x^2} \frac{\partial^2 \Psi(x)}{\partial x^2}. \quad (16.12)$$

We have an equation which says that the time rate of change of Ψ is proportional to Δx and the second derivative of the amplitude. It has the effect of damped oscillations in a way which is proportional to the square derivative of the amplitude with respect to position.

The correct quantum mechanical equation for the motion of an electron in free space was first discovered by Schrödinger. For motion along a line it has exactly the form of Eq. (16.12); if we replace ψ by ψ , the free-space mass of the electron, the motion equation like ours space the Schrödinger equation:

$$i\hbar \frac{\partial \Psi(x)}{\partial t} = -\frac{e^2}{2m} \frac{\partial^2 \Psi(x)}{\partial x^2}. \quad (16.13)$$

We do not intend to have you think we have derived the Schrödinger equation, not only with us, but you and every one thinking about it. When Schrödinger first wrote it down, he gave a long narrative to his friend, the other great Nobel laureate Niels Bohr, in which he explained what he had done. In this narrative he said some rather interesting things. Some of the coefficients he used were even, like, all that does not matter, the only important thing is that the ultimate equation gives a correct description of nature. I am purposefully digressing a bit simply to show you that the correct fundamental quantum mechanical equation is not just the same form you get for the limiting case of an electron or electron-like particle. This makes the wave function of the differential equation to be (6.13) as describing non-antisymmetric probability amplitude from one point to the next along the line. That is, than each point has certain amplitude to go to our pixel. It will be little. One has to have some amplitude to be at neighboring points. In fact the equation looks something like the diffusion equation which we have used in Lecture 1. But there is one main difference: the imaginary coefficient, i, factor of the time derivative makes the solution exponentially different from the ordinary diffusion, such as you would have for a gas spreading out along a thin tube. Oscillatory behavior gives rise to real exponential solutions. Whereas the solutions of Eq. (16.13) are complex waves.

* You can imagine that as the pixels x get closer together, the amplitude ψ is jumping from x_0 up to x_1 will increase.

16-1 The wave function

Show that you have some idea about how things are going to work, as you go back to the beginning and study the problem of describing the motion of an electron along a line without losing its initial state connected with atoms with lattice. We want to go back to the beginning and see what rules we have to use if we want to describe the motion of a free particle in space. Since we are interested in the behavior of a free electron, we come down to the shell up which another chapter of physics is based. You will see the ideas we have developed for dealing with a finite number of states will need some technical modification.

We begin by letting the state vector ψ stand for a state in which a particle is located precisely at the coordinate x . The energy value is along the line $E = E(x)$, Eq. 16.07, or 16.08. This is the corresponding state. We will take these states $|\psi\rangle$ as in these states and, if we include all the points on the line, we will have a complete set of states in one dimension. Now suppose we have a different kind of a state, say $|\psi_x\rangle$, in which the electron is distributed in some way along the line. One way of describing this state is to recall from Chapter 11 that the electron will be also found in each of the base states $|\psi\rangle$. We may give an infinite series of amplitudes, one for each value of x . We will write these amplitudes as $C(x)$. Each of these amplitudes is a complex number and since the C is just such complex number for each value of x , the amplitude $C(x)$ is called just a function of x . We will also write it as $C(x)$,

$$C(x) = \langle x | \psi \rangle \quad (16-1)$$

We have already discussed such amplitudes while they are continuous over with the coordinates when we talked about the variation of amplitude with time in Chapter 9. We observe here, for example, that a particle with a definite momentum should be expected to have a particular relation of x and amplitude in space. If a particle has a definite momentum p and wave number k defined over R , the amplitude is to be found at any position x would be like

$$\langle x | \psi \rangle = C(x) \propto e^{ikx}, \quad (16.05)$$

This equation expresses the important general principle of quantum mechanics which connects the base states corresponding to different wave numbers or different spatial distributions of the state of infinite momentum. The infinite momentum state is often more important than base states in other certain kinds of problems. The set of base states is, of course, usually acceptable for a description of a quantum mechanical situation. We will come back later to the matter of the relation between them. For the moment we want to stick to our connection of a description in terms of the states $|\psi\rangle$.

Before proceeding, we want to make one sort of change in notation which we hope will not be too confusing. The function $C(x)$, defined in Eq. (16.05), is of course here a wave vector, except on the particular point x under consideration. We should indicate that in some way. We should, for example, specify which function $C(x)$; we are talking about by a subscript, say, $C_0(x)$. Although this would be perfectly satisfactory notation, it is a little too cumbersome and is not the one you will find in most books. Most people simply omit the letter C and use the symbol ψ to define the function

$$\psi(x) = C_0(x) = \langle x | \psi \rangle. \quad (16.06)$$

Since this is the notation used by everybody else in the world, you might as well get used to it so that you will not be confused when you come across it somewhere else. Remember though, that we will now be using ψ in two different ways. In Eq. 16.04 ψ refers to a total wave given to a particular physical state of the electron. On the left hand side of Eq. 16.06, on the other hand, the symbol ψ is used to define a mathematical function of x which is equal to the amplitude to be associated with each particular displacement. We hope it will not be too confusing.

Once you get accustomed to the idea, conveniently, the function $\psi(x)$ is usually called "the wave function" — because it encodes all the relevant information about the system.

Since we have defined $\psi(x)$ to be the amplitude that an electron in the state ψ will be found at the position x , we would like to compute the absolute square of $\psi(x)$ to get probability of finding an electron at the position x . Unfortunately, the probability of finding a particle exactly at any one point is zero. The answer will, in general, be averaged out in a certain region of the line, and since, in any small piece of the line, there are an infinite number of points, the probability that it will be at any one of them is then be a finite number. We can only describe the probability of finding an electron in terms of a probability amplitude, which gives the relative probability of finding the electron at certain regions over others. *Again*, along the line. Let's take Δx to be a small interval around x . If we go to a small enough Δx in an applied situation, the probability will be varying smoothly from place to place, and the probability of finding the electron in any small finite line segment Δx will be proportional to Δx . We can modify our definition to take this into account.

We can think of the amplitude $\langle x | \psi \rangle$ as representing a kind of "imprint density" for all the possible states ψ in a small region. Since the probability of finding an electron in a small region Δx is proportional to the "intensity" of the wavefunction definition of $\langle x | \psi \rangle$, so that the following relation holds:

$$|\psi(x)|^2 \Delta x = |\langle x | \psi \rangle|^2 \Delta x$$

The amplitude $\langle x | \psi \rangle$ is therefore proportional to the "intensity" that an electron in the state ψ will be found in the box x , and the constant of proportionality is determined by the absolute square of the amplitude $|\langle x | \psi \rangle|$, giving the probability density of finding an electron in a small region. We can write, equivalently,

$$\text{prob}(x, \Delta x) = |\psi(x)|^2 \Delta x. \quad (16.17)$$

We will now come to modify some of our earlier equations to make them compatible with this new definition of a probability amplitude. Suppose we have an electron in the state $|\psi\rangle$ and we want to know the amplitude to find up in a different state $|\phi\rangle$, which may correspond to a different bound state condition of the electron. When we were talking about bound states in discrete states, we would have used Eq. (16.8). Before modifying our definition of the amplitudes we would have written

$$\langle \phi | \psi \rangle = \sum_{\text{all } n} \langle \phi | n \rangle \langle n | \psi \rangle. \quad (16.18)$$

Now, each of these amplitudes are normalized in the same way as we have been writing them, that is, sum of all the states in a complete region Ω would have to be 1, due to multiplying by Δx , and the sum over n values of $\langle n | \psi \rangle$ is simply because an integral. With our modified definition, the correct form becomes

$$\langle \phi | \psi \rangle = \int_{\text{all } \Omega} \langle \phi | n \rangle \langle n | \psi \rangle / \Delta x \, dx. \quad (16.19)$$

The amplitude $\langle \phi | \psi \rangle$ is what we are now calling $\psi(\phi)$ and, in a similar way, we will choose to let the amplitude $\langle \psi | \phi \rangle$ be represented by $\phi(\psi)$. Furthermore, since $\langle \phi | \psi \rangle$ is the complex conjugate of $\langle \psi | \phi \rangle$, we can write Eq. (16.8) as

$$\langle \phi | \psi \rangle = \int_{\text{all } \Omega} \psi^*(x) \phi(x) \, dx. \quad (16.20)$$

Here are new definitions everything follows with the same formulae as before if you always replace a summation sign by an integral over Ω .

We should mention one qualification to what we have been saying. Any suitable set of base states must be complete if it is to be used for an arbitrary

⁴ For a discussion of probability distribution see Vol. I, Section 6.4.

Consider now what is going on. For an electron's wavefunction it is not really sufficient to specify only the horizontal position because of course there are electrons moving up and down as well as left and right. One way of getting a complete set is to take two sets of states in a wavefunction space and have one for down spin. We will however not worry about such complications for the time being.

16-3 States of definite momentum

Say we have an electron in a state $|\psi\rangle$, which is described by the probability amplitude to find $\psi = \psi(x)$. We know that the momentum in which the electron is spread is along the line in a certain direction, so that the probability of finding the electron in a small interval dx at the location x is just

$$|p(x)|^2 dx = |\psi(x)|^2 dx.$$

What can we say about the momentum of this electron? We might ask what is the probability that the electron has the momentum p ? Let's start out by calculating the amplitude that the state $|\psi\rangle$ is in some momentum $|p\rangle$ (which we define to mean one with the definite momentum p). We can find the amplitude by using our basic equation for the states of amplitudes, Eq. (16.20). In terms of its states, we may

$$\langle \text{mom } p | \psi \rangle = \int_{-\infty}^{\infty} \langle \text{mom } p | x \rangle \psi(x) dx, \quad (16.21)$$

and the probability that the electron with initial wavefunction $|\psi\rangle$ should be given in terms of the absolute square of the amplitude. We have noted, however, a small problem about the normalization. In general we can't care about the probability of finding an electron with a momentum p since if you do at the momentum p , the probability that the momentum is exactly some value p may be zero unless the state $|\psi\rangle$ happens to be a state of definite momentum. Once $\langle \psi | \psi \rangle$ is 1, the probability of finding the momentum in a small range dp at the momentum p will weight a definite probability. This is the reason why the normalization of $|\psi\rangle$ is required. We will choose one of these which we think to be the appropriate, although that may not be apparent to you at the moment.

We take our normalizations such that the probability is related to the amplitude ψ

$$p(x) (p, dx) = \langle \text{mom } p | \psi \rangle^2 \frac{dx}{m}, \quad (16.22)$$

With this definition the normalization of the amplitude (temporarily) is determined. The amplitude (now ψ) is, of course, just the complex scaling of the amplitude (or more ψ) which is just the one we have written down in Eq. (16.18), with no normalization we have chosen, or forced out that the proper constant of proportionality in front of the exponential is just 1. Now this

$$\langle \text{mom } p | \psi \rangle = \langle \psi | \text{mom } p \rangle^* = e^{-ipx/\hbar}, \quad (16.23)$$

Eq. (16.23) then becomes

$$\langle \text{mom } p | \psi \rangle = \int_{-\infty}^{\infty} e^{i(px/\hbar)} \langle p | \psi, dx. \quad (16.24)$$

This combined with Eq. (16.22) allows us to find the momentum distribution for every x in Eq. (2)

Let's look at a particular example. To illustrate this let's take an electron scattered in a vertical region around $x = 0$. Suppose we have a wave function which has the following form:

$$\psi(x) = R_0 e^{-k|x|}. \quad (16.25)$$

The probability distribution in x for this wave function is the case the square in

$$\text{prob}(x, dx) = P(x) dx = R_0^2 e^{-2k|x|} dx. \quad (16.26)$$

The probability density function $P(x)$ is the Gaussian curve shown in Fig. 16-1. Most of the probability is concentrated between $x = -\sigma$ and $x = +\sigma$. We say that the "full-width" of the curve is σ . (Here σ is equal to the root-mean-square of the error.) The x for summing carry out according to the distribution. We would normally choose the constant K so that the probability density $f(x)$ is zero merely \pm equivalent to the probability per unit length of x of finding the electron at x , but here we take with this $f(x)dx$ is equal to the probability $\sim \sigma^{-1}$ of finding the electron in the near x . The constant K which does this can be found by requiring that $\int_{-\infty}^{+\infty} f(x)dx = 1$. Since there must be unit probability that the electron is found somewhere. Here we get just $K = (2\pi\sigma^2)^{-1/2}$. This has been checked that $\int_{-\infty}^{+\infty} e^{-x^2/\sigma^2} dx = \sqrt{\pi}$, see Vol. I, page 40-6.1.

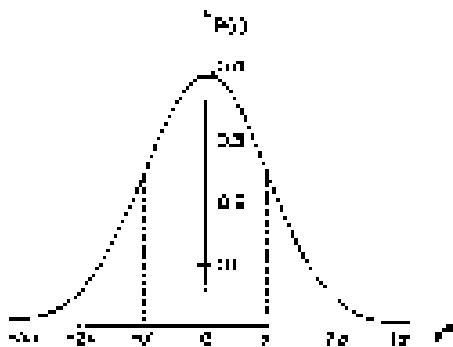

Fig. 16-1. The probability density for the wave function of Eq. (16-24).

Now let's find the distribution in momentum. To do this we $\langle p | \psi(p) \rangle$ and do the amplitude to find the connection with the momentum p .

$$\phi(p) = \langle p | m/m_p | \psi \rangle. \quad (16-27)$$

Substituting Eq. (16-25) into Eq. (16-26) we get

$$\phi(p) = \int_{-\infty}^{+\infty} e^{-x^2/\sigma^2} K e^{-ipx/\hbar} dx. \quad (16-28)$$

The integral can easily be evaluated as

$$K e^{-x^2/\sigma^2} \int_{-\infty}^{+\infty} e^{-ipx/\hbar} dx = K e^{-x^2/\sigma^2} \int_{-\infty}^{+\infty} e^{-i(p/\hbar)x^2} dx. \quad (16-29)$$

We can now make the substitution $u = x + (p/\hbar)x^2/2\sigma^2$, and the integral is

$$\int_{-\infty}^{+\infty} e^{-i(p/\hbar)x^2} dx = 2\pi\sqrt{\frac{\hbar}{p}}. \quad (16-30)$$

(The mathematicians would probably object to this way we go there, but the result is, nevertheless, correct.)

$$\phi(p) = (2\pi\sigma^2)^{-1/2} e^{-p^2/2\sigma^2}. \quad (16-31)$$

We note the interesting result that the amplitude function, in p has precisely the same mathematical form as the amplitude function in x , only the width of the Gaussian is different. We can write this as

$$\phi(p) = (2\pi\sigma^2)^{-1/2} e^{-p^2/\Delta^2}, \quad (16-32)$$

where the half-width Δ of the Gaussian distribution is related to the half-width σ of the distribution by

$$\Delta = \frac{\hbar}{2p}. \quad (16-33)$$

Our last step if we move the width of the distribution in x very small by making Δx small, ζ becomes large and the distance between x 's is very much spread out. On the contrary, if we have a narrow distribution in x , it must correspond to a spread out distribution in y . We can, if we like, consider ζ to be some measure of the uncertainty in the localization of the wavefunction and of the position of the electron in the state we are studying. If we call them Δ_x and Δ_y respectively, Eq. (16.33) becomes

$$\Delta_x \Delta_y = \frac{\hbar}{2}. \quad (16.34)$$

For example enough, it is possible to prove that for any error term Δ_x in the position in x , in y , the product $\Delta_x \Delta_y$ cannot be smaller than the one we have calculated. The Gaussian distribution gives the smallest possible value for the product of the root mean square errors. In general, we can say

$$\Delta_x \Delta_y > \frac{\hbar}{2}. \quad (16.35)$$

This is a quantitative statement of the Heisenberg uncertainty principle, which we have discussed qualitatively in my previous note. We have usually made the assumption above that the minimum value of the product $\Delta_x \Delta_y$ is of the same order as $\hbar/2$.

16-4 Normalization of the states in x

We return now to the discussion of the modifications to our basic principles which we received when we are dealing with a continuum of base states. When we have a finite number of discrete states in the continuum, for what must be satisfied by the set of base states is

$$C|\psi_i\rangle = \delta_{ij}. \quad (16.36)$$

If ψ_i is called i the base state, the amplitude to be at another base state is C . By choosing a suitable normalization, we have defined the amplitude C to be 1. These two conditions are described by Eq. (16.36). We want now to ask how this relation must be modified when we have the two states $|x\rangle$ of a particle on a line. If the particle is known to be in one of the base states $|\psi_i\rangle$, what is the amplitude that it will be in any other base state $|\psi_j\rangle$? If $|\psi_i\rangle$ and $|\psi_j\rangle$ are two different locations along the line, then the amplitude $\langle\psi_i|\psi_j\rangle$ is really 0, as that is consistent with Eq. (16.36). But if x and x' are equal, the amplitude $\langle\psi_i|\psi_j\rangle$ will not be 0, because of the new field normalization problem. To see how we have to proceed, bring up, we go back to Eq. (16.36), and apply this expression to the special case in which the state $|\psi\rangle$ is just the rest state $|\psi_0\rangle$. We write this form

$$C'|\psi\rangle = \int C'|\psi(x)\rangle dx. \quad (16.37)$$

Now the amplitude $C'|\psi\rangle$ is just what we have been calling the "function" $\psi(x)$. Still, the amplitude $C'|\psi\rangle$, since it refers to the same state $|\psi\rangle$, is the state function of the variable x , namely $\psi(x)$. We can, therefore, use its Eq. (5.32) to

$$\psi(x) = \int C'|\psi(x)\rangle dx. \quad (16.38)$$

This operation is to divide an amplitude, resulting from a arbitrary function $\psi(x)$, into components which completely determine the nature of the amplitude $C'|\psi\rangle$, which is, of course, just a function that depends on x and x' .

Our problem now is to find a function $C(x, x')$ which when multiplied into $\psi(x)$ and integrated over all x gives just the quantity $\psi(x')$. It turns out that there is no mathematical function which will do this "at least nothing like what we ordinarily mean by a "function."

Suppose we pick ψ to be the special number 0 and let ϕ be the single-valued $\psi(x)$ to be some function of x , let's say $A(x)$. Then Eq. (16.39) would read as follows:

$$s(t) = \int f(x)\phi(x) dx. \quad (16.40)$$

What kind of function $\phi(x)$ could possibly satisfy this equation? Since the integral must not diverge, it must be true $\phi(x)$ takes for values at x other than 0, $f(x)$ must clearly be 0 for all values of x except 0. But if $f(x)$ is 0 everywhere, the integral will be 0, too, and Eq. (16.40) will not do either. So we have an impossible situation: we wish a function to be 0 everywhere but at a point, and still to give a finite integral. Since we can't find a function that does this, the easiest way out is just to say that the function $\phi(x)$ is defined by Eq. (16.40). Namely, $\phi(x)$ is that function which satisfies (16.40) itself. The function which does this we shall therefore call $\delta(x)$ and call it δ -function. We shall also say that the $\delta(x)$ -function has the charge property $\delta(0)$, if it is integrated for $f(x)$ in the Eq. (16.40), the integral picks out the value $f(0)$ of $f(x)$. This is when x is equal to 0, and, since the integral must be independent of $f(x)$ for all values of x except 0, the function $\delta(x)$ must be 0 everywhere except at $x = 0$. Since obviously we write

$$\delta(0) = \delta(x) \quad (16.41)$$

where $\delta(x)$ is defined by

$$\delta(x) = \int \delta(x)\psi(x)dx. \quad (16.42)$$

Notice what happens if we use the *smooth* function $\psi(x)$ for the function ψ in Eq. (16.42). Then we have the result

$$1 = \int \delta(x)dx. \quad (16.43)$$

This is because $\delta(x)$ has the property that it is 0 everywhere except at $x = 0$ but has a finite integral equal to 1 only. We must realize that the $\delta(x)$ has such a definite value at one point that the total area under it is equal to one.

One way of imagining what this δ -function is like is to think of a sequence of rectangles—or any other stepped function $\psi(x)$ —which gets narrower and narrower and higher and higher, always keeping its width Δx , as depicted in Fig. 16.3. The integral of this function from $-x$ to $+x$ is always 1. If you multiply it by any function $f(x)$ and integrate the product, you get something which is approximately the value of the function at $x = 0$ (an approximation getting better and better as you use the narrower and narrower rectangles). You can if you wish imagine the δ -function in terms of this kind of limit. By process the only important thing, however, is that the δ -function is defined so that Eq. (16.41) is true for any $\psi(x)$; that is, $\delta(x)$ really *represents* the δ -function. Its properties are then as we have described.

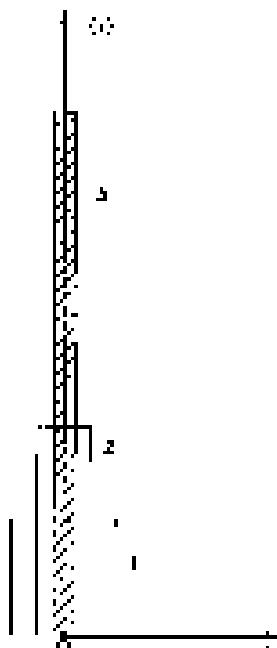

If we change the argument of the δ -function from x to $x - x'$, the corresponding relations are

$$\begin{aligned} \delta(x - x') &= 0, \quad x' \neq 0, \\ \int \delta(x - x')\psi(x)dx &= \delta(x'). \end{aligned} \quad (16.44)$$

If we use $\delta(x - x')$ for the additional $\psi(x)$ in Eq. (16.38), the equation is satisfied. Our reason this is that for non-zero values of x , the condition x corresponding to (16.38) is

$$(x' | x) = \alpha x - x'^2. \quad (16.45)$$

Fig. 16-3. A set of functions, of $\psi(x)$ and $\psi(x')$, which look more and more like $\delta(x)$.

We have now completed the necessary modifications of our basic equations which are necessary for dealing with the continuum of base states corresponding to two points along a line. The situation in three dimensions is fairly obvious; first we replace the coordinate x by the vector \mathbf{x} , then integrate over \mathbf{x} and we are replaced by integrals over x_1 , x_2 and x_3 . In other words, they become volume integrals. Finally, the one-dimensional δ -functions must be replaced by just the product of three δ -functions, one at x_1 , one in y_1 and the other in z_1 : $\delta(x - x_1)\delta(y - y_1)\delta(z - z_1)$. Putting everything together, we get the following set of equations for the amplitudes for particle motion in three dimensions:

$$\langle \psi | \psi \rangle = \int \langle \psi | \psi^*(x, y, z) \rangle d\mathbf{v} d\mathbf{l}, \quad (16.45)$$

$$\langle \psi | \psi \rangle = \langle \psi | \psi \rangle, \quad (16.46)$$

$$\langle \psi | \psi \rangle = \langle \psi | \psi \rangle,$$

$$\langle \psi | \psi \rangle = \int \psi^*(x, y, z) \psi d\mathbf{v} d\mathbf{l}, \quad (16.47)$$

$$\langle \psi | \psi \rangle = \langle \psi | \psi \rangle \delta(x_1 - x') \delta(y_1 - y') \delta(z_1 - z'), \quad (16.48)$$

What happens when there is more than one particle? We will tell you about how to handle two particles and you will easily see what you must do if you want to deal with a larger number. Suppose there are two particles, which we call particle No. 1 and particle No. 2. What shall we get for the base state? First, perfectly good or can be described by us is, that particle 1 is at x_1 and particle 2 is at x_2 , where we can write $x = (x_1, x_2)$. Now, then describing the motion of each separate does not right at base state. That's true since must define the condition of the relative system. You just not think that each particle moves independently as a wave in three dimensions. Any physical state ψ can be defined by a pair of all the coordinates (x_1, x_2, ψ) so that the two particles are located at x_1 and x_2 . This particular combination is therefore a function of the two sets of coordinates x_1 and x_2 . Generally such a function is known as the ψ as an oscillation that moves along in three dimensions. Neither it is really simple position of one individual wave, one for each particle. It is, in general, some kind of wave in the six dimensions defined by x_1 and x_2 . If there are two particles interacting with each other, there is no way of specifying what happens to one of the particles by looking at the wave function for it alone. The former goes does not go consistent in certain situations where the interactions made on one particle were claimed to be able to do what was going to happen to another particle, or were able to destroy an interference—very general people. All sorts of things like measure, they have tried to think of the wave function of one particle about, except that the overall wave function in the six-modes of two particles. The complete description can be given correctly only in terms of functions of the coordinates of both particles.

16.5 The Schrödinger equation

So far we have just been worrying about how we can deal the states which may evolve to elsewhere or anywhere or at the speed. Now we have to work about putting into a description the physics of what can happen in various circumstances. And here we have to worry about how states change with time. If we take a state ψ which goes over the another state ψ' which is also used to describe the situation for $t + \Delta t$ times by taking the wave function—which is just one amplitude $\langle \psi | \psi' \rangle$ a function of time as well as a function of the coordinates. Now take in a given situation ψ that is described by giving a time-varying wave function $\psi(\mathbf{r}, t) = \langle \mathbf{r}, t | \psi \rangle$. This time-varying wave function describes the evolution of successive states that occur as time develops. This is called “quantum superposition,” which gives the projections of the state ψ into the base states, which not always be the true superposition, but not we will consider it later.

In Chapter 8 we described how Eqs. (17.18) and (17.19) in terms of the diagonal A_{ii} . We saw that by some variation of the various amplitudes was given in terms of the matrix element

$$i\hbar \frac{\partial C_i}{\partial t} = \sum_j A_{ij} C_j. \quad (16.49)$$

This equation says that the time variation of each amplitude C_i is proportional to $i\hbar$ of the other amplitudes C_j , with the coefficients A_{ij} .

How would we expect Eq. (16.49) to look when we are using the continuum of states? Well, let's first remember that Eq. (16.49) can also be written as

$$i\hbar \frac{d}{dt} \psi(x) = \sum_j (x, \theta_j) \psi_j / \hbar \psi(x).$$

Now it is clear what we should do. With the wavefunction we would expect

$$i\hbar \frac{d}{dt} \psi(x) = \int (x, \theta) \psi(x) \psi'(x) dx. \quad (16.50)$$

The sum over the basis states ψ_j gets replaced by an integral over x' . Since (x, θ) is a distribution function of x , and we can write it as $\delta(x, x')$ which corresponds to θ_j in Eq. (16.49). Then Eq. (16.50) is the same as

$$i\hbar \frac{d}{dt} \psi(x) = \int \delta(x, x') \psi(x') dx' \quad (16.51)$$

with

$$\delta(x, x') = \langle x | \delta | x' \rangle.$$

According to Eq. (16.51) the rate of change of the $\psi(x)$ would depend on the value of ψ at x' times plus all the factors A_{ij} 's where the amplitude per unit time that the electron will jump from x to x' is δ and ψ is arbitrary. However, this rate amplitude is zero except for points at very close to x . This was shown in the example of the chain of atoms at the beginning of the chapter, Eq. (16.12), that the right-hand side of Eq. (16.13) can be expressed schematically in terms of δ and the derivatives $\delta/\delta x$ with respect to x , all evaluated at the position x .

For a particle moving freely in space with no forces, no disturbance, the solution of physics is

$$\int H(x, x') \psi(x') dx' = - \frac{\hbar^2}{2m} \frac{d^2}{dx^2} \psi(x),$$

where I have gotten from the Schrödinger. It's not possible to write anything more than this since our classical model of Schrödinger, invented as it was, struggle to find an understanding of the experimental observations of the real world. You can perhaps just somehow feel why it should be that way by thinking of our derivative of Eq. (16.51) which came about involving δ — the propagator of an electron in a crystal.

Of course, the particles are not very exciting. What happens if we put forces on the x ? Let's! Will the forces of the x be like forces described in terms of the scalar potential $V(x)$? What about forces due to linking of electric fields and magnetic fields? What about forces due to low energies so that we can ignore spin-orbit effects from relativistic theory, and the Hamiltonian which we did not yet discuss?

$$\int H(x, x') \psi(x') dx' = - \frac{\hbar^2}{2m} \frac{d^2}{dx^2} \psi(x) + V(x) \psi(x) \quad (16.52)$$

Again, you can get some idea as to the origin of this equation if you go back to the motion of an electron in a crystal, and see how the equations would have to be modified if the energy of the electron varied slowly from one atomic site to the other, as in the case of time and an electric field outside the crystal. Then § 12

the ω in E_F in Eq. (16.7) would vary slowly with position and would be constant if the term we have added in (16.52).

It may be worth noting why we want a right from $\tilde{\psi}_j$ in (16.51) to Eq. (16.52) instead of just plus some linear combination of the amplitudes $\tilde{\psi}_{j+1/2} = (\psi_j + \psi_{j+1})/2$. We did this because $\tilde{\psi}_{j+1/2}$ can only be written in terms of a single algebraic function, although the whole is equal on the right-hand side of Eq. (16.41); outside outwards of L you are, however, "at" your real coordinates. $\tilde{\psi}_{j+1/2}$ can be written in the following way:

$$\tilde{\psi}(x, \omega) = -\frac{N}{2\pi i} \delta'(\omega - x) - \tilde{\psi}(x) \omega + \omega^2,$$

where δ' denotes the second derivative of the delta function. This is the wavefunction but be replaced by a semirelativistic wavefunction (algebraic differential operator, where ω is complex conjugate)

$$\tilde{\psi}(x, \omega) = \left\{ -\frac{e^2}{m} \frac{d}{dx} + V(x) \right\} \tilde{\psi}(x, \omega).$$

We will not be using these terms, but will work directly with the form in Eq. (16.52).

If we now take expression as above in (16.52) for the integral in (16.51) we get the following differential equation for $\tilde{\psi}(x) = \tilde{\psi}(x, \omega)$:

$$i\hbar \frac{d\tilde{\psi}}{dx} = -\frac{e^2}{m} \frac{d^2}{dx^2} \tilde{\psi} + V(x) \tilde{\psi}. \quad (16.53)$$

It is fairly obvious what we should do instead of Eq. (16.53) to see the wavefunction solution in three dimensions. The only changes are that d/dx gets replaced by

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2},$$

and $V(x)$ gets replaced by $V(x, y, z)$. The amplitude $\tilde{\psi}(x, y, z)$ for an electron moving in a potential $V(x, y, z)$ obeys the differential equation

$$i\hbar \frac{d\tilde{\psi}}{dx} = -\frac{e^2}{m} \nabla^2 \tilde{\psi} + V(x) \tilde{\psi}. \quad (16.54)$$

This is called the Schrödinger equation, and was the first non-dimensional equation ever solved. It was written down by Schrödinger before any of the other quantum equations we have described in this book were discovered.

Although we have approached the subject along a completely different route, the year I started research marking the birth of the quantum mechanical description a matter occurred like Schrödinger's. First went down his equation to me. Not many years ago the internal atom of an α particle had been measured. Niels Bohr was able to understand what he had made by going why he was doing what he was doing, and especially how it could be that atoms could be stable. Although Bohr's theory did not give a description of the internal motion of an electron in a hydrogen atom which seemed to explain the observed spectrum of light emitted by this atom, the description did seem to result in this way to a good theory. Niels Bohr's theory of the atomic equations of motion of electrons in atoms was a theory from which atomic phenomena could be calculated one dimensionally, and in detail. In principle Schrödinger's equation is capable of explaining all atomic phenomena, except those involving magnetism and relativity. It explains the energy levels of an atom, and all the laws of chemical binding. This is, however, true only in principle. The mathematics, even however the computer, is more easily, very but not simple problems. Only the hydrogen and helium atoms have been solved to high accuracy. However, with some approximations, come fairly easily, many of the laws of atomic and nuclear atoms, and of the chemical binding, or molecules in general, otherwise. We know that you have a few approximations in some chapters.

The Schrödinger equation as we have written it does not take into account any magnetic effects. It is possible to take such effects into account in a more refined way by adding some terms to the equation. However, as we have seen in Volume I, a magnet is essentially a relativistic effect, and so a correct description of the motion of an electron in an arbitrary electromagnetic field can only be discussed in a more relativistic equation. The correct relativistic equation for the motion of an electron was discovered by Dirac a year after Schrödinger brought forth his equation, and takes on quite a different form. We will not be able to discuss it at all here.

Before we go on to look at some of the consequences of the Schrödinger equation, we would like to show you what it looks like for a system with a large number of particles. We will not be making any use of the variables, but just want to show it to you to emphasize that the wave function ψ is not simply an ordinary wave in space. It is a function of many variables. If there are many particles, the equation becomes

$$-\hbar \frac{\partial^2 \psi(r_1, r_2, \dots, r_n)}{\partial r^2} = \sum_i \frac{\hbar^2}{2m_i} \left[\frac{\partial^2 \psi}{\partial r_{i1}^2} + \frac{\partial^2 \psi}{\partial r_{i2}^2} + \frac{\partial^2 \psi}{\partial r_{i3}^2} \right] + V(r_1, r_2, \dots, r_n) \psi \quad (16.5)$$

The potential $V(r_1, r_2, \dots, r_n)$ corresponds obviously to the total potential energy of all the particles. If there are no external fields acting on the particles, the function V is simply the total kinetic energy of the motion of all the particles. That is, if the i th particle carries the charge q_i/q_0 , then the function V is simply

$$V(r_1, r_2, \dots, r_n) = \sum_{i=1}^n \frac{Z_i Z_i}{r_{ii}} \psi. \quad (16.6)$$

16.4 Quantized energy levels

In this chapter we will look in detail at a solution of Schrödinger's equation for a particular example. We would like now, however, to give you some idea of the most remarkable consequence of Schrödinger's equation—quantum mechanics. The surprising fact that a differential equation involving only continuous functions of continuous variables in space can give rise to quantum effects such as the discrete energy levels in an atom. The even more remarkable is how it can restrict an electron which is confined to a certain region of space by some kind of a potential "wall" must necessarily have only one or another of a series of well-defined discrete energies.

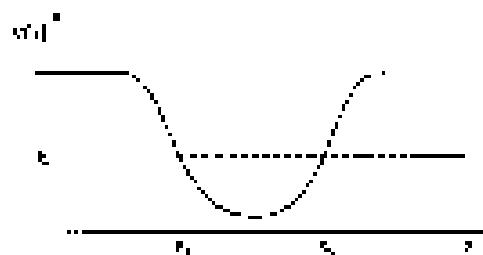

Fig. 16-3 A periodic wave for a particle moving along x .

Suppose we think of an electron in a one-dimensional situation in which its potential energy V is zero with t in a very situation by the graph in Fig. 16-3. We will assume that the potential is stationary—it doesn't vary with time. At a time t_1 later than time t_0 , we would like to find the solutions corresponding to states of definite energy, which means of definite frequency. Let's say a solution of the form

$$\psi = A \sin(\omega t + \phi), \quad (16.7)$$

[†] Requiring the condition of no other volume containing in which $\omega^2 = q_0/m$.
16-1

If we substitute this function into the Schrödinger equation, we find that the function $\psi(x)$ must satisfy the following differential equation:

$$\frac{d^2\psi(x)}{dx^2} + \frac{2m}{\hbar^2} [V(x) - E]\psi(x) = 0 \quad (16.28)$$

This equation says that at each x the second derivative of $\psi(x)$ with respect to x is proportional to itself, the coefficient of proportionality being given by the quantity $V(x) - E$. The second derivative of $\psi(x)$ is the rate of change of the slope. If the potential V is greater than the energy E , the potential, the rate of change of the slope of $\psi(x)$ will have the same sign as $\psi(x)$. This means that the value of $\psi(x)$ will be increasing away from the axis. That is, it will have, more or less, the character of the positive or negative exponential function. This is indicated in the regions to the left of x_1 and to the right of x_2 in Fig. 16.3, where V is greater than the bound energy E , the function $\psi(x)$ would have a break like the one in chapter 10.

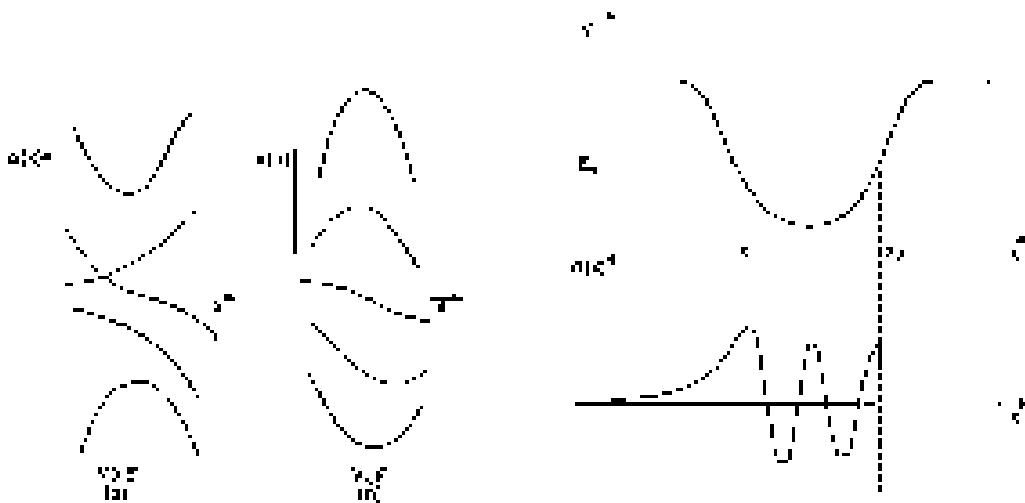

Fig. 16.4. Possible shapes of the wave function $\psi(x)$ for $V > E$ and for $V < E$.

Hg case. A wave function for the energy E which goes to zero for negative x .

shown in part (b) of Fig. 16.4.

On the other hand, if the potential $V(x)$ is less than the energy E , the second derivative of $\psi(x)$ with respect to x has the opposite sign from $\psi(x)$ itself, and the curve of $\psi(x)$ will always be concave toward the axis like one of the curves shown in part (a) of Fig. 16.4. The result is in such a region has, physically, roughly the "form" of a "mound" as in

Now let's see if we can construct graphically a solution for the function $\psi(x)$ which corresponds to a particle of energy E_1 in the potential V shown in Fig. 16.3. Since we are trying to describe a situation in which a particle is found inside the potential well, we want to look for solutions in which the wave amplitude either is very small values of x or is very outside the potential well. We can easily imagine a curve like the one shown in Fig. 16.5 which turns toward zero for large negative values of x and grows smoothly as it approaches x_1 . Since E is equal to V at x_1 , the x -coordinate of the function becomes zero at this point. Between x_1 and x_2 , the quantity $V - E_1$ is always a negative number, so the function $\psi(x)$ is always concave toward the axis and the curvature is a negative constant different than between x_1 and x_2 . If we continue the curve into the region beyond x_2 and x_3 , it should go more or less as shown in Fig. 16.5.

Now let's continue this curve into the region to the right of x_3 . There it comes away from the axis and takes off toward large positive values, as shown in Fig. 16.6. For the energy E_1 we have chosen the condition $|V(x)|$ is large and larger with x increasing. Thus, its curvature is also increasing if the potential continues to stay like V . The amplitude rapidly grows in numerical proportions.

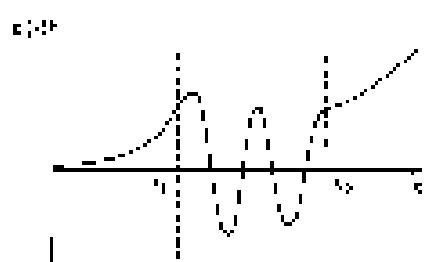

Fig. 16.5. The wave function part of Fig. 16.3 continued beyond x_3 .

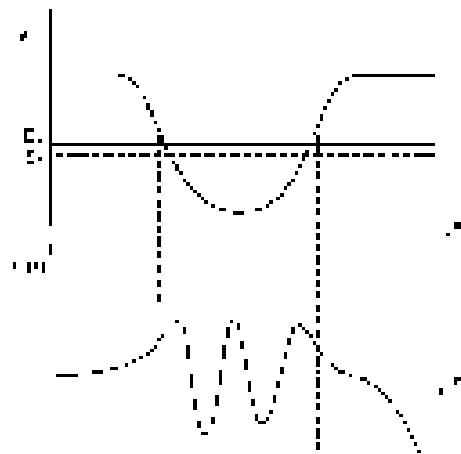

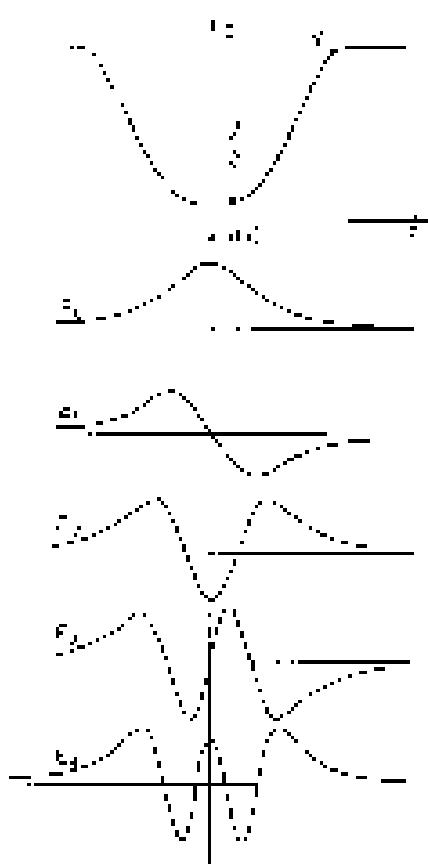

Fig. 16.2. The wave function $\psi(x)$ for an energy E , given by Eq. (16.1).

Fig. 16.3. A new solution for the energy E between E_1 and E_2 .

What does this mean? It implies that the particle is not "trapped" in the potential well. It is **much more likely** to be found *outside* of the well, than inside. For the whence we have manufactured, the electron is most likely to be found at $x = 1$ or, then $x = 2$ etc. We have failed to find a solution for a bound particle!

Let's try another energy, say one a little bit *higher* than E_1 , say the energy E_2 , i.e. Fig. 16.3. If we start with the same conditions as the last, we get the solution shown in Fig. 16.3. It's not *as though* we were going to be better, but it ends up just as bad as the solution for E_1 , except that now $\psi(x)$ is oscillating more and needs *more nodes* to get lower energy values!

Maybe the ψ is the clue. Since changing the energy E from between E_1 to E_2 causes the curve to flip from one side of the axis to the other, perhaps there is some energy lying between E_1 and E_2 for which ψ is a *real* (appreciable) negative value of x ? There is indeed, and we have sketched $\psi(x)$ for the solution in Fig. 16.4.

You should appreciate that the solution we have drawn in the figure is *not* a special case; if we were to vary up or down the energy even so slightly, the function would go over into curves like one of the others of the two broken-line curves shown in Fig. 16.3, and we would not have the proper conditions for a bound particle. We have obtained *one* solution if a particle is to be bound in a potential well, it can do so only if it has a very definite energy.

Does that mean that there is only one energy for a particle bound in a potential well? No. Other energies E are possible, you see energies too close to the barrier that the wave function we have drawn in Fig. 16.4 is no longer bounded in the region between x_1 and x_2 . If we were to pick an energy E which is lower than E_1 , we could choose a solution which crosses the axis only *once*, only twice, only once, or not at all. The possible solutions are sketched in Fig. 16.5. There are also n solutions (n infinite) corresponding to values of E which are higher than the ones shown. Our conclusion is that if a particle is bound in a potential well, its energy can take on only the certain special values in a discrete energy spectrum. You see how a differential equation can describe the basic fact of quantum theory.

We might remark one other thing. If the energy E is above the top of the potential well, then there are no longer any possible solutions, and any possible energy is permitted. Such solutions correspond to the scattering of free particles from potential wells. We have seen in example 6 such solutions when we considered the effects of impurity atoms in a crystal.

Fig. 16.5. The function $\psi(x)$ for the two lowest energy levels etc.

Symmetry and Conservation Laws

17-1 Symmetry

In classical physics there are a number of quantities which are conserved: position, energy, and angular momentum. Corresponding theorems about corresponding quantities also exist in quantum mechanics. The most beautiful thing of quantum mechanics is that the same rules—the laws can, in fact, be derived from very simple ideas; whereas in classical mechanics they are given by the seeming繁雜 of the laws of motion, in quantum mechanics we do an analogous thing to what we will do in quantum mechanics, but it can be done at a very simplified level. In quantum mechanics, however, the conservation laws are very deeply related to the principle of superposition of amplitudes, and to the symmetry of physical systems under various changes. This is the subject of the present chapter. Although we will apply these ideas mainly to the conservation of angular momentum, the central point is that the theorems about the conservation of all kinds of quantities are—in the quantum mechanics—related to the symmetries of the system.

We begin, therefore, by enquiring the question of symmetries of systems. A very simple example would be hydrogen molecule—we could equally well take the helium molecule. In which there are two atoms. For the hydrogen molecule we can look to see how states are in which the electron will be close near proton number 1, and another in which it is far away, but still near proton number 1. Its two states, which we called $|1\rangle$ and $|2\rangle$, are shown again in Fig. 17-1(a). Now, as long as the two nuclei are both outside the atom, that there is no interaction between the two protons. That is to say, if we were to reflect the system in the plane halfway between the two protons—by which we mean that everything on one side of the plane gets moved to the right, its position on the other side we would get the situation in Fig. 17-1(b). Since the protons are identical, the spectrum of reflection things $|1\rangle$ becomes $|2\rangle$ and $|2\rangle$ becomes $|1\rangle$. We'll call this reflection operator F and write

$$F|1\rangle = |2\rangle \quad F|2\rangle = |1\rangle. \quad (17.1)$$

so our F is an operator in the sense that it "does something" to a state to make a new state. One interesting thing is that if you map out the result, produces some sort of state of the system.

Now, if we try any of the wave functions we have described, has no evolution which can be defined by the usual successive action. Namely,

$$\psi_1 = \langle 1 | \hat{p} | 1 \rangle \quad \text{and} \quad \psi_2 = \langle 2 | \hat{p} | 2 \rangle$$

so the ψ_1 and ψ_2 elements we get if we multiply $\hat{p}|1\rangle$ and $\hat{p}|2\rangle$ in the left by $\langle 1 |$ and $\langle 2 |$ respectively. From Eq. (17.1) they are

$$\begin{aligned} \langle 1 | \hat{p} | 1 \rangle &= p_{11} = \langle 2 | \hat{p} | 1 \rangle = 0, \\ \langle 2 | \hat{p} | 2 \rangle &= p_{22} = \langle 1 | \hat{p} | 2 \rangle = 0. \end{aligned} \quad (17.2)$$

In the same way we can get p_{12} and p_{21} . The matrix of \hat{p} —and neglect of the wave function ψ_1 and ψ_2 —is

$$\hat{p} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}. \quad (17.3)$$

We see once again that the waves broaden the matrix. In classical mechanics we

Notes: Chapter 13, Sec. 1, Symmetry in Physical Laws

References: Angular Momentum in Quantum Mechanics
A. R. Edmonds, Princeton University Press, 1956

Hyp. 17-1. If the states $|1\rangle$ and $|2\rangle$ are reflected in the plane P-S, they come $|2\rangle$ and $|1\rangle$, respectively.

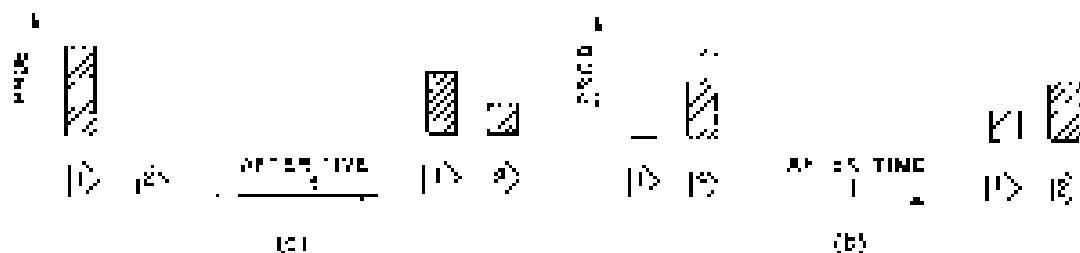

Fig. 17-2. In a symmetric system, if a pure $|1\rangle$ state develops in time it will tell a pure $|2\rangle$ state and develop as in part (c).

specifically interchanges. There are other technical differences— $\langle\psi|\psi\rangle$ is different between a "symmetric" and a "antisymmetric" state—but the distinction is something probably don't need to worry about. So whether Ψ defines an n -electron state or actually used to define a matrix of numbers, we can call it *interchangeable* or *invariant* in a sense.

Now we would like to gain a little insight. We will suppose that the system of the whole hydrogen molecular ion system is *symmetric*. Is there still time?

It depends on a choice, on which one to use. But if the system is symmetric the following just should obviously be true. Suppose we start with the system in the state $|1\rangle$ and find after an interval of time t that the system is now to be in a more correlated situation, in some linear combination of the two basic states. Remember that in Chapter 9 we used an instant "living for a period of time" by multiplying by the operator $e^{-iEt/\hbar}$. That means the "time" after a while, say 10 seconds, to be definite—say in some crazy way. For example, it might be $\sqrt{2}/3$ parts of the state $|1\rangle$ and $\sqrt{1/3}$ parts of the state $|2\rangle$, and we would write

$$|\Psi \text{ at } 10 \text{ sec}\rangle = C|1\rangle + D|2\rangle = \sqrt{2/3}|1\rangle + \sqrt{1/3}|2\rangle \quad (17.0)$$

Now we ask what happens if we start the system in the symmetric state $|1\rangle$ and wait for a second time, the same conditions? It is clear that if the whole is symmetric as we are supposing, we should get the state unchanged to (17.0).

$$|\Psi \text{ at } 15 \text{ sec}\rangle = T^2|1\rangle = C = \sqrt{2/3}|1\rangle + \sqrt{1/3}|2\rangle \quad (17.1)$$

The same ideas are sketched diagrammatically in Fig. 17-2. So if the physics does agree, it's consistent with some theory, and we work out the behavior of a particular atom, we also know the behavior of the rest, we would just by referring the original state to the symmetry plane.

We should like to do the same thing perhaps a bit more generally. We'd need a little more algebra. Let \mathcal{Q} be any sort of a number of operations that you do, \mathcal{Q} because to a system without changing the physics. For instance, let \mathcal{Q} be might be $C(\theta, \phi, \psi)$, the operation of a rotation in the plane between the two atoms in the hydrogen molecule. Or, in a system of n two-electron atoms, we might be thinking of the operation of swapping the two electrons. Another possibility would be in a spherically symmetric system, the operation of a rotation of the whole system through a finite angle around some axis, which wouldn't change the physics. Of course, we would normally want to give each physical operation a special name. For \mathcal{Q} , specifically, we will necessarily define $\mathcal{Q}(\theta, \phi, \psi)$ to be the operation "rotate the system about the z -axis by the angle θ ". By \mathcal{Q} we mean just any sort of the operations we have described in any other way, which leaves the basic physical situation unchanged.

Let's think of some more examples. If we have an atom with no *external* magnetic field or no external electric field, and if we want to turn the system into another antisymmetric, we'll be in some physical system. Again, the antisymmetric molecule is symmetric with respect to a reflection in a plane parallel to that of the two hydrogen. So now is there a no external field. Well, there is an electric field, when we make a reflection we would have to flip the electric field also.

and that changes the physical problem. But if we have no external field, the nucleus is symmetric.

Now let's consider a generic situation. Suppose we start with the state $|\psi_1\rangle$ and after some time or over many given physical conditions it has become the state $|\psi_2\rangle$. We can write

$$|\psi_2\rangle = \hat{U}|\psi_1\rangle \quad (17.6)$$

You can be thinking of Eq. (17.6) as "Now imagine we perform the operation \hat{U} on the whole system." The state $|\psi_1\rangle$ will have transformed into state $|\psi_2\rangle$, which we can also write as $\hat{U}|\psi_1\rangle$. Also the state $|\psi_2\rangle$ is changed into $|\psi_3\rangle = \hat{U}|\psi_2\rangle$. More generally, if you act just on the $\hat{\psi}$ (but not the \hat{U} , it's just a general property of systems), then, working for the same time under the same conditions, we should have

$$|\psi_3\rangle = \hat{Q}|\psi_2\rangle \quad (17.7)$$

[see Eq. (17.6)] Then we can write $\hat{Q} = \hat{U}$; for $|\psi_1\rangle$ and $\hat{Q}|\psi_1\rangle$ for $|\psi_3\rangle$ you can also write:

$$\hat{Q}|\psi_1\rangle = \hat{U}\hat{Q}|\psi_1\rangle. \quad (17.8)$$

Now we can replace \hat{Q} by $\hat{U}^\dagger\hat{Q}$ [Eq. (17.8)] to get

$$\hat{Q}\hat{U}|\psi_1\rangle = \hat{U}^\dagger\hat{Q}|\psi_1\rangle. \quad (17.9)$$

We must think to understand what this means. Thinking of the hydrogen atom it says there: "nothing is reflected and nothing is split." The expression on the right of Eq. (17.9)—with some as "nothing is reflected and nothing is split"—are equivalent on the left of Eq. (17.9). These should be the same so long as \hat{U} doesn't change under the reflection.

Since (17.9) is true for any starting state $|\psi_1\rangle$, it is really an equation about the operators:

$$\hat{Q}\hat{U} = \hat{U}\hat{Q}. \quad (17.10)$$

This is why we wanted to go to a more abstract measure of symmetry. When Eq. (17.10) is true, we say that the operators \hat{Q} and \hat{U} commute. We can then draw "top marks" in the following way. A classical system is symmetric with respect to the operator \hat{Q} when \hat{Q} commutes with it; the operation is by groups of time. [In terms of matrices, the product of two operators is equivalent to the trace product, so Eq. (17.10) also holds for the matrices \hat{Q} and \hat{U} for a system which is symmetric under the transformation \hat{Q} .]

Locally, since for infinitesimal times t we have $\hat{U} = 1 + i\hat{Q}/\hbar$ —where \hbar is the usual He (then in Sec. 5) you can see that if (17.10) is true, it is also true for

$$\hat{Q}i - \hat{Q}\hat{U}. \quad (17.11)$$

So (17.11) is the mathematical statement of the condition for the symmetry of a physical situation under the reflection \hat{U} . It shows a symmetry.

17-3. Symmetry and conservation

Before applying the result we have just found, we should like to discuss the idea of symmetry a little more. Suppose we have a very special state here after we operate only once with \hat{Q} , we get the same state. This is a very special case, but let's suppose it happens to be true for a state $|\psi\rangle$ and that $|\psi'\rangle = \hat{Q}|\psi\rangle$ is physically the same state as $|\psi\rangle$. That means that $|\psi'\rangle$ is equal to $|\psi\rangle$ except for some phase factor f . However, then happens? For instance, suppose that we

[†]In fact, if you can show that \hat{Q} is necessarily a Hermitian operator—which requires that the operator \hat{Q} is a real number times [a] complex number or both the sum of such numbers— \hat{Q} is a small enough time to be close to the identity. Any operator like a reflection in a mirror doesn't have any part of its hermiticity lost if $|\psi'\rangle$ and $|\psi\rangle$ have the same basis; they can only differ by a non-imaginary phase factor.

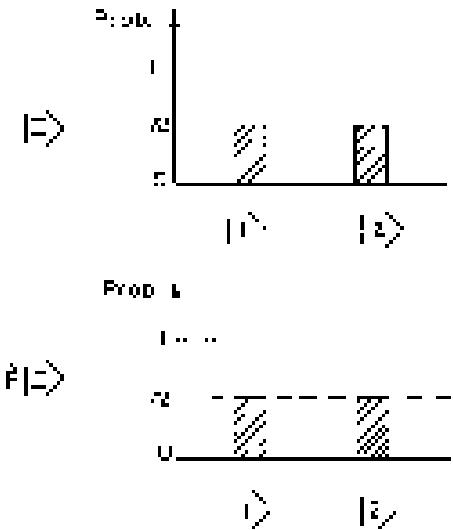

Fig. 17-3. The state $|1\rangle$ and the reflected $|2\rangle$ recorded by reflecting $|1\rangle$ in the central plane.

over in Fig. 17-2 for the case which we considered $|A\rangle$. There it is said that if the input amplitude is ψ_1 at the base states $|1\rangle$ and $|2\rangle$, the probabilities are shown as in Fig. 17-2(a). If we operate on $|1\rangle$ with the reflection operator R , it flips the state over changing $|1\rangle$ to $|2\rangle$ and $|2\rangle$ to $|1\rangle$, so that the probability is shown in Fig. 17-2(b). But notice just the state $|B\rangle$ is left over again. In other words, the state $|B\rangle$ has probabilities before and after reflection look just the same. However, there is a difference if we look at the amplitudes. For the state $|B\rangle$ the amplitudes are the same also, but the state $|B\rangle$ has amplitudes having opposite signs. In other words,

$$P(|B\rangle = P(|1\rangle) = \frac{|\psi_1|}{\sqrt{2}} = \frac{\psi_1 + i\psi_2}{\sqrt{2}} = \psi_1.$$
 (17.12)

$$P(|B\rangle = P(|2\rangle) = \frac{|\psi_1|}{\sqrt{2}} = \frac{\psi_1 - i\psi_2}{\sqrt{2}} = -\psi_2.$$

Now notice $\psi_1 = \psi_2$ unless $\theta = 0$ for the state $|B\rangle$ and $\theta \neq 0$ for the state $|B\rangle$.

Let's look at another example. Suppose we have a Rabi polarized photon propagating in the z-direction. If we do no rotation of the wave function, the z-component, we know that this just rotates the amplitude by $e^{i\theta}$ where θ is the angle of rotation. So for the situation we had in this case, ψ is just equal to the angle of rotation.

Now it is clear that \hat{Q} corresponds to the wave function operator $\hat{\psi}$ just as \hat{Q} is the plane of the state of the wave function $\psi = 0$ is free to rotate. In other words, if we come up with ψ , you can find the state ψ just after a rotation.

$$\hat{Q}(\psi, \psi_1) = |\psi_2\rangle \quad (17.13)$$

and if the symmetry of the equation makes you say that

$$\hat{Q}(\psi) = e^{i\theta} |\psi_2\rangle. \quad (17.14)$$

Then it is also true that

$$\hat{Q}(\psi_2) = e^{i\theta} |\psi_2\rangle. \quad (17.15)$$

This is clear, even

$$\hat{Q}(\hat{Q}\psi) = \hat{Q}(\psi, \psi_2) = \hat{Q}(\psi),$$

and if $\hat{Q}(\psi) = e^{i\theta} |\psi_2\rangle$, then

$$\hat{Q}(\psi_2) = \hat{Q}(\hat{Q}\psi, \psi_2) = \hat{Q}(\psi, \psi_2) = \hat{Q}(\psi).$$

The second of equalities follows from (17.13) and (17.15) for a unitary real operator from (17.14) and then the last two because $e^{i\theta}$ commutes with its conjugate.

So both certain symmetries something which is true initially is true for all times. But isn't that just a conservation law? Yes, it says that if you look at the right-hand side and the working out is complicated on the side because that an operator \hat{Q} is the necessary expression of the special procedure, take a unitary operation by a certain phase, then you know that the symmetry will be true of the final state. The same result can multiply the final state by the same phase factor. This is always true even though we may not know exactly what the internal mechanism of the converse which changes a system from the time to the final state. Even if we would like to look at the details of the machinery by which the system goes from one state to another, we can still see that if a thing is in a state with a certain symmetry character originally and if the time evolution for the many \rightarrow symmetrical under that symmetry operation, then the state ψ will have the same symmetry character for all times. That's the basis of all the conservation laws of quantum mechanics.

Let's look at a special example. Let's go back to the ψ^H system. Now we'll show that it really satisfies our definition of ψ^H . We want to take for P not just a

minus reflection, because that requires defining the plane in which we put the mirror. There is a special kind of reflecting that doesn't require the specification of a plane. Suppose we redefine the operation \hat{P} this way: First you reflect in a mirror in the x -plane so that's done, $\psi_1 \rightarrow \psi_1$, and then rotate you... in the system I'll reflect in a mirror so that's done to go to $-x$ and $y \rightarrow -y$. The whole thing is called an inversion. Every point is reflected through the origin to the diametrically opposite position. All the coordinates of everything are reversed. We will still use the symbol \hat{P} for the operation. It's shown in Fig. 13-1. It is a little more complicated than a simple reflection because it doesn't require that you specify what's called a plane normal for the reflection — you just specify only the point where it is, no other axes symmetry.

Now let's suppose that we have a state $|\psi\rangle$, which under the wave-sink operation goes to $|\psi'\rangle$, $\psi' = \hat{P}\psi$.

$$\hat{P}|\psi\rangle = P\hat{P}_1|\psi\rangle = P\hat{P}_1\psi_1 = |\psi'\rangle \quad (13.16)$$

Now suppose that we invert again. After two inversions we are right back where we started from — nothing is changed at all! We must have that:

$$\begin{aligned} \hat{P}^2|\psi\rangle &= \hat{P}\hat{P}_1|\psi\rangle = |\psi'\rangle \\ \text{Hence } \hat{P}^2 &= \hat{P}\hat{P}_1 = P\hat{P}_1P = (P\hat{P}_1)^2 = \hat{P}\hat{P}_1. \end{aligned}$$

It follows that

$$(\hat{P}\hat{P}_1)^n = \hat{P}^n\hat{P}_1^n.$$

So if the inverse operation is a symmetry operation of a state, there are only two possibilities for \hat{P} :

$$\hat{P}^2 = \pm 1,$$

which means that

$$\hat{P}_1|\psi\rangle = |\psi'\rangle \quad \text{or} \quad \hat{P}_1|\psi\rangle = -|\psi'\rangle. \quad (13.17)$$

Classically, if a state is symmetric under an inversion, the operation gives back the same state. In quantum mechanics, however, there are the two possibilities: we get the same state or we have the same state, $\hat{P}_1|\psi\rangle = |\psi\rangle$, but the state $|\psi\rangle$ has imaginary. Other the sign is inverted so that $\hat{P}|\psi\rangle = -|\psi\rangle$, we say that the state has odd parity. (See inversion rule.) \hat{P} is also known as the parity operator. The state $|\psi\rangle$ of the HJ has even parity, and the state $|\psi'\rangle$ has odd parity — see Eq. (13.17). There are, of course, cases which are not symmetric under the operation \hat{P} ; these are states with no definite parity. For instance, in the HJ system the state $|\psi\rangle$ has even parity, the state $|\psi'\rangle$ has odd parity, and the state $|\psi''\rangle$ has no definite parity.

When we speak of an operation like inversion being performed "on a physical system" we can think about it in two ways. One can think of physically moving a greater body to the inverse point $x' = -x$ in we run the risk of breaking up the same system from a new frame of reference $x' = y$, $y' = z$, $z' = -x$ the body $x = -x$, $y = -y$, and $z = -z$. Similarly, when we think of rotation, we can think of rotating bodily a physical system, or rotating the coordinate frame in the space in which we measure the system. Keeping the system "fixed" in space. Generally, the two points of view are completely equivalent. For rotation they are equivalent since first rotating a system by an angle θ is like rotating the reference frame by the negative of θ . In these lectures we have usually considered what happens when a projection is made in a new set of axes. What you get this way is the same as what you get if you leave the axes fixed and rotate the system back-and-forth by the same amount. What you do, that the signs of the angles are, *etc.*

[†]In older books you may find formulas with different signs; they are probably using different definitions of the angle.

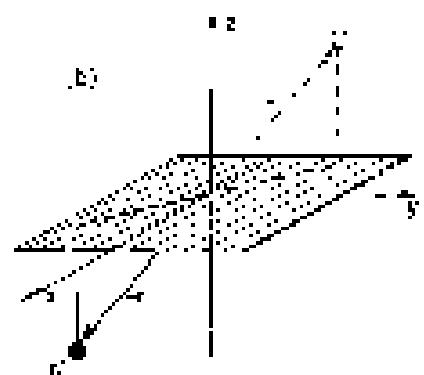

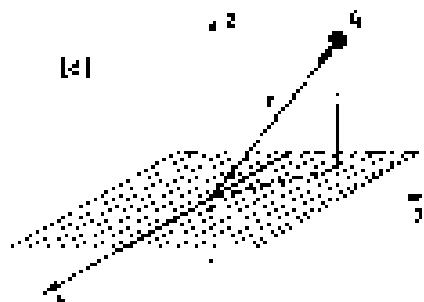

Fig. 13-1. The operation of inversion, \hat{P} . Whatever is at the point A at $t = t_0$ is moved to the point A' at $t = t_0$, $\hat{P} = \pm 1$.

Many of the laws of physics—both classical and quantum mechanics—involve the conservation of the coordinates. They are invariant with respect to an inversion. The laws of fluid dynamics, for instance, are unchanged if we change $x \rightarrow -x$, $y \rightarrow -y$, and $z \rightarrow -z$ in all components. This symmetry is important in gravity, and for the strong interactions of nuclear physics. Only the weak interactions are responsible for beta decay. So, let's take this symmetry. (We discussed this in more detail in Chapter 13, Sec. 13.1.) We will for now leave out any consideration of the β decay. Let's imagine any physical system where β decay is not expected to produce any appreciable effect. An example would be the emission of light by an atom—the same atom at different positions in space-time. Under these circumstances we have the following proposition. If a state originally had even parity, and if you look at the original β state at some later time, it will again have even parity. Furthermore, suppose β is an odd-parity operator in a way that it preserves even parity. If you look at the whole thing—including the photon state—the result since it is β again have even parity (because if you start with odd parity). The principle is called “*conservation of parity*.” (Even though many words (“*conservation of parity*” and “*selection symmetry*”) are closely interwoven in the quantum mechanics. Although until a few years ago it was thought the nature always conserves parity, it is now known that this is not true. In the beta decay of cobalt because the β decay reaction does not care the intrinsic symmetry rules is violated in the rule laws of physics.)

Now we can prove an interesting theorem (which is equivalent to various discrete-space theorems): Any state of definite energy which is not degenerate must have a definite parity. It must have either even parity or odd parity. Remember that we have a situation in which several states have the same energy—in fact such states are degenerate. Our theorem will not apply to them.)

For a state $|\psi\rangle$ in \mathcal{H} , if \mathcal{Q} is the energy, we know that

$$\mathcal{Q}|\psi\rangle = E|\psi\rangle \quad (7.13)$$

where E is just a number—the energy of the state. If we take any operator \mathcal{Q} which is a symmetry operator of the system we can prove that

$$\mathcal{Q}|\psi\rangle = c^*|\psi\rangle \quad (7.14)$$

in which c is a complex $\neq 0$ definite energy. Consider the two states $\langle\psi|\psi\rangle$ and $\langle\psi|\psi'\rangle$ from operating with \mathcal{Q} . If the physics is symmetric, $\langle\psi|\psi\rangle$ and $\langle\psi|\psi'\rangle$ the same energy as $|\psi\rangle$. But we have taken a situation in which there is only one state of that energy, $\langle\psi|\psi\rangle$ and $\langle\psi|\psi'\rangle$ are the same state—it is unity. So ψ is a photon. That's the physics argument.

The same thing comes out of our mathematics. Our definition of symmetry is $\mathcal{Q}|\psi\rangle = E|\psi\rangle$ in Eq. (7.13) (and for any state ψ ,

$$c\mathcal{Q}|\psi\rangle = \mathcal{Q}c|\psi\rangle \quad (7.15)$$

But we are considering only a state $|\psi\rangle$ which is a definite energy state, so that $\mathcal{Q}|\psi\rangle = E|\psi\rangle$. Since E is just a number (in Newtonian terms through \mathcal{Q} if we want), we have

$$\mathcal{Q}\mathcal{Q}|\psi\rangle = \mathcal{Q}E|\psi\rangle = E\mathcal{Q}|\psi\rangle$$

$$E\mathcal{Q}|\psi\rangle = P(\mathcal{Q}|\psi\rangle) \quad (7.16)$$

So $\mathcal{Q}|\psi\rangle = \mathcal{Q}^*|\psi\rangle$ is also a definite energy state of \mathcal{R} and with the same E . But by our logic, there is only one such state, it has to be that $\mathcal{Q}|\psi\rangle = c^*|\psi\rangle$.

What we have just proven is true for any operator \mathcal{Q} that is a symmetry operator of the physical system. Therefore, in a situation in which we consider only electrical forces and strong interactions—and in particular the first interaction symmetry is an accurate approximation, we have that $\mathcal{Q}|\psi\rangle = c^*|\psi\rangle$ (as we have also seen earlier in most chapters of this book). So any state of a definite energy (which is not degenerate) has just either an even parity or an odd parity.

13-3 The conservation law

We turn now to another interesting example of an operator: a rotation. We consider the special case of a dipole, i.e., rotating an atomic system by angle θ around its axis. We will call it operator $\hat{\theta}$ (though this is going to suggest that we have a physical system where we have no influences force up along the z -axis). And that is how a magnetic field is taken to be parallel to the z -axis so that there will be no change in the external conditions if we rotate the whole physical system about the z -axis. For example, if we have an atom in empty space and we rotate the electron around the z -axis by an angle θ , we have the same physical system.

Now then, there are wavefunctions which have the property that after an operation you get a new state which is the original one multiplied by some phase factor. Let me make a quick argument to show you just what I mean. If you trust the plane waves that always be proportional to the $e^{i\vec{k}\cdot\vec{r}}$. Suppose that you would measure only the amplitude. That's because this was the way by definition. If it's proportional to $e^{i\vec{k}\cdot\vec{r}}$ the effect of the rotation is given by a phase shift so that

$$\hat{\theta}(\phi_1, \phi_2) = e^{i\vec{k}\cdot\vec{r}} \phi_1,$$

two such rotations in succession would multiply the state by the factor $e^{i\vec{k}^2} = e^{i\vec{k}_1^2 + \vec{k}_2^2}$, thus

$$\hat{\theta}(\phi_1, \phi_2) = \hat{\theta}(\phi_1) e^{i\vec{k}_1^2} \phi_1 = e^{i\vec{k}_1^2} \hat{\theta}(\phi_1) \phi_1 = e^{i\vec{k}_1^2} \phi_1.$$

The phase change δ must be proportional to \vec{k}^2 . We are considering here those special states ϕ_1, ϕ_2 which

$$\hat{\theta}(\phi_1, \phi_2) = e^{i\vec{k}^2} \phi_1, \quad (13.2)$$

where \vec{k} is some real number.

We also know the remarkable fact that if a system is represented by a wavefunction and \vec{k} is the original one it happens in every case property that $(1+2)$ is true, then it will also have the same property later on. So this number \vec{k} is a very important one. If we know its value initially, we know its value at the end of the process. This is a number which is conserved during a sequence of no inputs. This means that we put out \vec{k} because it hasn't anything to do with the initial and final state because you can't do something in classical mechanics. In quantum mechanics we don't care so little—for each state of a single angular momentum about the z -axis. If we do that we find that in the limit of large systems the state quantity is equal to the x -component of the angular momentum of classical mechanics. So if we have a system for which a conservation law can never just produce a plus or minus, then we have a sense of definite angular momentum about that axis and the angular momentum is conserved. It is not new and forever. Of course, you can't talk about any axis and you just let it be a question of what the parameter for the various axes. You see that the conservation of angular momentum is related to the fact that when you rotate a system you get the same state with only a new phase factor.

One would like to show you how general this idea is. We will apply it to two other conservation laws which have exact correspondence in the physical ideas in the conservation of angular momentum. In classical physics we also have conservation of momentum and conservation of energy, and it is interesting to see that both of these are related in the same way to an operator by another.

¹ Very easily, we could also do it by a rotation of the physical system by $-\phi$: that the result will be the same is making the incident frame by $+\phi$.

² We can always choose a frame in which one of the fields provided there is only an z -field of a time, and its direction doesn't change.

³ For a finite pulse we should make this argument for small angles ϕ . Since one angle is the n^{th} derivative of time, $\phi = m_e K(\phi) = (\hbar/e)^2$ and the total phase change is n^{th} order. One will argue, and it is, therefore, proportional to ϕ .

Suppose that we have a physical system, an atom, some molecules or a atom, or a molecule, or some big atom if you want make any difference. If we take this whole system and move it over to a different place. So we have a Hamiltonian which has the energy that is independent of the state of movement of the atoms, and they may depend on the **displaced position** in space. Under these circumstances there is a special symmetry because we can perform a shift in space. Let's define $\delta \vec{r}$ as the separation of a displacement by the distance along the \vec{r} axis. Then for any state we can make this operation and get a new state. Well again there can be very specific states which lose the property that when you displace them by a along the \vec{r} axis you get the same state except for a phase factor. It's also possible to prove just as we did above that when this happens the phase must be proportional to $e^{i\omega t}$. In we can write ψ this special state $|\psi\rangle$

$$|\psi(\vec{r})\rangle = e^{i\omega t} |\vec{r}\rangle \quad (11.22)$$

The coefficient δ , when multiplied by \hbar , is called ω , an **operator of the momentum**. And the reason it is called that is that the number is numerically equal to the classical momentum p . So we have a large system. The general situation is this. If the Hamiltonian is unchanged when the system is displaced, and if the state starts with a definite momentum in the \vec{r} direction, then the momentum is the same even will remain the same in this system. The total momentum of a system before and after a collision after replacing \vec{r} will be the same.

There is another operation that's quite analogous to the displacement in space. I call it δt . Suppose that we have a physical situation where there is something constant that depends on time, and we start something off at a certain moment in a state, make and let it roll. Now, if we were to start the same thing again (in exactly the same way) our example is everything, except by a time δt and if nothing in the external environment depends on the absolute time, the development would be the same and the final state would be the same as the other. This result, except that it will give them after by the factor $e^{i\omega \delta t}$. Under these circumstances we can also find special states which lose the property that the development in time has the **exact** characteristic that the displaced state is just the old one plus, by a phase factor. That means it's easier than the most general since the phase change must be proportional to i . We can write

$$|\psi(t+\delta t)\rangle = e^{i\omega \delta t} |\psi(t)\rangle \quad (11.23)$$

It is recommended to use the negative sign in defining ω , with this convention about the sense of the system and its movement. So a system of finite energy is one which when displaced in time reproduces itself multiplied by $e^{-i\omega \delta t}$. (This is what we have said before when we did, in a quantum state of definite energy, an ω in a wavefunction with no \vec{r} -dependence.) It means that the system is in a state of definite energy, and the Hamiltonian doesn't depend on t , then no matter what, ω in the system will have these features at all later times.

You see, therefore, one rule is however the conservation law and the symmetry of the world. Symmetry with respect to displacement in time implies the conservation of energy, symmetry with respect to position in \vec{r} implies the conservation of the \vec{p} component of momentum. Symmetry with respect to rotation around the x , y , and z axes implies the conservation of the p_x , p_y , and p_z components of angular momentum. Symmetry with respect to reflection implies the conservation of parity. Symmetry with respect to the exchange of two directions implies the conservation of something we don't have a name for, and so on. Some of these principles have classical analogs and others do not. There are four conservation laws in quantum mechanics, but the one most universal mechanics, in at least, than we usually need most.

In order that you will be able to read other books on quantum mechanics, you must make a small adjustment since to describe the notation that people use. The operation of a derivative with respect to time is, of course, just the expression $i\hbar \partial / \partial t$.

time t , it's worth looking at it:

$$\delta_t |\psi\rangle = \delta(\epsilon - \tau, t) |\psi\rangle \quad (17.25)$$

We'd prefer like to do it in terms of infinitesimal displacements in time, or in terms of infinitesimal displacements in space, or in terms of rotations through infinitesimal angles. Since any finite displacement in a system can be reconstructed by a sequence of infinitesimal displacements, we might as well just do it in the infinitesimal case. The operator that infinitesimally displaces an object in time by ϵ is what we call *displacement*¹ in Chapter 3:

$$D(\epsilon|\psi\rangle) = |1 + \frac{i}{\hbar} \epsilon \hat{p}\rangle |\psi\rangle \quad (17.26)$$

Then D is analogous to the classical quantity we call *energy*, because if $D|\psi\rangle$ converges to be a constant (that is, if) $D|\psi\rangle = |\psi\rangle$, then that constant is the energy of the system.

The same thing is done for the other operators. If we displace a small displacement in x , say by the amount ϵ , a state $|\psi\rangle$ will, in general, pass over into some other state $|\psi'\rangle$. We can write

$$|\psi'\rangle = D_x(\epsilon|\psi\rangle) = \left(1 + \frac{i}{\hbar} \epsilon \hat{p}_x\right) |\psi\rangle \quad (17.27)$$

and as ϵ goes to zero, the $|\psi'\rangle$ should become just $|\psi\rangle$ or $D_x(0) = 1$, and so, could be the change of $D_x(\epsilon|\psi\rangle)$ from $|\psi\rangle$ could be proportional to ϵ . Define \hat{J}_x to be the operator p_x , i.e., the momentum operator—for the measurement of position.

For identical reasons, people usually write the small relation as

$$D_x(\epsilon|\psi\rangle) = \left(1 - \frac{i}{\hbar} \epsilon \hat{J}_x\right) |\psi\rangle \quad (17.28)$$

and call \hat{J}_x the *operator* of the component of angular momentum. For those quantitites for which $D_x(\epsilon|\psi\rangle) = \text{const}$, we can take any small angle—say don't expand the right-hand side to first order in the ϵ and get

$$D_x(\epsilon|\psi\rangle) = e^{i\epsilon \hat{J}_x} |\psi\rangle = (1 - i\epsilon \hat{J}_x) |\psi\rangle$$

Comparing this with the definition of J_x in Eq. (17.28), we get that

$$J_x |\psi\rangle = i\epsilon \hat{J}_x |\psi\rangle \quad (17.29)$$

In other words, if you rotate with J_x by a small finite angular increment ϵ , the state $|\psi\rangle$ is left in the same state; J_x is the amount of component of angular momentum. It is quite analogous to operating on a definite energy since each θ to get $\delta_\theta |\psi\rangle$.

We should now “do the obvious application of” the ideas of this chapter, i.e. of angular momentum—we show you how they work. The point is not easy to be really very simple. You knew before that angular momentum is conserved. The only thing you really have to remember from this chapter is that “a state $|\psi\rangle$ has to be property, but spin is nothing, though it's single, about the axis,” to be sure $i\epsilon \hat{J}_x |\psi\rangle$; it has to be something of angular momentum around θ , not ϵ . That's where θ has to be a number of it, to begin things.

17-4 Polarized light

What it all we would like to check is, for example, in Section 17-3 we showed that when RHC polarized light is viewed in a frame rotated by the angle $\pi/2$ about the \hat{z} -axis, it gets multiplied by $e^{i\pi/2}$. Does that mean then that the photons of light

¹except for the sign with the negative of the one we used in Section 17-3.

Left and right circularly polarized carry an angular momentum of one unit along the wave's direction of travel. If also incoherent, if we have a beam of light containing a large number of photons all circularly polarized the same way, so we would have in a classical view, it will carry angular momentum. If the total energy carried by the beam is E , then the angular momentum is $E/2\pi c \hbar$. Why? Because each photon carries the angular momentum \hbar , so there is a total angular momentum E/\hbar .

$$J = E \frac{\hbar}{c} \quad (7.10)$$

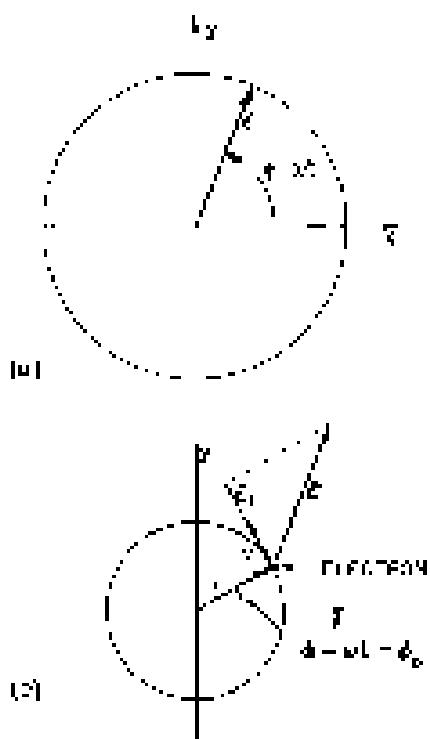

Fig. 17-5. (a) The electric field E in a circularly polarized light wave. (b) The motion of an electron being driven by the circularly polarized light.

Can we prove classically that light which is right circularly polarized carries an energy and angular momentum in proportion $E/\hbar c$? That that is a classical proposition of everything is right. Were we to take a test where we can go along the quantum theory in the classical limit. We should set up the classical physics checks. It will give us an idea whether we have a right to call it the angular momentum. Remember what circularly polarized light is, classically—it's described by an electron oscillating in equilibrium about an oscillating mean position. At a rate of ω , so that the results are periodic, as in Fig. 17-5(a), shown in Fig. 17-5(b). Now in space such light comes out in a wave which is going to absorb it, or at least some of it, and consider an atom in the wave according to the classical physics. We have often described the motion of the electron in the atom as a harmonic oscillator when one drives into resonance by an external electric field. Well suppose that the atom is isotropic, so that it can vibrate equally well in the x -or y -directions. This is the "circular polarized light, the transverse wave" approximation; displacement and velocity here are 90° behind the wave. The net result is that the electron moves in a circle, as shown in Fig. 17-5(b). The electron is displaced at some distance r from its equilibrium point about the origin and goes around with some frequency with respect to the wave ω . The relation between ω and r might be as shown in Fig. 17-5(c). As time goes on, the wave is held constant and the displacement rotates with the same frequency, so that relative motion goes clockwise some. Now, why should the work being done on this electron. The rate and energy is being put into this electron is \propto its velocity. Let's do the component of v_θ parallel to the velocity.

$$\frac{dv_\theta}{dt} = qE_r \quad (7.11)$$

But look, there is angular momentum being passed into the electron, because E_r is always in r -direction about the origin. The torque is qEr , which must be equal to the rate of change of angular momentum dJ/dt :

$$\frac{dJ_r}{dt} = qEr \quad (7.12)$$

Remembering that $r = r_0 \cos \omega t$, we have that:

$$\frac{dJ_r}{dt} = \frac{1}{2} \omega r^2$$

Therefore, if we integrate the total impulse component which is absorbed, it is proportional to the total energy, the situation. A proportionality being $1/\omega$ which agrees with Eq. (7.10). Light does carry angular momentum—but it carries it in light circularly polarized along the axis, and $= 1$ unit along the axis. It is left circularly polarized.

Now let's ask the following question: If light is linearly polarized in the direction, what is its angular momentum? Light polarized in the x -direction, can be represented as the superposition of RHC and LHC polarized light. There fore there is a certain amplitude for the angular momentum J_x and another

¹ It is usually very difficult to measure angular momentum of atomic systems, $\pm 1/2$. They can only have spin one-half, so with no angular momentum $m = 1/2$ with respect to any axis. Of course, if that the z -component of angular momentum is m . You don't need to align the x -axis the time.

amplitude that the angular momentum is $-A$, so it doesn't have a definite angular momentum. It has an amplitude to appear with $+A$, and an equal amplitude to appear with $-A$. The interference of these two amplitudes produces the $\langle A \rangle$ polarization, but it has equal probabilities to appear with plus or minus one unit of angular momentum. The netopic measurements made on a beam of linearly polarized light will show that it is this, a random orientation, because in the $\pi/2$ chamber of photons there are many more numbers of $|\text{D}\pi/2\rangle$ and $|\text{U}\pi/2\rangle$ photons contributing significantly amounts of angular momentum—the average angular momentum is zero. And in the classical theory you don't find the angular momentum unless there is some circular polarization.

We have said that a composite particle can have three values of J_z , namely $-J$, 0 , $+J$ (the transitions we saw in the Stern-Gerlach experiments). But light is screwy; it has only two states. It does not have the transitions. The strings back is related to the fact that "light comes and will. For a particle of spin J which is spinning ω , there are $J(J+1)$ possible states with values of J going in steps of 1 from $-J$ to $+J$. But it turns out that for given J there's going to be only the states with the components $\pm J$ along the direction of rotation ω . The example light does not have three states, but with the ω although a photon is still a object of spin, one thing is not true about it is that it is not in a state "based on what happens in the rotational space—that the said one particles contributes are necessary". That a particle of total angular momentum made about ω without changing the measurement axis. Particles were measured twice (the previous and the next) cannot be about, only rotations about the axis along the direction of motion do not change the orientation of the angular momentum. Rotations around ω does not only see influence to prove that these states are required, give that all of the ω axes are ω under rotations by the angle φ .

One further cold remark. For a very fast ω or like a general, uniform, rotation of the two spin states with respect to the line of motion ($-J$, $+J$) is really necessary. For instance when we spin one half particles—only the parts were the component of angular momentum according to the equation of states $= J/2$ exist at least (and only) magnetic moment ($\pm J/2$ for magnetons). When angular momentum is ω , only (so the energy is conserved, as it is for light) high components ($\pm J$, 0 , $-\omega$) are required.

17-6 The disintegration of the Λ^0

Now we want to give an example of how we use the theorem of conservation of angular momentum in a specifically quantum physical problem. We look at break up of the Lambda particle (Λ^0), which disintegrates into proton and a pion via a "weak" interaction.

$$\Lambda^0 \rightarrow p + \pi^-.$$

Assume we know that the pion has spin zero, that the proton has spin one-half, and that the Λ^0 has spin one-half. We would like to solve the Λ decay problem. Suppose that a Λ^0 were to be produced in a way that cause it to be completely polarized—by which we mean that its spin is, say, "up," with respect to some coordinate system (see Fig. 17-6a). Then what is ψ , in what probability will it disintegrate into the proton gives off an angle θ and π^- goes in the ϕ axis? In Fig. 17-6(b) to decide odds, what is the angular distribution of beta-decay? (Time!) We will look at the easiest case in the coordinate system in which the Λ^0 is at rest; we will measure the angle θ this set the ψ in Fig. 17-6a always be transverse to another frame if we were

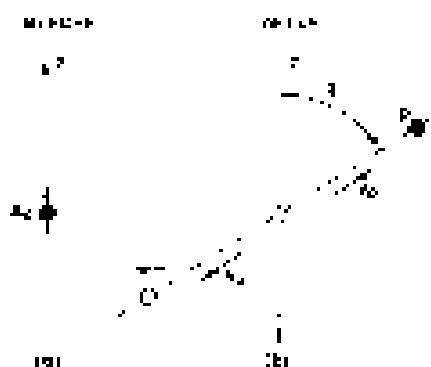

Fig. 17-6. A Λ^0 with spin "up" decays into a proton and a pion [in the CM system]. What is the probability that the proton will go off at the angle θ ?

* We have tried to make it sound as if the component of angular momentum along the direction of motion must form some more particle, but in reality, the type of C-S—and not something like A/λ . Even among all sorts of forms for all the Lorentz invariants, we can take just, we have. There is no law—well have a look about it—but Pauli-Weyl are known about such things.

BC-STATE	EF-STATE

↓↓	↓↓
yes	no
(a)	(b)

Fig. 17.7. Two possibilities for the decay of a spin-up ↑ particle into two going along the \hat{z} -axis. Only (b) conserves angular momentum.

We begin by looking at the second circumstance in which the proton is emitted into a small \hat{z} , the angle subtending the axis (Fig. 17.8). Before the proton is sent on its way it is both spin-up ↑, in part of the system. After a short time—say, 10 microseconds—the hadron is still there except that it is connected with the \hat{z} through the "spin-down" proton and a gluon. Suppose the gluon goes up along the \hat{z} -axis. Then, from the conservation of momentum, the proton must go down. Since the proton is a baryon half as large as a pion, it may be either "up" or "down". This is a principle, but it is possible, as shown in parts (b) and (c) of the figure.

The conservation of angular momentum, however, requires that the proton have spin $+1/2$. This is not really seen from the following reason. A particle moving along \hat{z} has zero spin and can be a very singular number in an absolute sense. If the \hat{z} is a regular baryon, only the spins can contribute to it. They can angular momentum about the \hat{z} with $1/2$ below the degeneracy, so it must also be $-1/2$ (Section 16.2). We can say that since the proton has no spin, the proton spin must be "up".

If you are worried that arguments of this kind may not be valid in quantum mechanics, we can always return to classical theory. The initial state (before the fragmentation), with $\psi = \psi_0(\hat{z})$, spin $+1/2$ has the property that "it is rotated about the \hat{z} " by the angle ϕ . The state after fragmentation by the pion has $\psi' = \psi_0(\hat{z}')$. (In contrast to standard quantum mechanics, ψ' is not a spin-half particle.) Since nature's behavior doesn't depend on our choice of axes, the final state ψ' must also have "it is rotated about the \hat{z}' ". We could write the final state as, for

$$\text{proton going } +\hat{z}, \text{ spin } +1/2; \text{ pion going } -\hat{z}'.$$

It is really no surprise to classify the gluon momenta, since in the frame we are using, the gluon always moves toward the proton, \vec{p}_g and \vec{p}_p are the components of the final momentum

$$\text{proton going } +\hat{z}, \text{ spin } +1/2.$$

Now what happens to this wave vector ψ' when we rotate the coordinates about the \hat{z}' axis by the angle ϕ' ?

Since the gluon and pion are moving along the \hat{z}' -axis of the system, but are separated by the rotation, (that's why we pick the coordinate axes to make the argument otherwise), also, nothing happens to the pion's momentum if it is spinless. The proton, however, has now one-half. If its spin is " $+1/2$ " it will undergo a phase change of $e^{i\phi'}$ in response to the rotation. All its spin were down, the phase change leaves the proton with spin " $-1/2$ ". But its phase change with rotation before and after the fragmentation must be the same if angular momentum is to be conserved. (And it is!) In, since there is no sensible interaction in the fragmentation, the only possibility is that the value spin will be " 0 ," little about going up; its spin must also be " up ".

This is realistic. Let's let the initial value of angular momentum be only the proton's spin, $\psi_0(\hat{z})$ going up (\hat{z}). This spin does not permit the process shown in part (a). Since we know that the fragmentation occurs, there is some amplitude for process (b) (proton going up with spin " up "). Well, we demand to the amplitude for the diagrams we see in this case to be $\psi_0(\hat{z}')$ instead of ψ_0 .

Now let's see what would happen if the "spin orientation" \hat{z}' alone. Again we ask about the decay on \hat{z}' : The proton goes up along the \hat{z}' -axis as shown in Fig. 17.8. You will appreciate that in this case the gluon must have spin "down" if angular momentum is to be conserved. Let's say the amplitude for such a diagram is a .

We can't say anything about the two amplitudes a and b . They depend on the angular momentum of \hat{z}' and on the energy, and we've yet to prove how to

Fig. 17.8. The decay along the \hat{z}' -axis for a ψ^2 with spin " up ".

* Now a more sophisticated, but the important, role the angularity of the proton mechanics is extremely important to you. You can speak about a gluon wave function and take the time to understand it in mathematical detail. In practice, however, you need not do this; you have the general idea, especially in the first few pages of the section.

undetectable from. We'll have to get them from experiment. But with just these two amplitudes we can find out what we want to know about the angular distribution of the disintegration. We only have to be careful always to define completely the states we are talking about.

We want to know the probability that the proton will go off at the angle θ with respect to the x -axis (into a small solid angle $d\Omega$) as drawn in Fig. 17-6. Each point is one α -particle in this direction and each is the x -axis. We know how to specify what happens along this axis. With respect to this new axis, the α no longer has its spin "up," but has a certain amplitude to have its spin "up" and another amplitude to have its spin "down." We have already worked these out in Chapter 6, and again in Chapter 16, Eq. (16.96). The amplitude to be spin "up" is $a \cos \theta/2$ and the amplitude to be spin "down" is $b = -a \sin \theta/2$. When the α spin is "up" along the x -axis it will emit a photon in the y direction with the amplitude a . So the amplitude to find an " $-y$ "-spinning photon coming out along the x' direction is

$$a \cos^2 \frac{\theta}{2}. \quad (17.33)$$

Similarly, the amplitude to find a "down"-spinning photon coming along the post x' is b , which is

$$-b \sin^2 \frac{\theta}{2}. \quad (17.34)$$

The two processes that these amplitudes refer to are shown in Fig. 17-7.

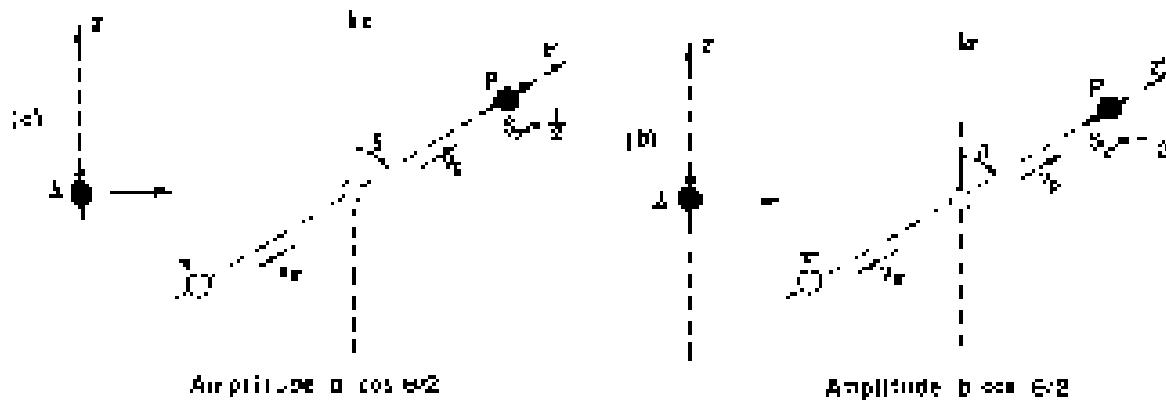

Fig. 17-7. Two possible decay states for the α .

Let's now ask the following easy question. If the α has spin up along the z -axis, what is the probability that the decay process will go off at the angle $\theta/2$? The two spin states ("up" or "down" along z) are distinguishable even though we are not going to look at them. So to get the probability we square the amplitude. The probability $f(\theta)$ of finding a proton in a small solid angle $d\Omega$ is

$$f(\theta) = |a|^2 \cos^2 \frac{\theta}{2} = \hat{p}^2 \sin^2 \frac{\theta}{2}. \quad (17.35)$$

Re-arranging that $\sin^2 \theta/2 = |\hat{p}|^2 = \cos^2 \delta$ and $\cos^2 \theta/2 = \sin^2 \delta$, we can write $f(\theta)$ as

$$f(\theta) = \left(\frac{a_i^2 + b_i^2}{2} \right) - \left(\frac{|p|^2 - \delta|^2}{2} \right) \cos \theta. \quad (17.36)$$

¹ We have chosen to use a or b in the complex and type the matrix elements for $S_{\alpha}(E)$. You would get the same answer for any other choice.

The angular distribution has the form

$$\langle \hat{p}_y \rangle = \langle \psi | \hat{p}_y | \psi \rangle = 0 \quad (17.35)$$

The probability δ has one part that is independent of θ and one part that varies linearly with $\cos \theta$. From measuring the angular distribution we can get δ and α and therefore, β and $|\psi\rangle$.

Now there are many other questions we can answer. Are we interested only in particles with spin "up" along the x -axis? Each of the terms in (17.35) and (17.36) will give us amplitude to find a particle with spin "up" along your spin "Down" and respect to the x -axis ($|+z\rangle$ and $| -z\rangle$). Spin "Up" will respect to the y -axis ($|+y\rangle$) and be orthogonal in terms of the basis states $|+z\rangle$ and $| -z\rangle$. We can then measure the two amplitudes (17.35) and (17.36) and the proper coefficients from 6.2 and (17.21) to get the total amplitude

$$\left(\cos^2 \frac{\theta}{2} + \delta \cos^2 \frac{\theta}{2} \right).$$

This square is the probability that the proton comes out of the angle θ with its spin the same as the ψ^k ("up" along the x -axis).

If parity were conserved, we could say one more thing. The deautlerization of Fig. 17.8 is just the reflection—in say, the x -plane of the deautlerization of Fig. 17.7†. If parity were conserved it would have a coefficient of $+1$ or -1 . Then the coefficient α of (17.37) would be zero, and the deautlerization would be equally likely to occur in all directions.

The experimental result is shown, however, that there is an asymmetry in the deautlerization. The measured angular distribution, over the range $0 < \theta < \pi/2$, is plotted in an additional line in Fig. 17.8. It has the form $|\psi\rangle = |\psi^k\rangle + \alpha \sin \theta |\psi^k\rangle$, and it is not zero, and

You see how much we can get from the conservation of angular momentum. We will give some more examples in the next chapter.

Conversely: By the methods in this section we can find the amplitude and the state $|\psi\rangle$ knowing $\langle \psi | \hat{p}_y | \psi \rangle$ is obtained in an additional line in Fig. 17.8 from the state $|\psi\rangle = |\psi^k\rangle + \alpha \sin \theta |\psi^k\rangle$, and it is not zero, and

$$\text{Spin-orbiting } \langle \psi | \hat{p}_y | \psi \rangle = H |\psi\rangle, \text{ spin } \langle \psi | \hat{p}_y | \psi \rangle = i\hbar\omega. \quad (17.38)$$

where H is the Hamiltonian of the world, or, at least, of whatever is reasonable for the theory. The conservation of angular momentum means that the Hamiltonian must have the property that

$$\text{Cyclic gauge } \langle \psi | \hat{p}_y | \psi \rangle = H |\psi\rangle, \text{ spin } \langle \psi | \hat{p}_y | \psi \rangle = i\hbar\omega. \quad (17.39)$$

By the amplitude β we mean that

$$\text{Spin-orbiting } \langle \psi | \hat{p}_y | \psi \rangle = H |\psi\rangle, \text{ spin } \langle \psi | \hat{p}_y | \psi \rangle = i\hbar\omega. \quad (17.40)$$

Conservation of angular momentum implies that

$$\text{Cyclic gauge } \langle \psi | \hat{p}_y | \psi \rangle = H |\psi\rangle, \text{ spin } \langle \psi | \hat{p}_y | \psi \rangle = 0. \quad (17.41)$$

If the amplitudes given in (17.33) and (17.34) are the ones, we can express them mathematically as follows. By (17.41) we know the amplitude and the β have spin along \hat{p}_y will decompose into a power having along the \hat{p}_y -direction with its sign plus to the \hat{p}_y -direction, or, similarly the amplitude

$$\langle \text{spin-orbiting } -\hat{p}_y, \text{ spin } +\hat{p}_y | H | \psi \rangle, \text{ spin } \langle \psi | \hat{p}_y | \psi \rangle = 0. \quad (17.42)$$

By the general methods of quantum mechanics this amplitude can be written as

$$\sum_i \langle \text{spin-orbiting } -\hat{p}_y, \text{ spin } +\hat{p}_y | H | \psi \rangle, \text{ spin } \langle \psi | \hat{p}_y | \psi \rangle, \quad (17.43)$$

†Remembering that the spin is a vector and the spin is the rotation.

where the sum is to be taken over the base states $\langle A, \beta \rangle$ of the system it creates. Since the hyperfine spin quantum number is zero, we can write this in the form

$$\begin{aligned} \text{operator giving } & \langle A, \beta | \psi_1(\vec{x}', \vec{p}') \rangle \langle \vec{A}, \beta | \psi_2(\vec{x}_1, \vec{p}_1) \rangle \\ & + \langle \psi_1(\vec{x}', \vec{p}') | \psi_2(\vec{x}_1, \vec{p}_1) \rangle \langle A, \beta | \psi_1(\vec{x}', \vec{p}') \rangle \langle \vec{A}, \beta | \psi_2(\vec{x}_1, \vec{p}_1) \rangle \end{aligned} \quad (17.4)$$

The first factor of the first term is a_1 , and the last factor in the second term is a_{22}^* . From the definition of ψ_1 in (17.1), and from (17.4) which is now fully symmetric by momentum conservation, the maximum factor $\langle A, \beta | \psi_1(\vec{x}', \vec{p}) \rangle$ in the first term is the diagonal wave function for half particles with spin β , p' along $\vec{\beta}$ and will have Lorentz spin β , p' along $\vec{\beta}$ and other α at the angle θ , which is one of $2\pi/3$ or $4\pi/3$. So (17.4) is just a scaled Ψ as we wrote in (17.3). The amplitude of (17.4) follows from the same kind of arguments for a spin "doubt" β -particle.

17.6 Summary of the rotation matrices

We would like now to bring together in one place the various things we have learned about the rotations for the fields of spin one-half and spin one. As they will be needed for further calculations, on the next page you will find tables of the two rotation matrices $R_1(\alpha)$ and $R_2(\beta)$ for spin one-half particles, for spin one particles, and for photons (spin one) with zero rest mass. For each spin we will give the terms of the matrix $\langle \psi | \vec{\psi}' \rangle$ corresponding to each component of the particle. They are, of course, exactly equivalent to the amplitudes like $\langle 1, \beta | 0, \beta' \rangle$ we have used in earlier chapters. We can see by $R_1(\alpha)$ that the state is expressed in a new coordinate system which is rotated enough to single out just the non-scattering always the angular part due to defining the primitive sectors of the rotation. By $R_2(\beta)$ we mean that the reference axes are rotated by the angle β about the \hat{n} axis. Knowing these two rotations, you can, of course, work out any arbitrary rotation. As usual, we write our \rightarrow as \rightarrow elements in the ring and our \leftarrow as a free state of the field (rotated!) charge and the state of the field as a base state of the old (unrotated) frame. You can inspect the entries in the tables in many ways. For instance, the entry $+e^2$ in Table 17.1 means that the \rightarrow \rightarrow element $\langle -| \psi | + \rangle = e^2$. If you take β so that $\hat{n} = j = e^{-i\beta^2/2}$, or that $\langle - | \psi | + \rangle = e^{i\beta^2/2}$ it's all the same thing.

$R(\theta)$	$ X\rangle$	$ Y\rangle$
$ X\rangle$	$e^{-i\theta}$	0
$ Y\rangle$	0	$e^{-i\theta}$

Angular Momentum

18-1 Electric dipole radiation

In the last chapter we developed the idea of the conservation of angular momentum in quantum mechanics and showed how it might be used to account for regular oscillations of the proton from the deionization of the hydrogen atom. We want now to give you a number of other, direct illustrations of the consequences of momentum conservation in atomic systems. Our first example is the radiation of light from an atom. The conservation of angular momentum (among other things) will determine the polarization and angular distribution of the emitted photons.

Suppose we have an atom which is in an excited state of definite angular momentum—say a spin of one—so it makes transitions to states having no magnetic field at a lower energy, emitting a photon. The problem is to figure out the angular distribution and polarization of the photon. If the nucleus is allowed exactly the same as the π^0 deionization, namely that the spin quantum number (spin one-half particles) would be opposite to the atom's spin one, there are three possibilities for the component of angular momentum. The value of m would be $+1, 0$, or -1 . We will take $m = +1$ for our example. Once you see how it goes, you can work out the others as well. We suppose that the atom is rotating with its angular momentum along the $+z$ axis (see Fig. 12-10), and that, with amplitude a along its right-hand polarized \hat{y} axis, it is also rotating. In addition, that the atom ends up with zero angular momentum— \rightarrow shown in part (b) of the figure. (We don't know the answer to that. But we do know that most unpolarized light has one unit of angular momentum out of its direction of propagation.) So after the photon is emitted, the electron would have to be as shown in Fig. 18-1(b)—the atom is again averaging to no magnetism

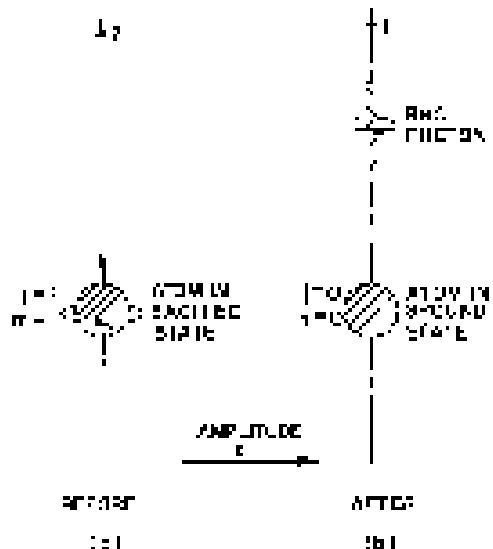

Fig. 18-1. An atom with $m_s = +1$ emits a Rabi photon along the \hat{y} -axis.

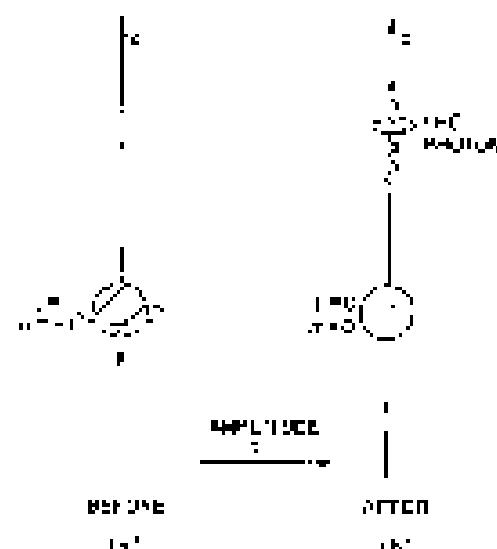

Fig. 18-2. An atom with $m_s = -1$ emits a Rabi photon along the $-\hat{x}$ -axis.

Added Note 1: Derivation of the selection rules

Added Note 2: Conservation of parity in photon annihilation

about the \hat{z} -axis, where we have assumed an atom whose low- $|m|$ state is spinless. We will let a stand for the amplitude for such an event. More precisely, we let a be the amplitude to emit a photon from a certain atomic configuration α , oriented on the \hat{z} -axis, during a time Δt . Notice that the amplitude to emit a LHC photon in the \hat{x} -hat direction is zero. The net angular momentum about the \hat{z} -axis would be -1 . Such a photon would form the system for a total of -1 , which would not conserve angular momentum.

Similarly, if the spin of the atom is initially “Down” ($-\frac{1}{2}$ along the \hat{z} -axis), a downward \rightarrow LHC polarized photon in the direction of $\hat{x}\hat{y} = -\hat{x}\hat{z}$, as shown in Fig. 18-2. We will let b stand for the amplitude for this event, meaning again the amplitude that the photon goes in a certain solid angle $d\Omega$. On the other hand, if the atom is in here $+$ state, a horizontal photon has a different, or all, possible photons can have only one angular momentum $+1$ or -1 along \hat{z} . Check!

Now, we’re going to do something new. Suppose we perform an inversion of the situation in Fig. 18-1, which means that we should imagine what the system would look like if we were to move each part of the system to an equivalent place on the opposite side of the origin. This does not mean that we should reflect the angular momentum vectors, because they are artificial. We should, rather, “turn the usual character” of the motion that would be responsible for such an angular momentum. In Fig. 18-1(a) and (b) we show what the process of Fig. 18-1 looks like before and after an inversion with respect to the center of the atom. Notice that the orientation of the atom is unchanged! In the inverted system of Fig. 18-1(c) we have an atom with $m = +1$ oriented $\hat{x}\hat{y}$ and \hat{z} oriented downward.

If we now rotate the system of Fig. 18-1(b) or 18-1(c) about the \hat{z} -axis, it becomes identical to Fig. 18-2. The combination of the inversion and rotation turns the second process into the first. Using Table 18-1, we see that a rotation of 180° about the \hat{z} -axis just changes $m = -1$ to state inversion $m = +1$, while so the amplitude b is not equal to the amplitude a except for a possibly sign change due to the inversion. The sign change in the transition was dictated by the parity of the initial and final state of the atom.

In other processes, parity is conserved, so the parity of the whole system must be the same before and after the position exchange. What happens will depend on whether the parities of the initial and final states of the atom, or even overall, — the angular distribution of the radiation will be different for different cases. We will take the common case of odd parity for both states and even parity for the transition, as will give what is called “electric dipole radiation.” (If the initial and final states have the same parity we say this is “magnetic dipole radiation,” which has the consequence of the radiation from an atom being a wave in a fixed direction of the \hat{z} -axis.) This is odd, since parity conserves angular momentum, which takes the system from (a) to (c) of Fig. 18-3. The final state of the atom, of course, ± 1 , its amplitude doesn’t change sign. That means it’s going to conserve parity, or equivalently it must be $a \pm b$, to a magnitude less than the amplitude total of the opposite sign.

We conclude that if the amplitude is a that an $m = +1$ atom will emit a photon upward, then for the general parity of the initial and final states the amplitude that an $m = -1$, atom will emit a LHC photon upward is $-a$.

We have all we need to know to find the amplitude for a photon to be emitted at any angle θ with respect to the \hat{z} -axis. Suppose we have an atom originally polarized with $m = -1$. We can consider the state only $+1$, 0 , and -1 states with respect to a fixed frame in the direction of the photon emission. The amplitudes for these three states are just the ones given in the lower half of Table 7-2.

[†] When we change (x, y, z) into $(x, -y, -z)$ you might think that all nature is reversed. That’s not true; just certain like displacements and velocities, but not for all. An inversion preserves momentum—or any vector that is a derived quantity such as a product of two particle vectors. Recall however that the electric component after an inversion.

[‡] You may notice in the argument we have just made on the basis that the final state we have been considering can not have a definite parity. You will find in added Note 2 at the end of this chapter another item of interest, when you may prefer.

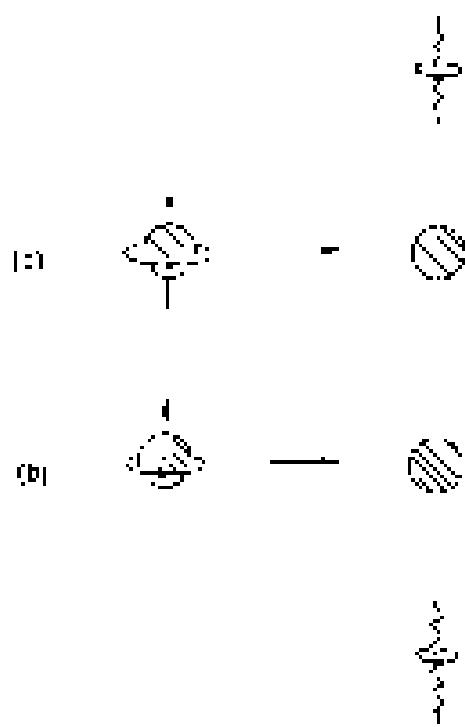

Fig. 18-3. If the process of (b) is transformed by an inversion through the center of the atom, it appears as in (d).

The amplitude for a RHC photon is emitted in the \hat{S} direction is the same as the amplitude for an LHC photon in the \hat{S} direction, except,

$$A_S = A_R(\theta) | \hat{S} \rangle = \frac{\pi}{2} C_1 \cos \theta. \quad (18.1)$$

The amplitude for the LHC photon is emitted in the \hat{S} direction is $-A_S$, unless the proper direction is $\hat{S} = -\hat{S}$ in the new direction. (See Table 17.2, if you like.)

$$-A_S = -A_R(\theta) = -\frac{\pi}{2} C_1 \cos \theta. \quad (18.2)$$

If you are interested in other polarizations you can find an amplitude formula from the superspace box. Use two amplitudes. To get the intensity of any polarization, just sum all of them; you must of course take the absolute square of the amplitudes.

18-2 Light scattering

Let's use these results to solve a somewhat more complicated problem, but also one which is considerably more real. We suppose that the source terms are sitting in the \hat{S} (around \hat{S}) ($\hat{S} = \hat{S}_0$) and scatter an incoming beam of LHC light. (Assume that the light is using only the \hat{S} cell, so no scattering outside \hat{S}). There photons coming up to the beam from the \hat{S} direction, as shown in Fig. 18-4(a). We can calculate the scattering of light in a two-step process. The photon is absorbed, and then is re-emitted. If we start with a RHC photon as in Fig. 18-4(a), and angular momentum is conserved, the beam will come in at $\hat{S} = +\hat{S}_0$ after the absorption, as shown in Fig. 18-4(b). We call the amplitude for this process A_R^* . The photon then emits a RHC photon in the direction \hat{S} , as in Fig. 18-4(c). The total amplitude that a RHC photon is scattered in the direction \hat{S} is just $A_R^* + A_R$. Let's call this scattering amplitude $(R^* + R)$; we have

$$(R^* + R) | \hat{S} \rangle = \frac{\pi}{2} C_1 (1 - \cos \theta). \quad (18.3)$$

There is also an amplitude R^* for a RHC photon \hat{S}' to be absorbed and that a LHC photon with be emitted. The product of these amplitudes has an $\langle R^* | S' | S \rangle = 6$, but a RHC photon is scattered as a LHC photon. Using (18.2), we have

$$\langle R^* | S' | R \rangle = -\frac{\pi^2}{2} (1 - \cos \theta). \quad (18.4)$$

Now let's look about what happens. The LHC photon comes in. With it is scattered, because with $\hat{S}' = -\hat{S}_0$. By these methods of angular \hat{S} we used in the preceding section, we can show that the amplitude must be $\langle R^* | S' | S \rangle = 1$. The amplitude that an electron in the $\hat{S} = -\hat{S}_0$ state will emit a RHC photon of the angle θ is minus the amplitude $(-1) R^*(\theta) = -1$, which is $1 - \cos \theta$. So we have

$$(R^* - S | R \rangle = -\frac{\pi^2}{2} (1 - \cos \theta). \quad (18.5)$$

Finally, the amplitude for a LHC photon to be scattered as a LHC photon is

$$\langle R^* | S | R \rangle = \frac{\pi^2}{2} (1 - \cos \theta). \quad (18.6)$$

(This is the two-photon states which cancel.)

If we make a measure unit of the scattered amplitude for the two-photon decay of an electron plus its bremsstrahlung, the frequency of one of the four amplitudes. For instance, with an incoming beam of LHC light the frequency of the RHC photon in the scattered radiation will be $|1 - \cos \theta|$!

This is π^2 very low, but suppose we scatter with linearly polarized light. What then? If they have \hat{S} -polarized light, it can be represented as a superposition

Fig. 18-4. The scattering of light by electrons via a two-step process.

XKCC and LHC light See note (see Section 1.4)

$$|\psi\rangle = \frac{1}{\sqrt{2}}(|X\rangle + |L\rangle) \quad (18.7)$$

Or, if we have polarized light, we would have

$$|\psi\rangle = \frac{1}{\sqrt{2}}(|R\rangle - |B\rangle) \quad (18.8)$$

Now what do you want to know? Do you want the amplitude that an unpolarized photon will scatter into a RHC photon at the angle? You can get it by the usual rule for summing amplitudes. First, multiply (18.7) by $\langle R' | S | X \rangle$:

$$\langle R' | S | \psi \rangle = \frac{1}{\sqrt{2}}(\langle R' | X | R \rangle + \langle R' | L | R \rangle), \quad (18.9)$$

and then use (18.1) and (18.2) for the two amplitudes. You get

$$\langle R' | S | \psi \rangle = \frac{\alpha}{\sqrt{2}} \cos \theta \quad (18.10)$$

If you wanted the amplitude that an x photon would scatter into a LHC photon, you would get

$$\langle R' | S | \psi \rangle = \frac{\alpha}{\sqrt{2}} \sin \theta. \quad (18.11)$$

Finally, suppose you want to know the amplitude that an unpolarized photon will scatter while keeping its polarization. What you want is $\langle Y | S | \psi \rangle$. This turns out to be

$$\langle R' | S | \psi \rangle = \langle R' | S' \rangle \langle R' | S | \psi \rangle + \langle R' | U | S' | S | \psi \rangle. \quad (18.12)$$

If you take just the real part,

$$|S'\rangle = \frac{1}{\sqrt{2}}(|R'\rangle - |B'\rangle), \quad (18.13)$$

$$|U\rangle = \frac{1}{\sqrt{2}}(|R'\rangle + |B'\rangle), \quad (18.14)$$

it follows that

$$\langle R' | B' \rangle = \frac{1}{\sqrt{2}}, \quad (18.15)$$

$$\langle R' | U \rangle = \frac{1}{\sqrt{2}}. \quad (18.16)$$

So you get that

$$\langle R' | S | \psi \rangle = \alpha \cos \theta. \quad (18.17)$$

This means that a beam of unpolarized light will scatter from an electron (at the x point) with an intensity proportional to $\cos^2 \theta$. If your light is polarized light, you had this:

$$\langle Y | S | \psi \rangle = 0. \quad (18.18)$$

So the unpolarized light is completely polarized in the y -direction.

Now we see something interesting. The result (18.17) and (18.18) correspond exactly to the classical theory of light scattering we gave in Vol. I, Section 3.6. When we imagined that the electron was bound in the atom by a linear restoring force—so that it acted like a classical oscillator, perhaps you are thinking: “It’s no such oscillator in the classical theory, so it gives the right answer only when $\theta = 0$ and $\theta = 90^\circ$.” For one thing, we have considered an isotropic unpolarized—the y -glow—case, which from $\theta = 0$ to $\theta = 90^\circ$ is excited with $E_y = 0$ ground state. If the excited state had split too, you would get a different result. Also, there is no reason why the model of an electron attached to a

spins and orbits by an overlapping electron. It should work for a single proton. But we know that it does not work, and at the present time and interest—incorrect right. And in a certain sense we are bringing the whole theory around to the real truth. Otherwise we have, in fact, a theory of two index of refraction, and of light scattering. By the classical theory, we have now shown the true quantum theory. Now the same result for the more common case. In fact we have now that the polarization of sky light, for instance, by *quantum* the two index approach, which is the only fully legitimate way.

I should like, of course, that there be theories which work on *suppose*, ultimately, by legitimate quantum arguments. Naturally, those ranges which we have used a great deal in calculating, or you see selected from us three parts of classical physics which still have some validity in quantum mechanics. You'll notice that we did not do so in *quantum* my model of the atom which has electrons just positioned in orbits. That's because such a model doesn't give results which agree with quantum mechanics. But the answer is a strong—*why* is not in a sense, is it?—the way in which “looks”—does work, because we used that model for the theory of the index of refraction.

10-3. The annihilation of positronium

We would like now to take an example which is more physical. The question concerning spin, although somewhat hypothetical, we hope not too much so. Our example is the system called “positronium,” which is an “atom” made up of an electron and a positive, a bound state of one and one e^+ . It's like a hydrogen atom, except that a positron replaces the proton. The angular law-like, the hyperfine along many axes. Also like the hydrogen, the ground state is split into a “positive structure” by the interaction of the magnetic moments. The spins of the electron and positron are both enabled, and they can be either parallel or antiparallel to any given axis. (In our ground state there is no other angular momentum in the Kondo model.) So there are five states. These are the only states of a symmetric system, all with the same energy, and one is a sort of twin very near a different energy. The energy splitting is, however, much greater than the 1-20 megacycles of hydrogen, because the reaction magnetic moment is so much larger, 1900 times stronger, than the present moment.

The most important difference, however, is that positronium cannot live forever. The position is the coordinate of the electron; they can annihilate each other. The two particles have opposite momentum, taking energy into each other which appears as two γ -ray photons. In the diagram, this is a good way: I have two massless two or more objects worth have zero rest mass.*

We begin by analyzing the disintegration of the spin-zero state of the positronium. I pointed out that the $\gamma\gamma$ decay with a lifetime of about 10^{-10} second. Initially, we have a positron and an electron moving here and with spins opposite, making the descrete system. After the disintegration there are two photons going off with equal and opposite momenta (Fig. 10-5). The momenta of each equal and opposite because the total momentum after the disintegration must be zero, as it was before, if we are taking the case of annihilation as zero. If the result could be not at 180°, we can't do $\psi\psi$ to solve the problem, and then from it in the ordinary way to the lab system. (So as we can do anything now; we have all the ways.)

First, we note that the angular distribution is not very interesting. Since the initial state has spin zero, it has no “spin” axis. It's something made out of two. The final state must then also be symmetric under π -rotations. This means that all singles the two single photons are equally likely—the amplitude is the same for a photon to go at $\theta = 0$ as at $\theta = \pi$. (Remember, since we have one of the photons in some effect on the other must be opposite.)

* In the chapter immediately after the word “way,” we do not have an easy way to distinguish who has the energy and power in the “masses” from the energy of an electron, because in your mind you think the particle has been “separated.” The true difference is that the present are *isolated* mass.

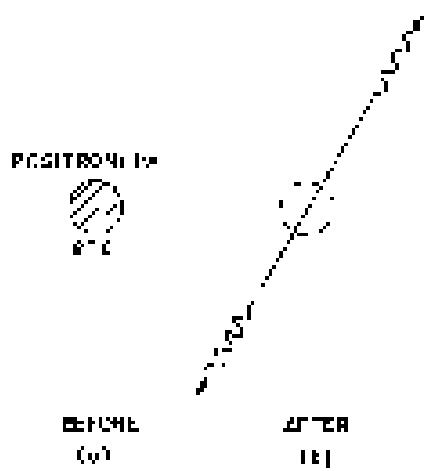

Fig. 10-5. The descrete annihilation of positronium.

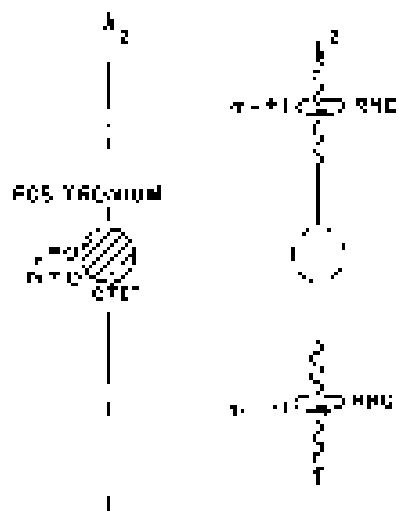

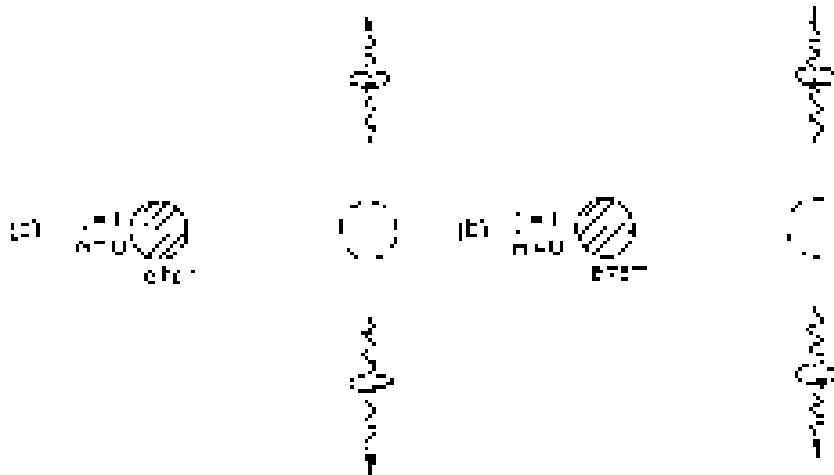

Fig. 1B a. Optimality for continuous mobility along the road.

The only remaining question, which we now want to focus on, is about the orientation of the directors. Let's call the directions of rotation of the two phasers as α (horizontal) and β (vertical). We ignore any rotation of one w.r.t. the other (parallel-axes rule for the rotations); we also choose the first description (right-angle) for a particular phaser rotation, always with respect to the orientation of rotation. Right-angle orientation (but if the phaser is going upward & RPS), then an angular momentum will be generated at the downstream polar position (RUC). It will carry $\pm \frac{1}{2}$ and $\mp \frac{1}{2}$ angular momentum components in its downstream direction, which means plus and minus one unit around the axis. The total will be zero, and the angular momentum after the steering system will be the same as before. See Fig. 1(b).

The static arguments show that if the upward helix placed a RHC, the downward can't be LHC. Then, the first state wouldn't be a unit of angular momentum - this is not guaranteed if the initial one has spin zero. Note that such a state is also not possible for the outer positronium ground state of spin zero, because it has three maxima of one unit of angular momentum in one ring; i.e.

Now we want to see if two-particle annihilation is not possible at all from these constraints. You might think that "well ok, just take a state which has zero angular momentum about the \hat{z} -axis" shows it's like no-gyrotron state, and could deinterfere with the ADL patterns. Certainly, the deinterference sketches in Fig. 18-2(a) conserves angular momentum about the \hat{z} -axis. But now look what happens if we rotate this system around the \hat{x} -axis by 180° : we get the picture shown in Fig. 18-2(c). It's exactly the same as in part (a) of the figure, *but* we have done a full change the two particles. If one particle is a base particle, if we flip it around, its amplitude has the same sign, so the amplitude for the deinterference is per (b) must be the same as in part (a). But we have assumed that the initial photons are spin-one. And when we rotate a spin-one object as a state with $m = 0$ (as 180°) about the \hat{x} -axis, its amplitudes change sign (see Table 17-2 for $e = \pi$). So the amplitudes for (3) and (4) in Fig. 18-2 would have opposite signs, and we can't make conservation of angular momentum work.

When $\lambda = 0$, then you would expect it to end up in the stationary state. All of the time and in the beginning, there exists $\mu = -1/6$, or $+1/3$ of the mass. So half of the time you would expect position and velocity. The other half

Hg. 10-7. For the $\beta \rightarrow \gamma$ state of polarization, the process (a) and (b) (Rb) relation between β 's are exactly the same.

* Note that we always calculate C_2 up to one decimal place above the diagonal or below the π^0 particle. If we try to go to 30% beyond the angle, we run into trouble with any other pions, as we will have to work around the possibility of "self" angles—meaning angles with a π^0 particle. For example, we can't say that the photons came really from the center of the experiment. They could have been coming from us from the far left or something like that. We don't have to worry about such problems unless we are interested in the distribution of medium.

of the two photons beam splitter and detector. That's after multiplying, but it agrees with previous work. The harder part is to do that and the time is 1000 times longer about 10⁻⁷ second. This is what is observed experimentally. We will now go into very much of the details of the spin calculations.

We know that if we only carry about single momenta, the spin-wave state of the descretional doublet has two LHC photons. There is also another possibility, it can split into two LHC photons as shown in Fig. 18-6. The next question is, where is the heavier because the amplitudes for these two possibilities decay inversely. We can find out from the conservation of parity.

To do that, however, we need to know the parity of the positive ion. Now theoretical physicists have come in a way that is not very to explain, but the parity of the electron and the position of its antiparticle must be opposite, so then the spin-wave quantum state of positronium must be odd. We will just assume that it is odd, and since we will get agreement with experiment, we can take that as sufficient proof.

Let's see then what happens if we make an antisym of the process in Fig. 18-6. When we do that, the two photons receive different spin polarizations. The inverted paraxial lenses look like Fig. 18-4. Assuming that the parity of the positronium is odd, the amplitudes for the two processes in Figs. 18-6 and 18-5 must have the opposite sign. Let's let |R, R> stand for the final state of Fig. 18-6 in which both vectors are RHC, and |L, L> stand for the final state of Fig. 18-5, in which both photons are LHC. The final state (labeled in Fig. 18-6) is

$$|\psi\rangle = |\text{R}, \text{R}\rangle - |\text{L}, \text{L}\rangle \quad (18.19)$$

The amplitude changes the RC in Eq. 18-3 and gives the value

$$\langle \psi | \psi \rangle = \langle \text{R}, \text{R} | \psi \rangle = -\epsilon_{123} = -1 \quad (18.20)$$

which is the negative of Eq. 18-3. So the final state |ψ⟩ has negative parity, which is the same as the fine spin wavestate of the positronium. This is the only final state that conserves both angular momentum and parity. There is zero amplitude that the incident ion into the state will occur, which we don't need to worry about here, however, since we are only interested in spin conservation the polarization.

What does the lifetime of Eq. 18-5 bear physically? One thing it does is the following. If we observe the two photons in two detectors which can't be able to detect separately the RHC or LHC photons, we will always see two RHC photons together, or two LHC photons together. That is, if you stand on one side of the positronium and examine the光 on the opposite side, you can measure the polarization and tell me whether it what polarization he got yet. You have a 50-50 chance of catching a RHC photon or a LHC photon; whichever one you get, you can prove that it will get the same.

Since there is a 50-50 chance to RHC or LHC polarization, it sounds as though it might be an linear polarization. Let's ask what happens if we measure the photon in counter that accept only linear polarized light. We change it is not as easy to measure the polarization as it is for light; there is no polarization when waves are, for such short wavelengths. But for something that is, to make the distinction easier. Suppose that you have a counter that only accepts light with polarization, and that there is a gap on the other side that also looks for linear polarization with, say, z-polarization. What is the chance that we pick up the two photons from an antineutron? What we need to ask is the amplitude that

ψ will be a state where I either ends up one, the amplitude

$$\langle \psi | \psi \rangle = P$$

which is, of course, just

$$\langle \psi | \psi \rangle = |\psi\rangle \langle \psi| = P \quad (18.21)$$

Now although we are working with two particle amplitudes for the two photons, we can hardly do just one. So single particle amplitudes, since

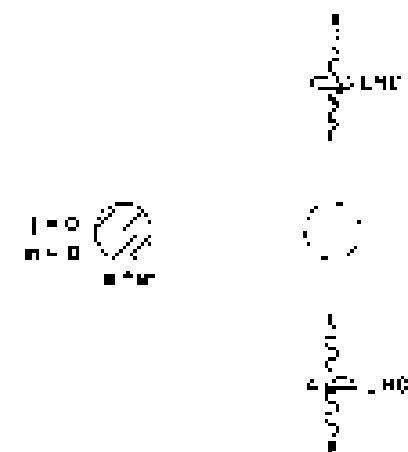

Fig. 18-6. Another doublet process for positron annihilation.

and α_2 does independently of the other. That means that the amplitude $(\alpha_1, \alpha_2) R_1 R_2$ is the product of the two independent amplitudes (α_1, R_1) and (α_2, R_2) . Using Eqs.(18.1), these two amplitudes are $1/\sqrt{2}$ and $i/\sqrt{2}$, so

$$(\alpha_1, \alpha_2) R_1 R_2 = -\frac{i}{2}.$$

Similarly, we find now

$$(\alpha_1, \alpha_2) L_1 L_2 = -\frac{i}{2}.$$

Substituting these two amplitudes into Eq.(18.2) we get that

$$(\alpha_1, \alpha_2) V_{L,R} = 0. \quad (18.2)$$

So there is a 50% probability that if you get a photon in your polarization detector, the other guy will also photon in his polarization detector.

Now suppose that the other guy has a counter for a photon in his. In some way yours. He would never get a count when you present. If you work it through, you will find that

$$(\alpha_1, \alpha_2) S = 0. \quad (18.22)$$

I will, naturally, also work out that if you set your counter for unpolarization, he will get a count about once only if he set his polarization.

Now this all leads to an interesting situation. Suppose you were to set up something like a series of switches which separated the photons into polarized and unpolarized beams, and put a counter in each beam. Let's say that the beam on the left goes to the other side goes the same thing you can always tell him which beam his photon is going to go into. Whether you and he get the photons to do, you can see which of your detectors caught the photon and he will know which of his counters had a photon. Let's say that in a certain chain you can tell that a photon went in to your detector; you can tell him that so must have been a counter in his parameter.

Now, if any people think quantum mechanics is not useful (and I have indeed seen that), they would like to think that since the photons are sent in groups along with a given wave function, they would think that since "they carry photon" has some "hampered" from polarization or unpolarization, there would be some chance of picking it up ... with the counter and that this chance shouldn't depend on whom some other person didn't set about a completely arbitrary photon. They might then "argue" that "since one detector shouldn't be able to change the probability that I will find something". One quantum mechanics says, however, that by looking at a source and on whose detector one you can precisely predict when the particle (or photon in either case) is going to be set, it is detected. This point was never accepted by Einstein, and he wanted to say it is a foolish "argument" because known as the "Einstein-Podolsky-Rosen paradox". But when the situation is described as we have done, it then does doesn't seem to be any paradox at all; it seems quite naturally that what is measured in one place is correlated with what is measured somewhere else. The argument that there is no "hidden" assumption here, like this:

- (1) If you have a counter which tells you whether your photon is RHC or LHC, you can predict exactly what kind of a photon (RHC or LHC) he will find.
- (2) The photons are received just, respectively, say, by partly RHC or partly LHC, some of one kind and some of the other.
- (3) Surely you cannot alter the physical nature of the photons by changing the kind of observation you make on your photons. No matter what measurements you make on your, his must still be either RHC or LHC.

I have here not mentioned our angle, which is multiplied times the amplitude for the transmission into the particular field wave, but we can see that there is no effect because we get the same probability when we look at the other side counter. See Eq.(18.21) that.

- (d) Now suppose he changes his setup so instead of 10 photons he has ten randomly polarized beams with a piece of plastic so that $\frac{1}{2}$ of his photons go either forward or backward, turning it into a 50% left-right beam. Let's say absolutely no way according to quantum mechanics, $\frac{1}{2}$ will go right, $\frac{1}{2}$ will go left. If 1 photon will pass. Then there is 50% probability it will pass to the x-beam and a 50% probability it will pass to the y-beam. And the same goes for a 17% photon.
- (e) Since each photon is RHC or LHC according to (c) and (d) each one must have a 50/50 chance of going into the x sector or the y beam and there is no way in practice which one it will go.
- (f) Yet the theory predicts that if you do your photon path through an experimenter you can set up each existing LHC and RHC will go into his y deflected beam. This is in contradiction to (c) so the theory is a paradox.

No... I apologize. I don't see the "paradox," however, because experimenter choice has the potentiality of biasing the results. We have already discussed the key to this "paradox" in our very first discussion of quantum-mechanical behavior in Chapter 23, Vol. 1. In the argument above, steps (d), (e), (f), and (g) are all correct but (c), and consequently (f), are wrong. They are not a true description of nature. An experiment says that as a measurement (say a RHC or a LHC photon) you can determine which of two alternative events occurs for that (see, e.g., RHC vs a LHC photon), and that even though you make your measurements you can only later measure what occurred earlier by changing the order. But it was probably the point of Chapter 23, Vol. 1, to point out that it begins nothing like the point in Nature. You have to consider the problem in terms of interfering amplitudes, and ψ -functions for each alternative. A measurement in which alternative actually occurs destroys the interference, but if a measurement is not made you would still say that "the latter value on the side is not seeming."

If you could determine for each event of your photons whether it was RHC and LHC, and also whether it was polarization (all for the same photon) there would indeed be a paradox. But you cannot do that. It is an example of the uncertainty principle.

Do you still think there is a "paradox"? Make up your mind; in fact, a paradox exists the definition of Nature, by setting up an idealized experiment that violates the theory of quantum mechanics would predict inconsistent results via two different arguments. Otherwise the "paradox" is only a paradox between theory and your feeling of what ought "right" to be."

Do you think that it is an "anomaly," but that it is still very justified? or that it can't happen? It is what makes physics funniness!

38-4 Rotation matrix for spin 1/2

By now you can see, or hope, one important idea of the simpler no-matter-is-in-understanding world we access. So far, we have considered only systems with spins in "total angular momentum" — $\ell = 0$, $\ell = 1$, or $\ell = 2$. There are, of course, some systems with higher ℓ , $\ell = 3$, etc. For analyzing such systems we would need to have tables of rotation amplitudes like those in Section 7.6. That is, we would need the matrix of ψ -functions for spin $\frac{1}{2}$, $\frac{3}{2}$, $\frac{5}{2}$, etc. Although we will not work out these tables in detail, we would like to show you how it is done, so that you can do it if you ever need to.

As we last saw in the one system which has been given ("total angular momentum") you said "you can't have an $\ell \neq -1$ state for which the component of angular momentum can have any one of the discrete values in the sequence $j_1, j_2 = 1, j_3 = 2, \dots, |J| = 0$, ..., $|J| = 3$, ... (all in units of \hbar). Calling the components of angular momentum of any particle and axis we can define a particular angular momentum state by giving the numerical values of the two "angular momentum quantum numbers" j_1 and j_2 . We can indicate such a state by the state vector $|j_1 j_2\rangle$. In the case of a spin $\frac{1}{2}$ system like the two electrons, then, $|j_1 j_2\rangle = |j_1 = \frac{1}{2}, j_2 = \frac{1}{2}\rangle$ or for a spinless system, the state would be written in the basis from $|+1\rangle, |0\rangle, |1\rangle, |0\rangle, |+, -1\rangle$. A spin zero particle has, of course, only the one state $|0, 0\rangle$.

Now we want to know what happens when we contract the general state. If we have a spin-one fermion and a spin-zero boson state of spins. First we know there is a number which characterizes the system, so it doesn't change. If we contract the two, all we do is get a multiple of the original ψ -valence for the state $|j, m\rangle$. In general, there will be a unitary implemented in the basis of Fermi's space which is the state $|j, m\rangle$, where m gives the new j -component to angular momentum. So what we want are all the j -basis elements $|l, m'\rangle R_{jl}$ for various rotations. We already knew this happens if we rotate by an angle θ about the x -axis. The new state is just the old one $|m\rangle$ dotted by $e^{i\theta \sigma_x/2}$ for the x -component. We can write this as

$$R(\theta)|j, m\rangle = e^{i\theta \sigma_x/2}|j, m\rangle \quad (18.24)$$

Or, if you prefer,

$$(j, m') R(\theta)|j, m\rangle = \delta_{lm'} e^{i\theta \sigma_x^2} \quad (18.25)$$

where $\delta_{lm'} = 1$ if $l = m'$ or zero otherwise.

The rotation about any other axis $R(\phi)$ will be a mixing of the various systems. We could of course try to work out the more complicated invariance relations described by the Euler angles θ, ϕ and ψ . But it is easier to remember that the more general such relation can be made up of the three rotations $R_x(\theta)$, $R_y(\phi)$, $R_z(\psi)$; so down below the matrix elements for a rotation about one particle, we will have all we need.

How can we find the rotation matrix $R(\phi)$ rotation by the angle ϕ about the y -axis for a particle of spin $j/2$? We can't tell you how to do it the hard way (we did what we have had). We do it the spin-one-half by a no-symmetry argument. We then did it for spin-one-half taking the special case of a spin-one system when two mixings of two spin-one-half particles. If we are going along with this and accept the fact that in the general case the systems depend only on the spin and are independent of how the little quarks of the object of spin j are put together, we can ignore the spin-one argument. In such a theory again, we can, for example, cook up an identical system of spin-1/2 or even spin-one-half objects. We can even insist one relation holds by insisting that they are all distinct particles. Use a generic α character, and a β one. By calculating such spin-one-half object, we can see what happens to the whole system—remembering that our assumptions are unchanged for the combined state. Let's see how it goes in this case.

Say we take the dumb spin model¹ objects α with value "up", we can imagine the particle $|+\rangle = |\alpha\rangle$. If we look at the system in a frame with about the z -axis by the angle ϕ , each α gets a plus, but gets multiplied by $e^{i\phi \sigma_y}$. We have three such factors in

$$R(\phi)|+\rangle = |+\rangle = e^{i\phi \sigma_y/2}|+\rangle = |\rangle \quad (18.26)$$

Exactly the state $|-\rangle = |-\rangle$ is just what we mean by the $\alpha = |\beta\rangle$ state, or the state $|\beta, -\rangle$.

If we now rotate the system about the y -axis, each of the spin-one-half objects α 's has some simple rule to be plus or minus minus, so the system will have a property of the eight possible combinations $|+ + +\rangle$, $|+ + -\rangle$, $|+ - +\rangle$, $|+ - -\rangle$, $| - + +\rangle$, $| - + -\rangle$, $| - - +\rangle$, or $| - - -\rangle$. It is clear, however, that these can be broken up into four sets, each set corresponding to a definite value of m . First we have $|+ + -\rangle$, for which $m = \frac{1}{2}$. Then there are the three states $|+ - +\rangle$, $| - + +\rangle$, and $| - - +\rangle$ —set with two positive and one minus. Since each spin-one-half object has the same chance of getting odd minus under the rotation, the amplitudes cancel. Thus these combinations should be equal. So just take the combination

$$\frac{1}{\sqrt{3}}(|+ + -\rangle + |+ - +\rangle - | - + +\rangle) \quad (18.27)$$

with the factor $1/\sqrt{3}$ just to normalize the state. If we believe this state is right to begin, we get a factor $e^{i\theta \sigma_x^2}$ for each plus, and $e^{i\phi \sigma_y^2}$ for each minus. Each sum in (18.27) is multiplied by $e^{i\theta \sigma_x^2}$, so there is a factor on factor $e^{i\theta \sigma_x^2}$. This is all to

not " + " pieces. From tables,

$$\begin{aligned} |+-+> &= \langle \bar{s}^2 \bar{s}^1 - \bar{s}^1 \bar{s}^2 \bar{s}^3 | + - + \rangle + \langle \bar{s}^2 \bar{s}^1 \bar{s}^3 | + - + \rangle \\ &= \langle \bar{s}^2 \bar{s}^1 | + - + \rangle + \langle \bar{s}^1 \bar{s}^2 | + - + \rangle = \langle \bar{s}^2 \bar{s}^1 | + - + \rangle \\ &\quad + \langle \bar{s}^1 \bar{s}^2 | + - + \rangle + \langle \bar{s}^2 \bar{s}^3 | + - + \rangle. \end{aligned} \quad (18.33)$$

Adding two similar expressions for $|+-+>$ and $|--+>$, and dividing by $\sqrt{4}$, we find

$$\begin{aligned} |\pm, \pm, \pm\rangle &= \sqrt{3} \langle \bar{s}^2 \bar{s}^1 | \pm, \pm, \pm \rangle \\ &\quad + \langle \bar{s}^1 \bar{s}^2 + \bar{s}^2 \bar{s}^1 | \pm, \pm, \pm \rangle \\ &\quad + \langle \bar{s}^2 \bar{s}^3 - \bar{s}^3 \bar{s}^2 | \pm, \pm, \pm \rangle \\ &\quad + \sqrt{3} \langle \bar{s}^2 \bar{s}^3 | \pm, \pm, \pm \rangle. \end{aligned} \quad (18.34)$$

Continuing the process we find all the elements $(S^i)^{(j)}$ of the ladder matrices now as given in Table 18-2. The first column can be from Eq. (18.22); the second from (18.24). The last two columns were worked out in the same way.

Table 18-2
Rotation matrix for a spin $\frac{3}{2}$ particle
(The coefficients a, b, c_1 and c_2 are given in Table 18-4.)

S^x, S^y	$\hat{a}_1 \rightarrow \hat{a}_2$	$ +\frac{3}{2}, \pm \frac{3}{2}\rangle$	$ +\frac{3}{2}, \mp \frac{1}{2}\rangle$	$ -, -\frac{1}{2}\rangle$
$(+, \pm \frac{3}{2})$	a^2	$\sqrt{3} a^2$	$\sqrt{3} a^2$	a^2
$(-, \pm \frac{3}{2})$	$\sqrt{3} a^2 b$	$a^2 b + 2 a b$	$a^2 b - 2 a b$	$\sqrt{3} a^2 b$
$(\pm, -\frac{3}{2}, \pm)$	$\pm \frac{1}{2} \sqrt{3} a^2$	$2 a^2 b \pm b^2$	$a^2 b - a b$	$\pm \sqrt{3} a^2 b$
$(\pm, -\frac{3}{2}, \mp)$	a^2	$\sqrt{3} a^2 b$	$\sqrt{3} a^2 b$	a^2

Now suppose the \hat{a} -frames were sets of "wheels" tied to \hat{x} by rotating \hat{y} about their planes. Then a, b, c_1 and c_2 have the values (see (18.24)) $a = b = \cos \theta/2$, $c_1 = -b = \sin \theta/2$. Using these values in Table 18-2 we get the forms which correspond to the entries $\langle \dots \rangle$ of Table 18-2, but now for a spin $\frac{3}{2}$ system.

The foregoing treatment was going through and merely generalized to a system of three spins in three states $|+, 0\rangle$, and can be put together like $|+, 0\rangle$, $|-, 0\rangle$, each of spin instead of 1. There are $3^3 = 27$ of them in the $|+, +\rangle$ frame only ($j = m$ in the $|+\rangle$ state), if one can take over all the possible ways this can be done, and the state is normalized by multiplying by a suitable constant. Three of you who are mathematically inclined may be able to show that the following result comes out:

$$\begin{aligned} \langle \pm, m' | \hat{a}_1 \hat{a}_2 \hat{a}_3 | \pm, m \rangle &= [1 + (-1)^{m_1 + m_2 + m_3}] + 2(-1)^{m_1} + M(3) \delta^{m_1 m_2 m_3} \\ &\quad \times \sum_{k_1, k_2, k_3} \frac{(-1)^{k_1 k_2 k_3} e^{2(k_1 \hat{a}_1^2 + k_2 \hat{a}_2^2 + k_3 \hat{a}_3^2)}}{(m_1 - m_1' - 2k_1)(m_2 - m_2' - 2k_2)(m_3 - m_3' - 2k_3)}, \end{aligned} \quad (18.35)$$

where k is to go over all k_1, k_2, k_3 which give terms $\neq 0$ in all the factors.

This is quite a messy formula, but with a good computer check Table 18-2 for $\beta = 1$ and its square tables of $\hat{a}_1 \hat{a}_2 \hat{a}_3$ for larger β . Several special matrix elements of extra importance and have been given specific names. For example the regular elements $\langle m_1, m_2, m_3 | \hat{a}_1 \hat{a}_2 \hat{a}_3 | m'_1, m'_2, m'_3 \rangle$ are known as the Legendre polynomials and are called P_{β} (page 6).

$$\langle m_1, m_2, m_3 | \hat{a}_1 \hat{a}_2 \hat{a}_3 | m'_1, m'_2, m'_3 \rangle = P_{\beta}(m_1, m'_1), \quad (18.36)$$

If you want details, etc., see given in an appendix at the end of the chapter.

The first few of these polynomials are:

$$P_0(\cos \theta) = 1. \quad (15.37)$$

$$P_1(\cos \theta) = \cos \theta. \quad (15.38)$$

$$P_2(\cos \theta) = \frac{1}{2}(3\cos^2 \theta - 1). \quad (15.39)$$

$$P_3(\cos \theta) = \frac{1}{2}(5\cos^3 \theta - 3\cos \theta). \quad (15.40)$$

15-5 Measuring a nuclear spin

We would like to show you one example of the application of the coefficients we have just described. It has to do with a nuclear, interesting experiment which you will not be able to understand, some physicists wanted to find out the spin of a certain excited state of the Ne^{20} nucleus. To do this, they bombarded a carbon target with a beam of accelerated carbon ions, and produced the desired excited state of Ne^{20} , called Ne^{20*} —in the reaction

where α is the α particle, or He. Seven of the excited states of Ne^{20*} produce the very same particles and energies in the reaction

So experimentally there are two α particles which come out of the reaction. We call them α_1 and α_2 , since they come off with different energies, they can be distinguished from each other. Also, by picking a particular energy for α_1 , we can pick out any particular excited state of the Ne^{20*} .

The experiment was set up as shown in Fig. 15-9. A beam of 16-Mev carbon ions was directed onto this sort of carbon. The first α -particle was detected by a silicon diffused junction detector marked $\alpha_1 \rightarrow \alpha_2$ to accept α -particles of the proper energy coming in the forward direction (with respect to the incident C^{12} beam). The second α -particle was picked up in the angle θ at the angle δ with respect to α_1 . The counting rate of coincidences (signals from α_1 and α_2) were measured as a function of the angle θ .

The idea of the experiment is the following. First, you need to know what the spins of C^{12} , C^{12} , and the α -particle are. If we call the direction of motion of the initial C^{12} the $-z$ -direction, then we know the Ne^{20*} must have zero angular momentum. Since the α orbit (None of the other particles has any spin) is C^{12} moves along the $-z$ -axis and the α leaves down the $-z$ -axis so they don't have any angular momentum about it. So whatever the spin of the Ne^{20*} is, we know that it is to the state $|1/2, 0\rangle$. Now what will happen when the Ne^{20*} disintegrates into O^{17} and the α ? Well, the α particle is passed up in the counter α_1 and to conserve momentum the O^{17} must go in the opposite direction. About the new axis though, now can have no component of angular momentum. The final state has zero angular momentum about the α axis, so the Ne^{20*} can disintegrate this way only if it has some angular state of m equal to zero, where m is the quantum number of the component of angular momentum about the α axis. Let's, the probability of observing α_2 at the angle θ 's (i.e. the square of the amplitude for this element)

$$|\langle \alpha_2 | \beta(\theta) | 1/2, 0 \rangle|^2 \quad (15.41)$$

To find the spin of the Ne^{20*} state in question, the intensity of the second α -particle was plotted as a function of angle and compared with the theoretical

^a We can neglect the recoil when the Ne^{20*} in the try collides. (In fact all we can calculate what it is and make a correction for it.)

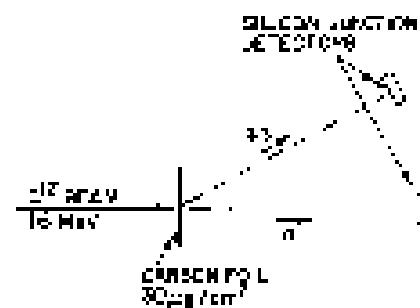

Fig. 15-9 Experimental arrangement used to determine the spin of certain states of Ne^{20*} .

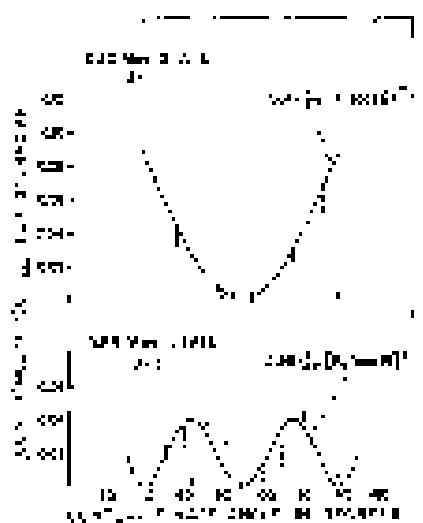

Fig. 18-10. Experimental results for the angular distribution of the s-particle from two excited states of He^{3+} produced by the setup of Fig. 18-9. [From J. A. Klemm, *Physical Review*, Vol. 173, p. 1633, 1962.]

curves for various values of θ . As we saw in the last section, the amplitude $(j_1, j_2; \vec{E}_1, \vec{E}_2 | \psi \rangle)$ depends on the functions P_j , respectively, for the possible angular distributions for spins j_1 and j_2 (see Eq. 18-2). The experimental results are shown in Figs. 18-10 for two of the excited states. You can see that the angular distribution for the 1s & 1s(1s) is in very good agreement with the curve for $(P_{1/2}, P_{1/2}; \psi)$, and it cannot be coincidence. The data for the 2s(2s) state, on the other hand, are quite different from the fit to the curve $|P_{3/2}, \psi\rangle$ of Fig. 18-9. The data do not seem to fit.

From this experiment we have been able to find out the angular momentum of two of the excited states of He^{3+} . This information can then be used for trying to understand what the configuration of protons and neutrons is inside this nucleus—the more general information about the mysterious nucleon states.

18-6 Composition of angular momentum

When we studied the hyperfine structure of the hydrogen atom in Chapter 12 we had to work out the internal states of a system composed of two particles which interact and can present each other the spin of one-half. We found that the four possible spin states of such a system could be put together into two groups, a group with one energy level called the "singlet" and a group with two energy levels called the "triplet". This is nothing like a particle of zero spin. There is nothing repeated two spin $\frac{1}{2}$ particles we can form a system whose "total spin" is not or zero. In this section we want to discuss in more general terms the spin states of a system which is made up of two particles of arbitrary spin. It is another important problem to add angular momentum in quantum mechanical systems.

Let's first review the results of Chapter 12 for the hydrogen atom—a brief summary to extend to the more general case. We began with two particles which could only be particle a (one electron and one proton), the proton having total spin $j_1 = \frac{1}{2}$, and its component of angular momentum m_1 , could have one of three values (actually 2, namely, $m_1 = +\frac{1}{2}$ or $m_1 = -\frac{1}{2}$). Similarly, the spin state of particle b is described by its spin j_2 and its component of angular momentum m_2 . Various combinations of the spin states of the two particles could be formed. For instance, we could have particle a with $m_1 = \frac{1}{2}$ and particle b with $m_2 = -\frac{1}{2}$, to make a state $|a, +\frac{1}{2}; b, -\frac{1}{2}\rangle$. In general, the combined states formed a system whose "system spin" or "total spin" or "total angular momentum" J could be 1, or 0. And the system could have a total amount of angular momentum M , which was $= 0, 0, +1$ when $J = 1$, or 0 when $J = 0$. In this new language we can rewrite Eq. 17-4 to give (18-19) as shown in Table 18-2.

In the table the left-hand column describes the compound state in terms of the total angular momentum J and the total magnet M . The right-hand column shows how these states are made up in terms of the results of the two particles a and b .

We want now to generalize this result to states made up of two objects and having arbitrary spins j_1 and j_2 . We can try considering an example for writing \langle

Table 18-2

Composition of angular momenta for two spin $\frac{1}{2}$ particles ($j_1 = \frac{1}{2}, j_2 = \frac{1}{2}$)

$J = 1, M = +1 = a, +\frac{1}{2}; b, +\frac{1}{2}\rangle$	
$J = 1, M = 0 = \frac{1}{\sqrt{2}}(a, +\frac{1}{2}; b, -\frac{1}{2}\rangle - a, -\frac{1}{2}; b, +\frac{1}{2}\rangle)$	
$J = 1, M = -1 = a, -\frac{1}{2}; b, -\frac{1}{2}\rangle$	
$ J = 0, M = 0\rangle = \frac{1}{\sqrt{2}}(a, +\frac{1}{2}; b, -\frac{1}{2}\rangle + a, -\frac{1}{2}; b, +\frac{1}{2}\rangle)$	

and $j_0 = 1$, namely, in the first sum, in which particle 0 is on the left and particle 1 is the nucleus→ deuteron state. We have then $|j_0 = j_1 = \frac{1}{2}\rangle$. The deuteron is formed of one proton and one neutron in a state whose total spin is zero, say $\sigma_1 = \sigma_2 = 0$. We want to discuss the hyperfine states of deuteron—just as we did for hydrogen, since the deuteron has three possible states $m_J = m_1 + m_2 = -1, 0, +1$, and the deuteron has two, $m_J = m_1 + \frac{1}{2}, -\frac{1}{2}$; there are two possible states in S^z given by the notation $|J, m_J, S, m_S\rangle$.

$$\begin{aligned} & |s_1=\frac{1}{2}, d, 1\rangle, \\ & |s_1=\frac{1}{2}, d, 0, +\frac{1}{2}\rangle, |s_1=\frac{1}{2}, d, 0, -\frac{1}{2}\rangle, \\ & |s_1=\frac{1}{2}, d, -1, 0\rangle, |s_1=\frac{1}{2}, d, 0\rangle, \\ & |s_1=\frac{1}{2}, d, -1\rangle \end{aligned} \quad (18.42)$$

You will notice that we have grouped the states according to the values of the sum of m_J and m_S —from largest to decreasing value.

Now we ask: What happens to these states if we project onto a different coordinate system? If the new space is just orthogonal to S^z axes by definition, S^z does not change, so m_J, m_S does not depend by

$$S^z|m_J, m_S\rangle = m_S|m_J, m_S\rangle. \quad (18.43)$$

The rotation may be thought of as the product of a rotation about S^z and a rotation about S^x contributed independently by each factor. The factor of $R(0)$ is of the form $e^{i\theta S^x}$, so if the state $|J, m_J, S, m_S\rangle$ has a component of angular momentum along S^x ,

$$M = m_J + m_S. \quad (18.44)$$

The M -component of the total angular momentum is the sum of the M -components of angular momentum of the parts.

In the list of (18.42), therefore, the states in the top line are $M = +\frac{1}{2}$, the two in the second line have $M = -\frac{1}{2}$, the two in line three have $M = -\frac{1}{2}$, and the last state has $M = -\frac{3}{2}$. We can immediately see possibility of an exchange of the combined total total angular momentum must be $\frac{1}{2}$, and thus we have four states with $M = +\frac{1}{2}, 0, -\frac{1}{2}$, and $-\frac{3}{2}$.

There is only one candidate for $M = -\frac{3}{2}$, so we know already that

$$J = \frac{1}{2}, M = -\frac{3}{2} \leftrightarrow |s_1=\frac{1}{2}, d, -1\rangle. \quad (18.45)$$

But what is the state $|J = \frac{1}{2}, M = \frac{1}{2}\rangle$? We can write it in the second line of (18.42) and the last row linear combination of them would also have $M = \frac{1}{2}$. So, in general, we might expect to find that

$$|J = \frac{1}{2}, M = \frac{1}{2}\rangle \sim |s_1=\frac{1}{2}, d, 0\rangle + |s_1=\frac{1}{2}, d, -1\rangle. \quad (18.46)$$

These are odd integer numbers. They are called the Clebsch-Gordan coefficients. Our next problem is to find out what they are.

We can find out easily if we just remember that deuteron is made up of a neutron and a proton, and write the deuteron states out more explicitly using the rules of Table 18.3. If we do this, the states listed in (18.42) will look as shown in Table 18.4.

We want to form the four states of $J = \frac{1}{2}$, using the states in the table. But we already know the answer, because in Table 18.1 we have states of spin $\frac{1}{2}$ formed from three spin one-half particles. The first state in Table 18.1 has $|J = \frac{1}{2}, M = -\frac{1}{2}\rangle$, and it is $|+-+\rangle$, where—in our present notation—is the combination $|p_1=+1, n_1=+, p_2=+\rangle$, or the first state of Table 18.4. But this state is also the same as the first in the list of (18.42). So the answer is in (18.45). The second line of Table 18.1 corresponds changing the spin quantum number—thus

$$\begin{aligned} & |J = \frac{1}{2}, M = -\frac{1}{2}\rangle = \frac{1}{\sqrt{3}}(|s_1=\frac{1}{2}, d, 0\rangle + |s_1=\frac{1}{2}, d, -1\rangle \\ & + |s_1=\frac{1}{2}, d, -1\rangle + |s_1=\frac{1}{2}, d, 0\rangle) \end{aligned} \quad (18.47)$$

Table 18-4
Angular momentum states for doublet electrons.

$m = \frac{1}{2}$	
$ s,+\frac{1}{2}; d, +\frac{1}{2}\rangle$	$= s, +\frac{1}{2}; n, +\frac{1}{2}; d, +\frac{1}{2}\rangle$
$m = \frac{1}{2}$	
$ s,-\frac{1}{2}; d, 0\rangle$	$= \frac{1}{\sqrt{2}} (s,+\frac{1}{2}; n,+\frac{1}{2}; d, -\frac{1}{2}\rangle + s,+\frac{1}{2}; n, -\frac{1}{2}; d, +\frac{1}{2}\rangle)$
$ s,-\frac{1}{2}; d, +\frac{1}{2}\rangle$	$= s, -\frac{1}{2}; n, +\frac{1}{2}; d, +\frac{1}{2}\rangle$
$m = -\frac{1}{2}$	
$ s,+\frac{1}{2}; d, -1\rangle$	$= s, +\frac{1}{2}; n, -\frac{1}{2}; d, -\frac{1}{2}\rangle$
$ s,-\frac{1}{2}; d, 0\rangle$	$= \frac{1}{\sqrt{2}} (s, -\frac{1}{2}; n, -\frac{1}{2}; d, -\frac{1}{2}\rangle - s, -\frac{1}{2}; n, -\frac{1}{2}; d, +\frac{1}{2}\rangle)$
$m = \frac{3}{2}$	
$ s,-\frac{1}{2}; d, -1\rangle$	$= s, -\frac{1}{2}; n, -\frac{1}{2}; d, -\frac{1}{2}\rangle$

The right sides can easily be put together from the two entries in the second row of Table 18-4 by taking $\sqrt{2/3}$ of the first term with $\sqrt{1/3}$ of the second. That is, Eq. (18.47) is equivalent to

$$|\mathbf{j} = \frac{3}{2}, M = \frac{3}{2}\rangle = \sqrt{2/3} |s, +\frac{1}{2}; d, 0\rangle + \sqrt{1/3} |s, -\frac{1}{2}; d, 0\rangle. \quad (18.48)$$

We have found our two Clebsch-Gordan coefficients α and β in Eq. (18.46):

$$\alpha = \sqrt{2/3}, \quad \beta = \sqrt{1/3}. \quad (18.49)$$

Following the same procedure we can find that

$$|\mathbf{j} = \frac{3}{2}, M = -\frac{3}{2}\rangle = \sqrt{1/3} |s, +\frac{1}{2}; d, -1\rangle - \sqrt{2/3} |s, -\frac{1}{2}; d, 0\rangle. \quad (18.50)$$

And, of course,

$$|\mathbf{j} = \frac{3}{2}, M = -\frac{1}{2}\rangle = |s, -\frac{1}{2}; d, -1\rangle. \quad (\text{ESI})$$

These are the three $l=3$, m combination of spin 1 and spin 1 to make a total $J = \frac{3}{2}$. We summarize in Box 18-3, and in Table 18-5.

We have, however, only four states here while the system has nine combinations for six possible states. Of the two states in the second line of (18.42) we have used only one here, combining to form $|\mathbf{j} = \frac{3}{2}, M = -\frac{1}{2}\rangle$. There is another two combinations orthogonal to the one we have taken which also has $M = -\frac{1}{2}$, namely

$$\sqrt{1/3} |s, +\frac{1}{2}; d, 0\rangle - \sqrt{2/3} |s, -\frac{1}{2}; d, +1\rangle. \quad (18.51)$$

Table 18-5

The $J = \frac{3}{2}$ states of the deuteron atom

$ \mathbf{j} = \frac{3}{2}, M = +\frac{3}{2}\rangle = s, +\frac{1}{2}; d, +\frac{1}{2}\rangle$	$ \mathbf{j} = \frac{3}{2}, M = -\frac{3}{2}\rangle = \sqrt{1/3} s, +\frac{1}{2}; d, 0\rangle + \sqrt{2/3} s, -\frac{1}{2}; d, 0\rangle$	$ \mathbf{j} = \frac{3}{2}, M = -\frac{1}{2}\rangle = \sqrt{1/3} s, +\frac{1}{2}; d, -1\rangle - \sqrt{2/3} s, -\frac{1}{2}; d, 0\rangle$	$ \mathbf{j} = \frac{3}{2}, M = -\frac{1}{2}\rangle' = s, -\frac{1}{2}; d, -1\rangle$
$ \mathbf{j} = \frac{3}{2}, M = -\frac{1}{2}\rangle$			
$ \mathbf{j} = \frac{3}{2}, M = -\frac{1}{2}\rangle'$			
$ \mathbf{j} = \frac{3}{2}, M = -\frac{1}{2}\rangle''$			

Similarly, the two states in the third line of (18.22) can be combined to give two orthogonal states, each with $M = \pm \frac{1}{2}$. The one corresponding to $f = \frac{1}{2}$ is

$$\sqrt{2} |\psi_e(\vec{q}, d=1)\rangle = \sqrt{1/2} |\psi_e(-\vec{q}; d=0)\rangle. \quad (18.55)$$

These are the two remaining states. They have $\psi_e(\vec{q}, d=0) = \psi_e(-\vec{q})$, and must be the associated components of $f = \frac{1}{2}$, so we have

$$\begin{aligned} |\psi_e(\vec{q}; M=1)\rangle &= \sqrt{1/2} |\psi_e(\vec{q}, d=0)\rangle - \sqrt{1/2} |\psi_e(-\vec{q}, d=1)\rangle, \\ |\psi_e(\vec{q}; M=-1)\rangle &= \sqrt{1/2} |\psi_e(\vec{q}, d=1)\rangle + \sqrt{1/2} |\psi_e(-\vec{q}, d=0)\rangle. \end{aligned} \quad (18.56)$$

We can verify that these two states combine correctly like the string of a spin-one-half object by writing out the coordinate parts of terms of the result on the present states—using Table 18-1. The first state in (18.56) is

$$\begin{aligned} \sqrt{1/2} |\psi_e(\vec{q}, d=0)\rangle &= |\psi_e(+\frac{1}{2}, n=1, p=0)\rangle - |\psi_e(+\frac{1}{2}, n=1, p=1)\rangle \\ &= \sqrt{1/2} |\psi_e(\vec{q}, n=1, p=0)\rangle. \end{aligned} \quad (18.57)$$

which can also be written

$$\begin{aligned} \sqrt{1/2} \sqrt{1/2} |\psi_e(\vec{q}, n=1, p=0)\rangle &= |\psi_e(+\frac{1}{2}, n=1, p=0)\rangle \\ &+ \sqrt{1/2} (\psi_e(+\frac{1}{2}, n=1, p=0)^\dagger \psi_e(+\frac{1}{2}, n=1, p=0)). \end{aligned} \quad (18.58)$$

Now look at the terms in the first curly brackets, and most of the n and p indices disappear. Tracing this back up from a state like the bottom line of Table 18-5, and combining the angular momentum. Only the momenta of $f = \frac{1}{2}$, so the whole of the first curly bracket of (18.56) becomes under expansion like a constant, namely $\propto \delta_{n1}\delta_{p0}$ with $f = \frac{1}{2}$, $M = \pm \frac{1}{2}$. Following the state relations (18.24), we see that in the second curly bracket of (18.56) each term and hence from right to left produces zero angular momentum, and only the proton contributions—with $n_p = \frac{1}{2}$ —cancel. The term is left like an object with $f = \frac{1}{2}$, $M = \pm \frac{1}{2}$, so the whole expression of (18.56) transforms like $f = \pm \frac{1}{2}$, $M = \pm \frac{1}{2}$ as it should. The $M = -\frac{1}{2}$ state which corresponds to (18.56) can be written given by changing “ $\psi_e(\vec{q}, \dots)$ ” to “ $\psi_e(-\vec{q}, \dots)$ ” to get

$$\begin{aligned} \sqrt{1/2} [\sqrt{1/2} |\psi_e(-\vec{q}, n=1, p=0)\rangle - |\psi_e(-\vec{q}, n=1, p=1)\rangle] \\ + \sqrt{1/2} [\psi_e(-\vec{q}, n=1, p=0)^\dagger \psi_e(-\vec{q}, n=1, p=0)]. \end{aligned} \quad (18.59)$$

You can easily check that this is equal to the second line of (18.24), as it should be. The last term of that joint is left to the two states of a spin-one-half object. So you require two contractions. A $\delta_{n1}\delta_{p0}$ and a $\delta_{n1}\delta_{p1}$ or vice versa in a spin pairing, four of which give the states of a spin-1 object (Table 18-2) and two of which are like an object of spin one-half (18.54).

The last row of Table 18-5 and of Eq. (18.54) are obtained by making use of the fact that the deuteron is made up of a neutron and a proton. The form of the equations does not depend on other special circumstances. But the spin one object pair, together with any spin one-half object, the composition laws (and hence the identities) are the same. The set of arguments in Table 18-5 means that if the two nucleons are rotated around, say, the y -axis—so that the states of the spin one-half pair are one of the spin one particle change according to Table 1F (and Table 8-2). The three combinations on the right-hand side will change in the proper way for a spin 2 object. Under the same rotation the states of (18.54) will change to the states of a spin one-half object. The labels depend only on the

Table 18-6

Composition of a spin-one-half particle ($j_1 = \frac{1}{2}$)
and a spin-zero particle ($j_2 = 0$).

$J = \frac{1}{2}, M = \langle J \rangle = \langle j_1, j_2; \lambda_1, \lambda_2 \rangle$
$\psi(\vec{q}, \vec{p}) = \frac{1}{\sqrt{2}} (\psi_{+}(\vec{q}, \vec{p}; \lambda_1) + \psi_{-}(\vec{q}, \vec{p}; \lambda_1))$
$J = \frac{1}{2}, M = +\frac{1}{2} = \sqrt{\frac{1}{2}} (\psi_{+}(\vec{q}, \vec{p}; \lambda_1) - \sqrt{2/3} \psi_{-}(\vec{q}, \vec{p}; \lambda_1))$
$J = \frac{1}{2}, M = -\frac{1}{2} = \langle j_1 = \frac{1}{2}, j_2 = 0 \rangle$
$\psi(\vec{q}, \vec{p}) = \frac{1}{\sqrt{2}} (\psi_{+}(\vec{q}, \vec{p}; \lambda_1) - \sqrt{2/3} \psi_{-}(\vec{q}, \vec{p}; \lambda_1))$
$J = \frac{1}{2}, M = -\frac{1}{2} = \sqrt{\frac{1}{2}} (\psi_{+}(\vec{q}, \vec{p}; \lambda_1) + \sqrt{2/3} \psi_{-}(\vec{q}, \vec{p}; \lambda_1))$

relative position $\psi(\vec{q}, \vec{p})$. The spin states of the two original particles have not in any way on the energies of their angular momenta. We have only made use of this fact to work out the formulas by choosing a special case in which one of the components can be itself made up of two spin-one-halfs. Let us, however, drop this restriction. We have, perhaps, more useful ranges in Table 18-6, changing the notation "a" and "b" to "j" and "j'" to emphasize the generality of the conclusions.

Suppose we have the general problem of finding the states which can be formed when two objects of arbitrary spins are combined. For one has j_1 , the z-component of j_1 runs over the $j_1 = \pm 1$ values from $-j_1$ to $+j_1$ and the other has j_2 , with its components m_2 running over the values from $-j_2$ to $+j_2$. The combined state $|j_1, m_1; j_2, m_2\rangle$ and there are $(2j_1 + 1)(2j_2 + 1)$ different states. Now what states of total spin J can be found?

The total z-component of angular momentum M is equal to $m_1 + m_2$, and this is one of the allowed according to M (see in 18.42). The largest M is unique; it corresponds to $m_1 = j_1$ and $m_2 = j_2$, and is, therefore, just $j_1 + j_2$. This means that the largest total spin J is also equal to the sum $j_1 + j_2$:

$$J = (M_{\text{max}})^{1/2} = j_1 + j_2.$$

For the first M value $m_1 + m_2$ (or M_{min}), there are two states (either m_1 or m_2 is positive less than its maximum). They must contribute one state to the set which goes with $J = j_1 + j_2 - 1$, and the one left over will belong to a new set with $J = j_1 + j_2 - 1$. The next M value—the third from the top of the list—can be formed in three ways. (Between $M = j_1 - 1, m_1 = j_1$; from $m_1 = j_1, m_2 = 1$; and from $M = j_1, m_1 = j_1 - 1$). Two of these belong to groups already started above. The third will be the state of $J = j_1 + j_2 - 2$ and can be included. The argument continues until we reach a stage where, in effect we can no longer add more sets down to one of them to make new states.

Let j_1 be the smaller of j_1 and j_2 if they are equal take the larger. Then only j_1 values of J are required—going in integer steps from $j_1 = j_2$ down to $j_1 = -j_2$. That is, when two objects of spin j_1 and j_2 are combined, the system can have a total angular momentum J equal to any one of the values

$$J = \begin{cases} j_1 + j_2 \\ j_1 + j_2 - 1 \\ \vdots \\ j_1 - j_2. \end{cases} \quad (18.59)$$

(By writing $j_1 - j_2$ instead of $j_2 - j_1$ we can avoid the extra assumption that $j_1 \geq j_2$.)

For each of these J values there are the $2J + 1$ states of different M values with M going from $-J$ to $+J$. Each of these is formed from the combinations of the original states $|m_1, m_2; j_1, j_2\rangle$ with appropriate factors—the Clebsch-Gordan coefficients.

coefficients not just particular terms. We can consider two possibilities, give the “unmixed” or the state $|J_1, M_1, J_2, M_2\rangle$, which agrees with the state $|J, M\rangle$. So each of the Clebsch-Gordan coefficients $C_{JM}^{J_1M_1J_2M_2}$, if you wish, are indices identifying its position in the columns like those of Tables 13-2 and 13-3. That is, calling these coefficients $C(J,M,J_1,M_1)$, we could express the equality of the second line of Table 13-6 by writing

$$C_{J=1, M=1; J_1=1, M_1=0} = \sqrt{2}/2,$$

$$C_{J=1, M=1; J_1=1, M_1=1} = \sqrt{1/2}.$$

We left out calculating here the coefficients for any other special cases. You can, however, find tables in many books. You might wish to try another special case for yourself. The next one to do would be the composition of two spin one in Table 13-6. We give just the final result in Table 13-7.

These kinds of the composition of spin $\frac{1}{2}$ momenta are very important in particle physics—where they have numerous applications. Unfortunately, we lack no time to look at more examples here.

Table 13-7

Composition of two spin-one particles ($J_1 = 1, J_2 = 1$)

$ J = 2, M = -2\rangle$	$= J_1 = 0, M_1 = -1\rangle$
$ J = 2, M = -1\rangle$	$= J_1 = \frac{1}{\sqrt{2}}(a_1 - 1; b) + \frac{1}{\sqrt{2}}(a_2; b, 0)\rangle$
$ J = 2, M = 0\rangle$	$= \frac{1}{\sqrt{6}} a_1(1, 0, -1)\rangle + \frac{1}{\sqrt{6}} a_1(-1, 0, 1)\rangle + \frac{2}{\sqrt{6}} a_2(0, 0, 0)\rangle$
$ J = 2, M = 1\rangle$	$= \frac{1}{\sqrt{2}} a_2(0, 0, -1)\rangle - \frac{1}{\sqrt{2}} a_2(0, 0, 1)\rangle$
$ J = 2, M = 2\rangle$	$= a_2(0, 0, 0)\rangle$
$ J = 1, M = -1\rangle$	$= \frac{1}{\sqrt{2}} a_1(0, 0, 0)\rangle - \frac{1}{\sqrt{2}} a_2(0, 0, 0)\rangle$
$ J = 1, M = 0\rangle$	$= \frac{1}{\sqrt{2}} a_1(0, 0, 0)\rangle + \frac{1}{\sqrt{2}} a_2(0, 0, 0)\rangle$
$ J = 1, M = 1\rangle$	$= \frac{1}{\sqrt{2}} a_2(0, 0, 0)\rangle + a_1(0, 0, 0)\rangle - a_2(0, 0, 0)\rangle$

Added Note 1: Iteration of the rotation matrix.

For those who would like to see the details, we sketch here how the general rotation matrix for a system with spin $\frac{1}{2}$ and angular momentum λ , J , is built, and very incidentally check out the general case. One can prove the idea, you can find the general results in tables in many books. On the other hand, after proving this, for you might like to see, for your own interest and enjoyment even the very complicated formulae of quantum mechanics, such as Eq. (13.35), i.e., those in the description of atomic transitions.

[†] A longer proof of the result is given in Box 13-2, but we leave the general proof to another day.

[‡] The material of this appendix was originally included in the body of the theory. But the regular treatment necessarily excludes it, so a detailed treatment of the general case.

We extend the argument of Section 16.1 to a system with spin s , which we consider to be made up of $2j$ semi-integer objects. We start with $m = j$ would be $| + \dots + + |$ (with j plus signs). For $m = j - 1$, there will be 21 terms like $| + \dots + - | + \dots + - +$, and so on. Let's consider the general case in which there are n classes and s members with $s = j$. Under a permutation the n products of the n places will contribute $\Gamma^{(n)}$. The result is a phase change of $i(\gamma^{(n)} - \gamma^{(n)})$. You get that

$$m! = \frac{\Gamma^{(n)}}{n!}. \quad (16.29)$$

Just as for $J = \frac{1}{2}$, each state of definite m must be the linear combination with plus signs if it has even m and with minus signs if it has odd m , according to every possible arrangement which has n pluses and s minuses. We argue that you can't just count the states in \mathcal{H}_{tot} with such arrangements. To normalize them again we should divide the sum by the sign product of the numbers. We can write

$$\begin{aligned} \left[\frac{(v+s)^{1/2}}{s!} \right]^{n!} & \left(| + \dots + + | + \dots + - + \dots - \right) \\ & \rightarrow \{ \text{all rearrangements of } (v+s) \} = (v+s)! \quad (16.30) \end{aligned}$$

with

$$J = \frac{\Gamma^{(n)}}{n!}, \quad m = \frac{\Gamma^{(n)}}{s!}. \quad (16.31)$$

It will help us work if we now go to yet another notation. Once we have defined the states by Eq. (16.30), the two numbers v and s define a state just as well as J does. It will help us keep track of things if we write

$$| v, s \rangle = | \rangle \quad (16.32)$$

where, using the equations of (16.07)

$$v = j + \infty = s = J + m.$$

Now we would like to write Eq. (16.30) with a new special notation as

$$| v, s \rangle = | \rangle = \left[\frac{(v+s)^{1/2}}{s!} \right]^{1/n!} (| + \rangle^v | - \rangle^s)_{\text{perm}}. \quad (16.33)$$

Note that we have swapped the exponent on the factor in front to plus $\frac{1}{2}$. We do that because now we just $J = (v, s)$, which remains inside the curly brackets. Comparing (16.33) with (16.30) it is clear that

$$| v, s \rangle = | v, s \rangle_{\text{perm}}$$

is just a shorthand way of writing

$$| - + \dots - - \rangle = \frac{1}{N} \{ \text{all rearrangements} \},$$

where N is the number of 1000 entangles in the bracket. The reason that this notation is convenient is that each term in each permutation, all of the plus signs contributes the same factor, so we get this factor to the v th power. Similarly, all times in the minus terms contributes a factor to the s th power no matter what the sequence of the terms is.

Now suppose we repeat our system by one spin addition, the particle. When we write $R_1(| \rangle)$, where $R_1(| \rangle)$ acts just on each $+|$, it gives

$$R_1(| \rangle) | + \rangle = | + \rangle^C | - \rangle^S, \quad (16.34)$$

where $C = \cos \theta/2$ and $S = \sin \theta/2$. When $R_1(| \rangle)$ operates on each $-|$, it gives

$$R_1(| \rangle) | - \rangle = | - \rangle^C | + \rangle^S$$

So we write it

$$\begin{aligned} R_0(\theta) \cdot \gamma &= \left[\frac{\partial}{\partial \theta} \left(\frac{\partial \theta}{\partial x} \right)^{-1} \right]^{1/2} \delta_{\mu\nu} (\theta) + \gamma = \delta_{\mu\nu} \gamma \\ &= \left[\frac{\partial}{\partial \theta} \left(\frac{\partial \theta}{\partial x} \right)^{-1} \delta_{\mu\nu} (\theta) - \left(\frac{\partial}{\partial \theta} \delta_{\mu\nu} (\theta) \right) \right] \gamma_{\text{new}} \\ &= \left[\frac{\partial}{\partial \theta} \left(\frac{\partial \theta}{\partial x} \right)^{-1} (-(\theta + \gamma) \gamma) (-(\theta + \gamma) \gamma + \theta^2) \right] \gamma_{\text{new}}. \end{aligned} \quad (13.6)$$

Now recall Fermat's rule to be expanded up to its appropriate power and the new expression's expansion (up to γ). This means $\theta \rightarrow \theta + \gamma$ to all powers from zero to $(r-1)/2$. Let's look at the terms which have γ to the $r/2$ power. They will appear always multiplied with γ^r in the θ^r power, since $r = 2k + r'$. Suppose we collect γ^r such terms. For each term, then they will have some numerical coefficient involving the factors of the binomial expansion as well as the factors C and S . Since we want this factor γ^r , T in Eq. (13.6) $\rightarrow T \ln \lambda / \gamma$ we

$$R_0(\theta) \cdot \gamma = \sum_{r=0}^{\infty} (\theta + \gamma)^{r/2} \gamma^r \gamma_{\text{new}}. \quad (13.6)$$

Now let's say we divide R_0 by the factor $(\theta + \gamma)^{r/2} \gamma^{r/2}$ and γ^r the quantity γ_{new} . Equation (13.6) is then equivalent to

$$R_0(\theta) \cdot \gamma = \sum_{r=0}^{\infty} \delta_{\mu\nu} \left[\frac{\partial}{\partial \theta} \left(\frac{\partial \theta}{\partial x} \right)^{-1} (\theta + \gamma)^{-r/2} \gamma^r \right] \gamma_{\text{new}}. \quad (13.6')$$

(We could justify that the equation reduces to γ by the comparison with (13.6) since the same expression that appears in (13.6))

We know the definition of $\delta_{\mu\nu}$ the remaining factors are the right-hand side of Eq. (13.6) but just for clarity, so we have that

$$R_0(\theta) \cdot \gamma = \sum_{r=0}^{\infty} R_r(\theta) \gamma^r \quad (13.6)$$

where $\gamma \rightarrow \gamma + \theta + \gamma = \theta + 2\gamma$. This means, of course, the coefficients R_r are just the matrix elements we wrote, exactly

$$R_r(\theta) \gamma^r = \delta_{\mu\nu}. \quad (13.6)$$

Now we just have to calculate each the $\delta_{\mu\nu}$ in (13.6) with various θ 's. Comparing (13.6) with (13.37), and remember that $\theta = \gamma - x = \gamma - \theta$ we see that we just get the expansion of $\theta^{r/2} \gamma^r$ in the following expansion:

$$\left(\frac{\partial \theta}{\partial x} \right)^{1/2} (\ln \theta - \theta \ln \theta) \theta^r = \theta^{r/2} \gamma^r. \quad (13.6)$$

It is now a fairly trivial task to take the expansion up to the limit of the sum, and expand the terms up to the given power of γ and θ . If you work it out, you find that the coefficient of $\theta^{r/2} \gamma^r$ in (13.6) is

$$\left(\frac{\partial \theta}{\partial x} \right)^{1/2} \sum_{k=0}^r (-1)^k S_{r-k, k} \frac{\theta^k}{k!} \frac{\gamma^r}{(r-k)!} = \frac{\theta^r}{(r-1)!} \frac{\gamma^r}{(r-1)!} = \frac{\theta^r}{(2r-2)!} \gamma^r. \quad (13.6)$$

The sum is to take over all integers k which give terms of odd or greater than two factors. This expression is then the matrix element we wanted.

Finally, we can return to our original notation by $x \rightarrow x + \theta$ and $\theta \rightarrow \theta$.

$$x = y - \theta, \quad \theta' = y - \theta \theta, \quad x' = x - \theta, \quad \theta' = y - \theta$$

Making these substitutions, we get Eq. (13.34) \rightarrow Section 13.4.

Added Note 2: Conservation of parity in photon emission

In section 1 of this chapter we considered the emission of light by an atom in a given term in a certain state. Despite the symmetric state of eqn 9, if it is an odd state just the even up or $\downarrow - \downarrow$ component will survive along the $-z$ -axis at an LHC photon along the $-z$ -axis. Let's call these two states of the electron $|E_{\alpha}\rangle$ and $|E_{\beta}\rangle$. Neither of these states has a definite parity. But how Ψ is the parity odd? $\langle E_{\alpha}|P|E_{\beta}\rangle = \langle E_{\alpha}|D_{\mu\nu}^{\dagger}(L_{\mu\nu})|E_{\beta}\rangle$.

What about the wavefunction that is obtained in a state of definite parity must have a definite parity, and our argument that parity is conserved in Ψ is preserved. Students can find similar discussions of this problem from chapter 6 for the emission of a photon into a definite parity. In fact if we consider the complete final state which contains contributions to the emission due to initial terms of order ϵ in the Schrödinger equation, we obtain the complete final state.

If we wish we can look only at final states that do have a definite parity. For example, consider a final state $|\psi\rangle$ which turns out to happen to be a RHC photon going along $+z$ and some longitudinal and transverse LHIC photons going along $-z$. We get while

$$|\psi\rangle = c_1 |E_{\alpha}\rangle + c_2 |E_{\beta}\rangle \quad (18.73)$$

The parity expectation of this state is

$$\langle \psi | P | \psi \rangle = \langle c_1 | E_{\alpha} | P | E_{\beta} \rangle + \langle c_2 | E_{\beta} | P | E_{\alpha} \rangle \quad (18.75)$$

This state will be $\Psi(|\psi\rangle)$ if $\delta = \pi/2 = \omega$, so a final state of even parity is

$$|\psi\rangle = c_1 |E_{\alpha}\rangle + |E_{\beta}\rangle \quad (18.76)$$

and a state of odd parity is

$$|\psi\rangle = c_1 |E_{\alpha}\rangle - |E_{\beta}\rangle \quad (18.77)$$

Next, we wish to consider the decay of an excited state of odd parity to a ground state of even parity. If $\omega/\epsilon \ll 1$ we expect the final state of the photon must have odd parity. This is confirmed in (18.77). The amplitude $\langle \psi | P | \psi \rangle$ is zero, the amplitude to have $L_{\mu\nu}^{\dagger}(L_{\mu\nu}) \neq 0$.

Now notice what happens when we perform the integral of (18.77) about the origin. The initial coherent state of the atom has mean momentum $p = 0$ and no energy in ϵ , corresponding to $\Omega = 0$ in (18.7). And the evolution of the final state gives

$$\langle \psi | \text{RHC}(\omega) | \psi \rangle = \epsilon \langle | E_{\beta} \rangle | L_{\mu\nu} | \rangle \quad (18.78)$$

Comparing this expression with (18.7), you see that the assumed parity of the final state, the amplitude to set a LHIC photon going $-z$ from the $m = -1$ initial state is the negative of the amplitude to set a LHIC photon from the $m = +1$ initial state. This agrees with the result we found in Section 1.

The Hydrogen Atom and The Periodic Table

19-1 Schrödinger's equation for the hydrogen atom

The most direct evidence in the history of the quantum theory was the understanding of the details of the spectra of some simple atoms and the table mapping of the periodicities which was found in the table of chemical elements. In this chapter we will at least bring our quantum mechanics to the point of one important achievement, specifically to a understanding of the spectrum of the hydrogen atom. We will at the same time arrive at a qualitative explanation of the electronic properties of the chemical elements. We will then be satisfying in detail the behavior of the electron in a hydrogen atom for the first time making a detailed calculation of its distribution in space according to what was developed in Chapter 15.

For a complete description of the hydrogen atom we would describe the motion of both the proton and the electron. It is possible to do this in quantum mechanics in a way that is analogous to the classical idea of describing the motion of each particle relative to the center of mass, but we will not do so. We will pursue an approximation in which we consider the proton to be very heavy, so we can think of it as fixed at the center of the atom.

We will make another approximation by forgetting that the electron has a spin and should be described by the laws of mechanics. Some small corrections to our treatment will be required since we will be using the non-relativistic Schrödinger equation and will disregard magnetic effects. Small magnetic effects occur due to from the electron's precession since the proton is a circulating charge which produces a magnetic field. In this field the electron will have a different energy with its spin up than with it down. The energy of rotation will be shifted a little bit from what we will take to be zero. We will ignore this small energy shift. Also we will imagine that the electron is just like a gyroscope moving around in space always keeping the same direction of spin. Since we will be considering the atom in space the total angular momentum will be constant. In our approximation we will assume that the angular momentum of the electron spin stays the same, so all the rest of the angular momentum of the atom, which is usually called "orbital" angular momentum, will also be conserved. To our sufficient approximation the electron moves in the hydrogen atom like a particle without spin, the angular momentum of the motion is a constant.

With these approximations the amplitude to find the electron at a different place in space can be represented by a function of position in space and time. We let $\psi(r, \theta, \phi, t)$ be the amplitude to find the electron somewhere at the time t . According to the quantum mechanics the rate of change of the amplitude will then be given by the Hamiltonian operator working on the wave function. From Chapter 16,

$$\frac{\partial \psi}{\partial t} = E\psi. \quad (19.1)$$

But

$$E = -\frac{\hbar^2}{2m} \nabla^2 - V(r). \quad (19.2)$$

Here m is the electron mass, and $V(r) > 0$ is the potential energy of the electron in the

19-1 Schrödinger's equation for the hydrogen atom

19-2 Spherically symmetric solutions

19-3 Series with no angular dependence

19-4 The general solution for hydrogen

19-5 The hydrogen wave functions

19-6 The periodic table

charge field of the proton. Taking $r \rightarrow \infty$ large distances from the proton we can write⁴

$$\nabla^2 = -\frac{e^2}{r}$$

The wave function ψ must then satisfy the equation

$$\frac{\partial \Psi}{\partial r} = -\frac{e^2}{2m} \nabla^2 \Psi = -\frac{e^2}{r} \Psi. \quad (19.1)$$

We want to look for definite-energy states, so we try to find solutions which have the form

$$\psi(r, \theta) = e^{-iErt/\hbar} R(\theta) \Psi(r). \quad (19.2)$$

So $\Psi(r, \theta)$ must then be a solution of

$$-\frac{\hbar^2}{2mr^2} \nabla^2 \Psi = \left(E + \frac{e^2}{r}\right) \Psi, \quad (19.3)$$

where E is some constant, the energy of creation.

Again the potential-energy term depends only on the radius, so it's often more convenient to solve this equation in polar coordinates r, θ , the radial and angular ones. The Laplacian is defined in rectangular coordinates by

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}.$$

We want to use instead the coordinates r, θ, ϕ shown in Fig. 19-1. These coordinates are related to x, y, z by

$$x = r \sin \theta \cos \phi, \quad y = r \sin \theta \sin \phi, \quad z = r \cos \theta.$$

It's a rather tedious mess to work through the algebra, but you can easily show that (for any function $f(y) = f(x, y, z)$)

$$\nabla^2 f(x, y, z) = \frac{1}{r^2} \frac{\partial^2}{\partial r^2} (rf) + \frac{1}{r^2} \left[\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial f}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2 f}{\partial \phi^2} \right]. \quad (19.4)$$

So in terms of the polar coordinates, the equation which is to be satisfied by $\Psi(r, \theta, \phi)$ is

$$\frac{1}{r^2} \frac{\partial^2}{\partial r^2} (r\Psi) + \frac{1}{r^2} \left\{ \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial \Psi}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2 \Psi}{\partial \phi^2} \right\} = -\frac{2m}{\hbar^2} \left(E + \frac{e^2}{r}\right) \Psi. \quad (19.5)$$

19.2 Spherically symmetric solutions

Let's first try to find some very simple functions that satisfies the Schrödinger equation in (19.5). Although the wave function ψ will, in general, depend on the angles θ and ϕ as well as on the radius r , we can see whether there might be a special situation in which ψ does not depend on the angles. For a wave function that doesn't depend on the angles, most of the difficulties will change in any way if you rotate the coordinate system. That means that all of the components of the angular momentum are zero. Since ψ must correspond to a state whose total angular momentum is zero. (Actually, it is only the orbital angular momentum which is zero because we still have the spin of the electron, but we are ignoring that part.) A state whose zero orbital angular momentum is caused by a special symmetry is called an "s-state" (you can remember "s" for spherically symmetric!).

⁴ *Angular ℓ quantum numbers*

Since some special numbers are part of the common vocabulary of science physics, you will have to learn them. We will help out by putting them together in a short "vocabulary" box in the chapter.

Now this is not going to depend on α since then the entire Laplace transform only depends on α . So (19.2) becomes much simpler:

$$\frac{1}{r} \frac{d^2}{dr^2} (\psi) = -\frac{1}{\alpha^2} \left(E + \frac{r^2}{r} \right) \psi. \quad (19.3)$$

Before you start to work on solving this equation, it's a good idea to get rid of all constants. We like to do this by making some scale changes. These simplifications will be easier. If we make the following substitutions:

$$r = \frac{\mu^2}{m^2} \rho, \quad (19.4)$$

and

$$E = \frac{\mu^2}{\hbar^2} \epsilon, \quad (19.5)$$

then (19.3) becomes (after multiplying through by ρ)

$$\frac{d^2 \psi(\rho)}{d\rho^2} = -\left(\epsilon - \frac{2}{\rho} \right) \psi. \quad (19.6)$$

These scale changes mean that we are measuring the Coulomb potential energy E in units of "natural" atomic units. That is, $\rho = 5.29$, where $a_0 = 5.29 \text{ fm}^{-1}$ is called the "Bohr radius" and is about 0.028 fm inverse. Similarly, $\epsilon = E/E_\infty$ with $E_\infty = m^2 c^2 / \hbar^2$. The energy is called the "Rydberg" and is about 13.6 electron volts.

Since the ρ variable appears on both sides, it is convenient to work with it rather than with ψ itself. Doing

$$\phi(\rho) = \psi(\rho), \quad (19.7)$$

we have the more complicated equation

$$\frac{d^2 \phi}{d\rho^2} = -\left(\epsilon - \frac{2}{\rho} \right) \phi. \quad (19.8)$$

Now we'd like to find some function ϕ which satisfies Eq. (19.8). In other words, we just want to solve a differential eqn. i.e. linear theory. There is no general, generic, method for solving any given differential equation. You just have to fiddle around. Our equation is not easy, but people have found that it can be solved by the following procedure. First we replace ϕ , which is some function of ρ , by a product of two functions

$$\phi(\rho) = \rho^{-2} \psi(\rho). \quad (19.9)$$

The justification is that you are factoring a "out" of $\phi(\rho)$. You can verify this by taking the first derivative of ϕ plus shifts one problem forward by the right hand side of (19.8).

Substituting (19.9) into (19.8), we get the following equation for ψ :

$$\frac{d^2 \psi}{d\rho^2} - 2\rho \frac{d\psi}{d\rho} - \left(\frac{2}{\rho} + \epsilon - \frac{2}{\rho^2} \right) \psi = 0. \quad (19.10)$$

Since we are free to choose ϵ , let's choose

$$\epsilon^2 = -\alpha. \quad (19.11)$$

and get

$$\frac{d^2 \psi}{d\rho^2} - 2\rho \frac{d\psi}{d\rho} + \frac{1}{\rho^2} \psi = 0. \quad (19.12)$$

You may think we've made life difficult when we wrote (19.11). But here's a happy thing about our new equation is that it can be solved easily in terms of a power series in ϵ . It is possible, in principle, to solve (19.12) that way too. But it is

much harder.) We are saying that Eq. (19.17) is satisfied by some $\phi(\mu)$ which can be written as a series

$$\phi(\mu) = \sum_{k=0}^{\infty} a_k \mu^k, \quad (19.18)$$

in which the a_k are constant coefficients. Now all we have to do is find a suitable infinite set of coefficients a_k which satisfy this equation. The first derivative of this $\phi(\mu)$ is

$$\frac{d\phi}{d\mu} = \sum_{k=1}^{\infty} k a_k \mu^{k-1},$$

and the second derivative is

$$\frac{d^2\phi}{d\mu^2} = \sum_{k=2}^{\infty} k(k-1) a_k \mu^{k-2}.$$

Using these expressions in (19.17) we find

$$\sum_{k=0}^{\infty} \mu^k - 1 + a_0 \mu^{-2} - \sum_{k=1}^{\infty} k a_k \mu^{k-1} + \sum_{k=2}^{\infty} k(k-1) a_k \mu^{k-2} = 0. \quad (19.19)$$

Now, we can't tell if we have succeeded, but we hope so! Let's add better if we replace the first sum by an integration. Since the first term of the sum is zero, we can replace μ^k by $\mu - 1$ without changing anything in the infinite series. Just the change the first sum can equally well be replaced as

$$\sum_{k=0}^{\infty} \mu^k + (-1)^k a_k \mu^{k-1}$$

Now we can put all the sums together to get

$$\sum_{k=0}^{\infty} ((k+1)a_{k+1} - 2ka_k + 2a_0) \mu^{k-1} = 0. \quad (19.20)$$

This expression must vanish for all powers of μ , except μ^0 . It can do that only if the coefficient of each power of μ is separately zero. We will have a solution, for the given equation if we can find a set a_k for which

$$(k+1)a_{k+1} - 2ka_k + 2a_0 = 0. \quad (19.21)$$

For $k=0$ or 1 , this is certainly easy to arrange. Pick any a_0 you like. Then generate all of the other coefficients from

$$a_{k+1} = \frac{2ka_k - 2a_0}{k+1}. \quad (19.22)$$

With this you see a_0 , a_1 , a_2 , a_3 , and so on, and each pair a_k , a_{k+1} certainly satisfy (19.21). We get a series for $\phi(\mu)$ which satisfies (19.17). With it we can make a function which satisfies Schrödinger's equation. Notice that the solution depends on the external energy through the last two values of a ; there is no general a_0 .

You have a solution, but what does it represent physically? We can get an idea by seeing what happens for the positive-negative values of μ . On these, the high-order terms of the series are the most important, so we should look at what happens for large k . When $k \gg 1$, Eq. (19.22) is approximately of the form

$$a_{k+1} \approx \frac{2a}{k} a_k,$$

which means that

$$a_{k+1} \approx \frac{(2a)^k}{k!} a_0. \quad (19.23)$$

But these are just the coefficients of the series for $e^{2a/\mu}$, the function of μ is a rapidly increasing exponential. Every couple of bits μ^2 to produce $e^{2a/\mu}$ see Fig. 19.4.

Eq. (19.14) still gives a solution for $\psi(r)$ which goes like e^{kr} for large r . We have found some bound state solutions but not a physical one. It represents a situation in which the electron is most likely to be near the proton. It is always more likely to be found at a very large radius r . A wave function for a bound electron must go to zero for large r .

We have to think what the best possible way to have the game, and that is obvious. It is just happened by luck that α were equal to $1/3$, where α is only inverse, then Eq. (19.12) would make ω_{fr} = 0. All hope is lost would also be zero. We want ω_{fr} to have an infinite series in a finite polynomial. Any polynomial increases more slowly than e^{kr} , so the term e^{kr} will eventually beat it down, and the function ψ will go to zero for large r . The only bound-state solutions are those for which $\alpha = 1/3$, with $n = 1, 2, 3, 4$, and so on.

Looking back to Eq. (19.16), we see that the bound state solutions to the spherically symmetric wave equation can be stated when

$$-\frac{1}{r^2} - \frac{1}{r^3} + \frac{1}{16} \cdots \cdots \cdots \cdots \cdots \cdots$$

The allowed energies are just those that lie below the Rydberg, $E_R = -m^4/2k^2$, or the energy of the zero-energy level is

$$E_0 = -E_R \frac{1}{n^2}. \quad (19.20)$$

There is, unfortunately, nothing mysterious about negative numbers for the energy. The energies are negative because when we write down its $V = -e^2/r$, we picked our zero point as the energy of an electron free floating far from the proton. When it is close to the proton, its energy is less, so somewhat below zero. The energy is lowest (most negative) for $n = 1$, and increases toward zero with increasing n .

Before the discovery of quantum mechanics, it was known from experimental studies of the spectrum of hydrogen that the energy levels could be described by Eq. (19.21), where R_H was found over the observations to be about 13.6 electron-volts. Bohr then derived a model which gave the same equation and predicted that E_0 should be $m^4/2k^2$. But it was the greatest success of the Schrödinger theory that it could reproduce this result from a basic equation of motion for the electron.

Now that we've resolved our first concern, let's look at the nature of the solutions we get. Putting all the pieces together, each solution looks like this:

$$\psi_n = \frac{C_n(r)}{r} = \frac{e^{-\alpha r}}{r} \psi_n(r) \quad (19.21)$$

where

$$\psi_n(r) = \sum_{i=1}^n a_i r^i \quad (19.22)$$

and

$$a_{n+1} = \frac{n a_n}{(n+1) \alpha}, \quad (19.23)$$

So long as we are entirely interested in the relative probabilities of finding the electron at various places we can pick any number of such terms. We may as well do $a_{n+1} = 1$ (people often choose a_1 so that the wave function is "normalized," that is, so that the integrated probability of finding the electron anywhere in the atom is equal to 1. We have no need to do that just now.)

For the lowest energy state, $n = 1$, and

$$\psi_1(r) \sim e^{-\alpha r}. \quad (19.24)$$

For a hydrogen atom in its ground (lowest-energy) state, the amplitude of finding the electron at any point drops off exponentially with the distance from the proton. It is most likely to be found right at the proton, and the cut-off distance at which the amplitude is about one unit in ρ , or about one Bohr radius, is

Energy $E = 2$ goes to a higher level. The wave function for this state will have two terms. It is

$$\psi_{200} = \left(1 - \frac{r}{a}\right)e^{-r/a^2} \quad (19.29)$$

The wave function for the $1s$ level is

$$\psi_{100} = \left(-\frac{10}{a^3} + \frac{2}{a^2}r^2\right)e^{-r/a^2} \quad (19.30)$$

The wave functions for these first three levels are plotted in Fig. 19.2. You can see the general trend. All of the wave functions approach zero rapidly for very large r values, oscillating a few times. In fact, the number of "nodes" is just equal to $n - 1$. For example, the one $1s$ node corresponds to $n_1 = n - 1$.

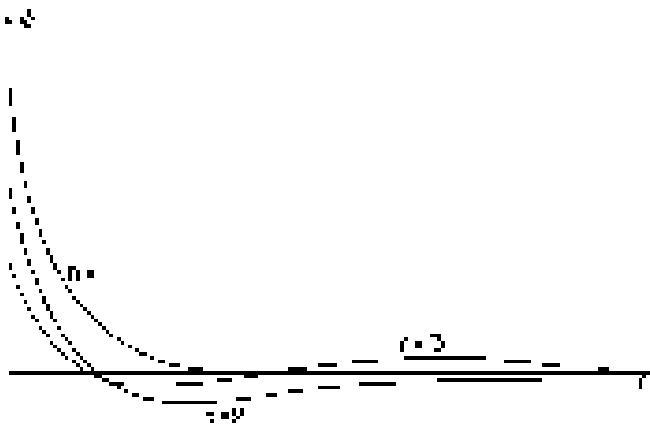

Fig. 19.2. The wave functions for the first three n -values of the hydrogen atom. (The scales are chosen so that the total probabilities are equal.)

19.3 States with an angular dependence

In the wave description of the $1s$, we have found that the probability amplitude to find the electron is spherically symmetric, depending only on r , the distance from the proton. There is no net overall angular momentum. We would like to know about states which may have some angular dependence.

We could, I'm afraid, just investigate the already mathematical problem of finding the functions $\psi(r, \theta, \phi)$, which satisfy the differential equation (19.7), putting in the additional physical conditions that they only represent l numbers ($l = 0, 1, 2, \dots$) for large r . You will find this in some of many books. We are going to take a short cut by using the knowledge we already have about how angular momentum is represented.

The hydrogen atom at any $2l$ level n is a particle with a certain "spin" l , the quantum number of the angular momentum. But if the spin comes from the electron's internal spin, and perhaps its electronic motion, Ψ for each of these two components can independently form an excellent system, and yet still retain both the spatial and time-only about the "orbital" together information. The orbital motion behaves, however, just like a coin. For example, if the orbital spin is turned to zero, the component of angular momentum can be $l = 0, 1, 2, \dots, l$ (for up, or down, respectively, measuring it, $m_l = 0, \pm 1, \dots, \pm l$). Also, all the rotation in addition to other properties we have worked out will apply. (In our discussion we will be ignoring the electron's spin; if we speak of "angular momentum" we will mean only the orbital term.)

Since the potential V at which the electron moves depends only on r , the two components of the Hamiltonian is constant under all rotations. It follows that the angular momentum and its components are conserved. (This is the famous reason why "central field" magnetohydrodynamics may represent not a basic feature of the Coulomb's law problem.)

Now let's think of some possible state of the economy; its income angular structure will be characterized by the quantum number ℓ . Depending on the "orientation" of the total angular momentum with respect to the z -axis, the z-component of angular momentum will be m , which is one of the $2\ell + 1$ possibilities between $-\ell$ and ℓ . Let's say $m = 1$. What what amplitude will the electron be found at some distance r from the origin? At a distance r , the basis cannot have any radial angular momentum around the z -axis. Alright, suppose it is zero, then there can be some nonzero amplitude to find the electron at each distance from the position. We'll call this amplitude $F(r)$. It is the amplitude to find the electron at the distance r up along the z -axis, when the system is in the state $|\ell, m\rangle$, by which we mean orbital spin 1 and a component $m = 1$.

If we know $A_r(r)$ everything is known. For any state $|\ell, m\rangle$ we know the amplitude $A_{\ell m}$ to find the electron anywhere in the atom. Now! Watch this. Suppose we have the atom in the state $|\ell, m\rangle$, that is the amplitude to find the electron at the angle θ , and the distance r from the origin. Put a new z' -axis, say z' , at the angle α (Fig. 19-3), and ask what is the amplitude that the electron will be at the distance r along the new axis z' ? We know that it cannot be found along z' unless its z-component of angular momentum, say m' , is zero. When m' is zero, however, the amplitude to find the electron along z' is $A_{\ell m}$. Therefore the result is the product of two factors. The first is the amplitude that an atom in the state $|\ell, m\rangle$ along the z -axis will be in the state $|\ell, m' = 0\rangle$ with respect to the z' -axis. Actually this amplitude by $R_{\ell m}(\theta)$ and you have the amplitude $A_{\ell m}(r)$ to find the electron at (r, θ, ϕ) with respect to the original axes.

Let's write it out. We have worked out earlier the transformational matrices for rotations. Going from the frame x, y, z to the frame x', y', z' of Fig. 19-3, we have once last rotated the z' -axis by the angle α , and then rotated about the new x' -axis (ℓ) by the angle θ . The combined rotation is the operator

$$R_{\ell m}(\theta) R_{\ell m}(\alpha)$$

The amplitude to find the state $|\ell, m' = 0\rangle$ after the rotation is

$$|\ell, m | R_{\ell m}(\theta) | \ell, m' \rangle. \quad (19.37)$$

Our result then is

$$A_{\ell m}(r) = |\ell, 0 | R_{\ell m}(\theta) | \ell, m' \rangle \langle \ell, m' | r \rangle. \quad (19.38)$$

Two orbital motion can have only integral values of ℓ . If the electron can be found anywhere $m \neq 0$, there is some amplitude to have $m = 0$ in that direction. And $m = 0$ occurs exactly in integral spins. The selection rules for $\ell = 1$ are given in Table 17-2. For larger ℓ you can use the general formulae we worked out in Chapter 18. The matrices for $S_x(\theta)$ and $S_y(\theta)$ appear again, but you know how to combine them. For the general case you would operate the matrix $|J, m |$ and operate with $R_{\ell m}(\theta)$ to get the new state $R_{\ell m}(\theta) | J, m \rangle$. Then you operate on this state with $S_x(\theta) + S_y(\theta) + S_z(\theta)$ and $S_z(\theta)$ which is just $\ell = 1, m = 0$. Multiplying by $|J, m |$ gives the answer already (19.11).

The various elements of the rotation operator have algebraic differences of i and $-i$. The joint distribution function which appears in (19.38) also shows up in many kinds of problems which involve waves in spherical geometry, and in fact have a special name. Not everyone uses the same convention, but one of the most common ones is

$$|\ell, 0 | R_{\ell m}(\theta) | \ell, m' \rangle = i \ell m' Y_{\ell m'}(\theta). \quad (19.39)$$

The functions $Y_{\ell m'}(\theta)$ are called the spherical harmonics, and i is just a normalization factor which depends on the definition chosen for $Y_{\ell m}$. For the usual definition

$$\psi = \frac{e^{-\frac{r^2}{2}}}{\sqrt{3\pi}}, \quad (19.40)$$

With this notation, the hydrogen wave functions can be written:

$$\psi_{100}(r) = Y_{100}(\theta) \psi_1(r) \quad (19.41)$$

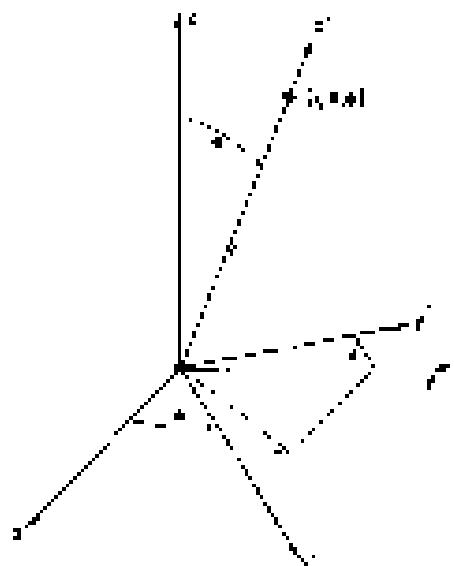

Fig. 19-3. The angle β , α , γ is an orientation of the x', y', z' coordinate frame.

The angle θ (where $\theta \neq 90^\circ$) is important not only in many quantum-mechanical problems but can in many areas of classical physics. In such the θ operator appears with no interpretation. As another example of the use of quantum mechanics, consider the deexcitation of a neutron state by $N\gamma$ radiation or thermal γ , the last chapter which decays by emitting two photons and going into $1S^1$:

Suppose that the excited state has some spin (necessarily an integer) so that the "component" of angular momentum is m . We might now ask the following question: what is the amplitude that we will find the neutron going off at a direction θ with respect to the x -axis and the angle ϕ with respect to the y -axis? as shown in Fig. 17.4.

To solve this problem we take $\langle 1S | \gamma | 1S \rangle$, the Clebsch-Gordan coefficient. A decay in which one particle goes straight and only emits energy from a source is zero. Thus $\langle 1S | \gamma | 1S \rangle = 0$ and the two particles have spin zero, and because their sum is that they may couple momentum about the x -axis. The total A is amplitude a $1S^1$ into solid angle. Then, to find the my amplitude for a decay is the infrared angle of Fig. 17.4 all we need to know is what amplitude the given initial state has zero angular momentum about the decay direction. The amplitude for the decay of S and g is then a three-dimensional unit vector ($| \psi \rangle$) with respect to the x -axis will be $\langle \psi | \psi \rangle$ the state $|\psi\rangle$ with respect to x , the decay direction. The final amplitude is just what we have written in (17.2). The probability to see the particle at θ, ϕ is

$$P(\theta, \phi) = n^2 |\langle 1S | \psi | \psi \rangle \langle \psi | 1S \rangle|^2$$

As an example, consider a situation with $\theta = 135^\circ$ and $\phi = 0^\circ$. The values of n from Table 17.2 we know the necessary amplitudes. They are

$$\begin{aligned} \langle 1, 0 | R_x(0)R_y(0) | 1, -1 \rangle &= -\frac{1}{\sqrt{2}} \sin \pi/2, \\ \langle 1, 0 | R_y(0)R_z(0) | 1, 0 \rangle &= 0.65, \\ \langle 1, 0 | R_z(0)R_y(0) | 1, -1 \rangle &= -\frac{1}{\sqrt{2}} \cos \pi/2. \end{aligned} \quad (17.26)$$

Now are the three possible angular distribution amplitudes depending on the nature of the initial nucleus.

Amplitudes such as the ones in (17.26) appear often and are sufficiently simple that they are given several names. If the angular distribution amplitude is proportional to my value of the first function, it is the combination of the two, "The system has an overall angular momentum of $m = 1$." Or we may say, "The $N\gamma$ system is a wave packet." Or we say, "The angular momentum is $m = 1$." Because there are so many ways of saying the same thing it is useful to have a dictionary. If you are going to understand what other physicists are talking about, you will just have to memorize the language in Table 17.2 for your collection of orbital angular momentum:

If the orbital angular momentum is $m = 0$, then there is no change except you rotate the coordinate system without variation with angle, the "independence" of angle is an $m = 0$ function, say $1, 0$ is an $m = 0$ function, and there is only one term in (17.26) if the angular dependence is concerned. If the orbital angular momentum is 1, then the amplitude of the angular variation may be any one of the four functions given, depending on the value of $m = 1$, it may be a linear combination, these are called "vector," and there are three of them. If the orbital angular momentum is 2, then there are the five functions shown. Any linear combination is called an " $m = 2$ " or a "tensor" amplitude. Now you can immediately guess what the next letter is—what should come after $1, 0, 2, 3$? Well, of course, it's $4, 5, 6$, and so on forever and always. The letters don't mean anything—(they just carry over something—they meant "the 2 lines," "principal" lines, "diffuse" lines and so on).

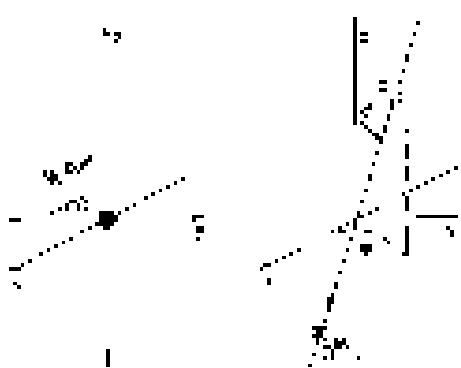

Fig. 17.4. The decay of an excited state of $N(1S)$.

Table 19-1

Multiplets of orbital angular momentum
($l = 0, 1, 2, \dots, n - 1$)

Orbital angular momentum, l	Angular component, m	Angular dependence of amplitude	Sign	Number of states	Central parity
0	0	1	+	1	-
1	-1	$\frac{1}{\sqrt{2}}(\sin \theta e^{i\phi})$	-	2	-
1	0	$\frac{1}{\sqrt{2}}(\cos \theta)$	+	2	+
1	+1	$\frac{1}{\sqrt{2}}(\sin \theta e^{-i\phi})$	-	2	-
2	-2	$\frac{\sqrt{6}}{4}(\sin^2 \theta e^{i\phi})$	-	1	-
2	-1	$\frac{\sqrt{3}}{2}(\sin \theta \cos \theta e^{i\phi})$	-	4	-
2	0	$\frac{1}{2}(3 \cos^2 \theta - 1)$	+	5	+
2	+1	$\frac{\sqrt{3}}{2}(\sin \theta \cos \theta e^{-i\phi})$	-	4	-
2	+2	$\frac{\sqrt{6}}{4}(\sin^2 \theta e^{-i\phi})$	-	1	-
3	-3	$\frac{1}{2}\sqrt{10}(\sin^3 \theta e^{i\phi})$	-	1	-
3	-2	$P_2(\cos \theta)$	-	3	-
3	-1	$\frac{1}{2}\sqrt{15}(\sin^2 \theta \cos \theta e^{i\phi})$	-	6	-1
3	0	$\frac{1}{4}(5 \cos^3 \theta - 3 \cos \theta)$	+	7	-
3	+1	$\frac{1}{2}\sqrt{15}(\sin^2 \theta \cos \theta e^{-i\phi})$	-	6	-1
3	+2	$\frac{1}{2}\sqrt{10}(\sin^3 \theta e^{-i\phi})$	-	1	-
3	+3	$\frac{1}{2}\sqrt{6}(\sin^3 \theta e^{i\phi})$	-	1	-

"three-quantum" uses of the optical spectra of atoms. But those were in the days when people did not know where the three came from. All of them were given special names, so we may just call them p_0, p_1 , and p_2 .

The angular functions in the last group above, p_{-1}, p_0 , and p_1 , are antisymmetric about the horizontal. States that repeat out in front. Sometimes, they are called "oblique harmonics," and sometimes P_{-1} , etc. Sometimes they are zero at $\theta = \pi/2$, and, if $m = 0$, simply as $P_0(m=0)$. The functions $p_2(\cos \theta)$ are called the "Legendre polynomials" in physics, and the functions $p_m(\cos \theta)$ are called the "associated Legendre functions." You will find tables of these functions in many books.

Note, particularly, that all the amplitudes p_m given have the property that they have the same parity; for odd m they change sign under π inversion and for even m they don't change. So we can write the parity of a state of orbital angular momentum $|l, m\rangle$ as

As we have seen, these angular distributions may give rise to a nuclear disintegration or some other process, as in the distribution of the amplitude to line an electron from one place to another place in the hydrogen atom. For instance, if an electron is in a plane ($\theta = \pi/2$), the amplitude to find it in the point θ is dependent on the angle ϕ in many possible ways—but all are linear combinations of the three functions for $l = 1$ at Table 19-1.

Of course the case $l = 0$ is special. That's interesting. That means that the amplitude is positive only in the upper part ($\theta < \pi/2$), negative in the lower part ($\theta > \pi/2$), and is zero when $\theta = \pi/2$. Required the amplitude to be real and nonzero only by finding the exact ϕ values with $\theta = \pi/2$ shown in Fig. 19-5, and it is dependent of ϕ ; this angle's existence is responsible for the fact that in molecular binding the electron can't be in $\theta = \pi/2$. Let's refer again to our diagram of arrangement in the atom. At the direct vertices of interest almost all

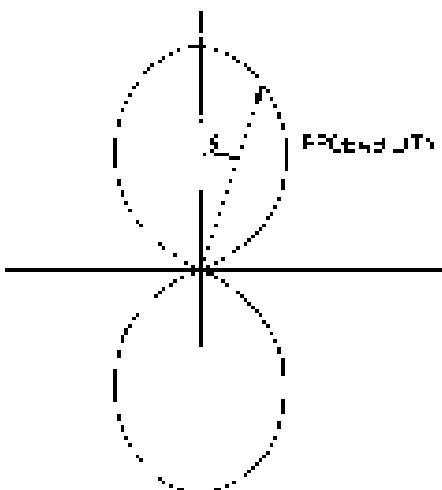

Fig. 19-5. A polar graph of $|\psi|^2/\lambda$, which is the relative probability of finding an electron at various angles from the z -axis for a given l . In each sketch, $\theta = \pi/2$ and $\phi = 0$.

14-4 The general solution for hydrogen

In Eq. (19.35) we have written the wave functions for the hydrogen atom as

$$Y_{l,m}(\theta) = R_{l,m}(r, \theta) Y_l^m(\theta). \quad (19.37)$$

These wave functions must be solutions of the Schrödinger equation (19.7). To do this with the r -wave, $R_{0,0}(r, \theta, \phi)$ in Eq. (19.37) into (19.7), you get

$$\begin{aligned} \frac{\partial^2}{\partial r^2} (r^2 R_{0,0}) - \frac{E_0}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial R_{0,0}}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 R_{0,0}}{\partial \phi^2} \\ = -\frac{2m}{\hbar^2} \left(E_0 + \frac{l^2}{r^2} \right) R_{0,0}. \end{aligned} \quad (19.38)$$

Now multiply through by r^2/r , and rearrange terms. The result is

$$\begin{aligned} \frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial R_{0,0}}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2 R_{0,0}}{\partial \phi^2} \\ = -\left[\frac{r^2}{\hbar^2} \left[\frac{\partial^2}{\partial r^2} (r^2 R_{0,0}) + \frac{2m}{\hbar^2} \left(E_0 + \frac{l^2}{r^2} \right) \right] \right] Y_{0,0}. \end{aligned} \quad (19.39)$$

The left-hand side of this equation depends on θ and ϕ , but not on r . We consider what value we choose for r , the left side doesn't change. This means that we can fix the right-hand side. Although the quantity in the square brackets has r 's all over the place, the whole quantity cannot depend on r , otherwise we wouldn't have an equation valid for all r . As you can see, the bracket does depend on r via E_0 . It must be zero (constant). Its value may well depend on the l -value of the wave we are applying, since the function R_0 must be the one appropriate to that state; well call the constant K_0 . Equation (19.39) is therefore equivalent to two eqs., which

$$\frac{1}{\sin \theta} \frac{\partial}{\partial \theta} \left(\sin \theta \frac{\partial R_{0,0}}{\partial \theta} \right) + \frac{1}{\sin^2 \theta} \frac{\partial^2 R_{0,0}}{\partial \phi^2} = K_0 Y_{0,0}, \quad (19.40)$$

$$\frac{1}{\hbar^2} \frac{\partial^2}{\partial r^2} (r^2 R_0) + \frac{2m}{\hbar^2} \left(E_0 + \frac{l^2}{r^2} \right) R_0 = K_0 Y_{0,0}. \quad (19.41)$$

Now look at what we've done. For any state described by l and m , we know the function $Y_{l,m}$; we can use Eq. (19.40) to determine the constant K_0 . Putting K_0 into Eq. (19.41) we have a differential equation for the function $R_0(r)$. If we can solve that equation for $R_0(r)$, we have all of the pieces to put into (19.37) to give $\Psi(r)$.

What is K_0 ? First, notice that it must be the same for all m (which go with a particular l), so we can pick any m we want for $Y_{l,m}$ and plug it into (19.40) to solve for K_0 . Perhaps the easiest one to use is $Y_{0,0}$. From Eq. (18.24)

$$\langle 0,0 | 1,0 \rangle = e^{i k_z} \langle 0,0 | 1,0 \rangle. \quad (19.42)$$

The matrix element for $R_0(r)$ is also quite simple:

$$\langle 0,0 | R_0(r) | 1,0 \rangle = \delta(l,1) \delta(m,0), \quad (19.43)$$

where δ is some number ± 1 . Combining the two, we obtain

$$Y_{0,0} = e^{i k_z} \sin \theta. \quad (19.44)$$

You can with some work show that the constant of Eq. (19.37) is not 0, but it is also easy to work out from first principles following the ideas of Section 17.4. A state $| 1,0 \rangle$ can be made out of 21 spin-one-half particles all with spins up; since the state $| 1,0 \rangle$ would have 1 up and 1 down. Under σ_z rotations, the amplitude that all up-spins are up is $+1/\sqrt{2}$, and that all up-spins goes down is $-i/\sqrt{2}$. We are looking for the amplitude that all up-spins stays up, while the other two up-spins go down. The amplitude for that is $(+i/\sqrt{2})(-i/\sqrt{2})$, which is the same as $\delta(l,1)$.

Picking out function ψ_0 from Eq.(19.3) gives

$$E_0 = \frac{1}{2} \theta^2 - \frac{1}{r_0}. \quad (19.4)$$

Now that we have computed E_0 , Eq.(19.4) tells us about the total energy $E_0(\theta)$. And, of course, just like Schrödinger's equation with the angular component, by its equivalent $K(E)/r^2 = \nabla^2 \psi_0 + E_0(\theta) \psi_0$ (Eq.(19.3)) in the form of Eq.(19.4), we have:

$$\frac{1}{r^2} \frac{\partial^2}{\partial \theta^2} \psi_0 = -\frac{2m}{\hbar^2} \left[\frac{1}{r^2} \frac{\partial^2}{\partial r^2} \psi_0 + \frac{E_0(\theta) - 1/r^2}{2mr^2} \right] \psi_0. \quad (19.5)$$

A centrifugal term has been added to the potential energy. Although at first this term may seem mathematical, it does have a simple physical origin. We will give you an explanation where it comes from in terms of conservation arguments. But perhaps you will not find it quite so mysterious.

Think of a classical particle moving around an elliptical orbit. The total energy is conserved and is the sum of the potential and kinetic energies:

$$E = E(r) + \frac{1}{2} m v^2 = \text{constant}$$

In general, since the radial motion is radial or spherically symmetric, we can write

$$v^2 = r^2 \dot{\theta}^2 + \frac{r^2 \dot{r}^2}{r^2}.$$

Now the angular momentum vector is conserved and is equal to $L = m r^2 \dot{\theta}$. So we can write

$$m r^2 \dot{\theta} = L, \quad \text{or} \quad \dot{\theta} = \frac{L}{m r^2}$$

and the energy is

$$E = \frac{1}{2} m r^2 \dot{r}^2 + \frac{L^2}{2m r^2} + \frac{L^2}{2mr^2}.$$

If there were no angular momentum we would have just the first two terms. Adding the angular momentum L does two things: first what's left of the term L^2/mr^2 is the potential energy contribution. But this is almost exactly the same term in Eq.(19.4) (the only difference is that (L^2/mr^2) appears as the angular momentum term instead of (L^2/mr^2) as in Eq.(19.3)). But we have seen, back in Chapter 10, Volume 1, Section 10.7.1 that this is not the situation that is usually referred to when a quantum-mechanical argument with a correct classical-mechanical calculation. We can then understand the new term as a "correction" (or "perturbation") which goes like the coupling force in the equation of the equations of motion for a classical system. (See the discussion of "perturbations" in Volume 1, Section 10.7.)

We are now ready to solve Eq.(19.4) for $\psi_0(\theta)$. It is very much like Eq.(19.3); the same technique will work again. Expanding ψ_0 as before, and you get in Eq.(19.4) what will look the odd-shaped term

$$(V + 1) \sum_{n=0}^{\infty} a_n \theta^{2n}. \quad (19.6)$$

This can now also be written as

$$(V + 1) \left\{ \frac{a_0}{\theta} + \sum_{n=1}^{\infty} a_n \theta^{2n-1} \right\}. \quad (19.7)$$

(We have taken out the a_0/θ term and rearranged the remaining terms as shown by Eq.(19.6) instead of Eq.(19.4) we have:

$$\sum_{n=0}^{\infty} (V + 1) \theta^{2n-1} a_n = -2ma^2 - 1/a^2 \theta^2. \quad (19.8)$$

See Appendix A for the solution.

There is only one term in ψ_{nlm}^+ that is odd by m . The coefficient of $m=0$ is zero (unless $l=0$ and we have our previous solution). Each of the other terms is made even by having the x_2 and x_3 terms come out even for even m . This leads to Eq. (19.33) by

$$\alpha_{nlm} = \frac{2\pi l+1}{2l+1} - \frac{\pi m}{l(l+1)} = \frac{\pi}{l(l+1)}. \quad (19.33)$$

This is the only significant change from the spherically symmetric case.

As before the series must terminate if we are to have solutions which can represent R and ψ_{nlm} too. The series will end at $k = n$ if $n > l$. We get again the same separation eq. (19.1), thus it must be equal to $1/k$, where k is some integer. However, Eq. (19.33) also gives a new restriction. It requires k to be equal to l , so the denominator becomes zero and α_{nlm} is infinite. That is, unless $n = l$, Eq. (19.33) implies that all successive α_{nlm} are zero until we get to $k = l$, which can't be done. This means that k must start at $k = l$ and end at n .

The final result is that for any l there are many possible solutions which are given by R_{nlk} , where $k \geq l + 1$. Each solution has its energy

$$E_{nlk} = \frac{me^2}{2k^2} \left(\frac{1}{n^2} \right). \quad (19.34)$$

The wave function for the state of this energy with the angular quantum number k and m is

$$\psi_{nlkm} = R_{nlk}(r) Y_{lm}(x), \quad (19.35)$$

with

$$dE/dk = e^2 \sum_{n=1}^{\infty} \frac{4\pi^2}{n^2}. \quad (19.36)$$

The coefficients a_k are obtained from (19.30). We have finally a complete description of the states of a hydrogen atom.

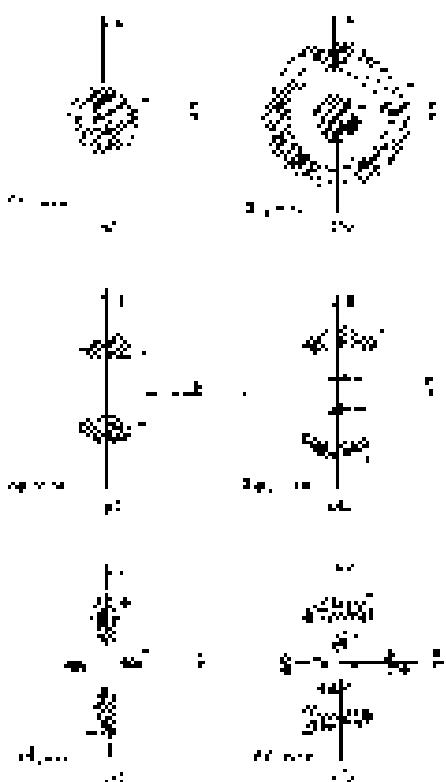

Fig. 19-6 Energy levels showing the angular nature of some of the hydrogen wave functions. The second column, top down, are the methylene wave functions. The plus and minus signs show the relative sign of the amplitude in each region.

19-5 The hydrogen wave functions

We're now in a position to discuss the Schrödinger's equation for an electron in a hydrogen atom characterized by three quantum numbers n, l, m , all integers. The angular distribution of the electron amplitude can't be arbitrary since it must satisfy the condition $\int \psi^2 d\tau = 1$. This is satisfied by the quantum number of total angular momentum and is the "magnitude" quantum number, which can take the values $-l, -l+1, \dots, l-1, l$. For each angular configuration, various possible radial distributions R_{nlk} of the electron amplitude are possible, those calculated by the formula given earlier, which can happen if $k \geq l + 1$. The energy of the state depends only on n , the n regions were nonoverlapping.

The lowest energy, or ground state is one state. It has $l = 0$, $n = 1$, and $m = 0$. It is a "degenerate" state: there's only one $k = 1$ energy, and it's spherically symmetric. The amplitude is finite the electron is a maximum at the center, and falls off monotonically with increasing distance from the center. We can visualize the electron amplitude as a blob as shown in Fig. 19-6(a).

There are other states with higher energies, for $n = 1, 2, 3, \dots$ the next energy there's only one version ($k = 0$), and they are all spherically symmetric. These states have quadrupoles which alternate in sign and we have three with nonvanishing m : the same $n = 1$ hydrogen model will form three planes passing through zero. One possibility of $n = 2$, $l = 1$, for example, will look as sketched in Fig. 19-6(b). (The $l = 1$ states indicate regions where the amplitude is large, while the plus and minus signs indicate the relative phases of the quadrupole.) The energy levels of the system are shown in the first column of Table 19-1.

There are also the l states which $n = 2$. For example, which could be $l = 2$ or greater. There are three states of the same size $k = 2$, and the $m = -1, 0, 1$, and $m = -2$. The energy levels are as shown in Fig. 19-2. The angular dependences of these states are given in Table 19-2. For instance, for $m = 0$, if $n = 3, l = 1$,

amplitude is positive for $\sin \theta = 0$, it will be negative for $\theta = 90^\circ$. There is a nodal plane consistent with the λ -spins. For $m > 2$ there are also spherical nodes. The $n = 2, m = 0$ amplitude is sketched in Fig. 19-6(a), and the $n = 2, m = 2$ wave function is sketched in Fig. 19-6(b).

Now in the three first states we represent a kind of "quantum" of spin, there should be similar contributions with the peaks of amplitude along the x axis or along the y -axis. Are these perhaps the $m = +1$ and $m = -1$ states? Now obviously we have three states with m values plus, say three combinations of the λ 's. These will also be stationary states of the stand energy. It turns out that the "x" state—which corresponds to the "elliptical" $m = 0$ state of Fig. 19-6(a)—is a linear combination of the $m = +1$ and $m = -1$ states—the corresponding "y" state is another combination. Specifically, we mean that

$$\begin{aligned} \psi_{\text{tot}}^{\text{x}} &= 1.00 \\ \psi_{\text{tot}}^{\text{y}} &= \frac{1}{\sqrt{2}}(1.00 + i) \\ \psi_{\text{tot}}^{\text{z}} &= \frac{1}{\sqrt{2}}(1.00 - i) \end{aligned}$$

These stages I took the same when referring to other particular cases.

The states $n = 2$ have five possible values of m for each energy. The lowest-energy levels ($n = 1$) in the hydrogen atom shown in Fig. 9-3. The angular dependences get more complicated. Just as you can see, the $m = 0$ state has two nodal planes in the wave function reversed phase from $m = +1$ to $m = -1$ as you go around from the north pole to the south pole. The rough form of these situations is sketched in (a) and (c) of Fig. 19-6 for the $m = 0$ states with $n = 3$ and $n = 4$. Again, the larger n 's have spherical nodes.

We will now try to describe why there are the possible states. You will find the hydrogen wave functions described in more detail in many books. Two good references are L. Pauling and J. A. Wilson, *Introduction to Quantum Mechanics*, McGraw-Hill (1935); and R. B. Leighton, *Principles of Modern Physics*, McGraw-Hill (1959). You will find in the chapters of some of the functions and pictorial representations of many states.

We would like to mention one singular feature of the wave functions the figure 19-6 for $n > 0$ the amplitudes are zero at $r = 0$ cm. This is not surprising, since it is hard for an electron to have enough momentum when its radius r is very small. As this process, r higher and, the more the amplitudes are "pushed away" from the center. If you look at the way the radial functions $R(r)$ vary for small r , you find from (19.5) that

$$R_{n,l}(r) \sim r^l.$$

Such a dependence on r means that for larger r 's you have to go further from $r = 0$ before you get an appreciable amplitude. This behavior is naturally determined by the centrifugal force given in the radial equation, but something will apply for any potential $V(r)$ values lower than E_n^2 for small r , which does obtain potentials $V(r)$.

19-4 The periodic table

We would like now to apply the theory of the hydrogen atom in an approachable way to get some understanding of the chemist's periodic table of the elements. For an element with atomic number Z there are Z electrons held together by the electric attraction of the nucleus but with mutual repulsion of the electrons. The general case is given below, it has been given Schrödinger's equation for Z electrons in a Coulomb field. For helium the equations is

$$-\frac{\hbar^2 \partial^2}{2m} \psi = -\frac{e^2}{4\pi \epsilon_0 r_1} (1/r_1) + \left(-\frac{2e^2}{r_1} - \frac{2e^2}{r_2} - \frac{e^2}{r_{12}}\right) \psi$$

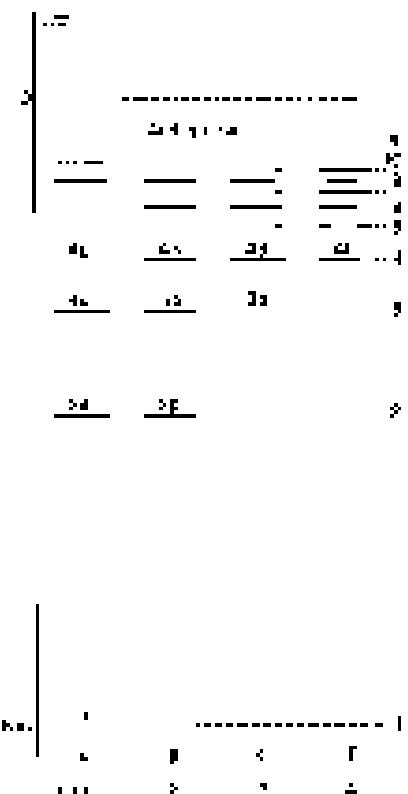

Fig. 19-7. The energy level diagram for the hydrogen atom.

where $\hat{V}_1^2 = -\frac{e^2}{r_1}$ is the potential which operates on r_1 , the distance of one electron. \hat{V}_2 depends on r_1 and $r_{12} = r_1 - r_2$. This is the part reflecting the spin of the electrons. To find the stationary states and energy levels we would have to find ψ in terms of $\hat{\psi}$ in form

$$\psi = \hat{\psi}(r_1, r_{12}) e^{-iE t / \hbar}$$

The general form depends on $\hat{\psi}$, which is a function of six variables—the coordinates and spins of the two electrons. Numerical methods for solving this Schrödinger equation for the lowest energy states have been developed by a myriad methods.

With 1, 2, 3, 4, 5 each one it is hopeless to try to obtain exact solutions without using computers to see that quantum mechanics has given us some understanding of the parameters. It is possible, however, even with a stopgap approximation—and some guesswork—understanding, at least qualitatively, many chemical properties which show up in the periodic table.

The chemical properties of atoms are determined primarily by their bound energy states. We can use the coupling appropriate theory to find these states and their energies. First, we neglect the effect of spin, saying that we neglect the exclusion principle and say that any particular electronic state can be occupied by only one electron. This means that any particular orbital configuration can have up to two electrons—one with spin up, the other with spin down. Next we disregard the details of the interactions between nucleons in our field approximation, and we just take a nuclear mass as a constant plus the combined field of the nucleus and all the other electrons. For them, with the 10 electrons, we say that one increases an average potential due to the nucleus plus the other nine electrons. We are given then that in a hydrogen-like atom for each proton we get a E_p which is a $1/r$ -field modified by a spherically symmetric charge density coming from the other electrons.

In this model each electron acts like an independent particle. The angular dependence of its wave function will be just the same as the ones we had for the hydrogen atom. There will be various orbitals, and so on, and they will have the same probabilities as. Since k_F is no longer given as $1/a$, the radial part of the wave functions will be somewhat different, but as far as qualitatively the same, so we will use the same radial quantum numbers n . The energies of the states will also be somewhat different.

II

With these ideas, let's see what we get. The ground state of hydrogen has $l = m = 0$ and $s = 1/2$ (so the electron configuration is $1s$). The energy is -13.6 eV . This means that it takes 13.6 electron volts to pull the electron off the atom. We call this the "ionization energy", E_I . A more reasonable energy seems that it is harder to pull the electron off. And, in general, that the material is chemically less active.

III

Now take helium. Both electrons can be in the same lowest state (one spin up and the other spin down). In this lowest state the $\hat{V}_1^2 + \hat{V}_2$ is a potential which is for small r_{12} a sum of two fields $1/r_1$ and for very large r_{12} a Coulomb field for $z = 2$. The result is a "hydrogen-like" result with a somewhat lower energy. But electron escape identical to states ($l = 0, m = 0$). The observed ionization energy for helium (one $1s$) is 24.6 electron volts. And the "shell II" is now full—so it only two occurs—there is practically no tendency for an electron to be attracted from another atom. Hence ∞ chemically inert.

IV

The ground hydrogen has a charge of $-e$. The electron charge is $+e$ so hydrogen-like, and the three electrons all occupy the lowest three energy levels. Two will go into $1s$ and one third will go into $2s$ state. But $m_l = 0$ or $l = 0$ in hydrogen these states have the same energy, but in this atom they

don't, for the following reason. Remember that a $2s$ orbital has some emptiness to be near the nucleus while the $2p$ state does not. That means that a $2s$ electron will feel some of the triple-electron charge of the L electrons but that a $2p$ electron will stay out where the field looks like the Coulomb field of a single charge. The extra attraction lowers the energy of the $2s$ state relative to the $2p$ state. The energy levels will be roughly as shown in Fig. 19-8, which you should compare with the corresponding diagram for hydrogen in Fig. 19-7. Be^{+1} from now will have two electrons in $1s$ states and one in a $2s$. Since the $2s$ electron has a higher energy than a $1s$ electron, it is relatively easily removed. The ionization energy of lithium is only 5.3-electron volts, and it is quite reactive chemically.

So you can see the patterns which develop; we have given in Table 19-2 a list of the first 36 elements, showing the states occupied by the electrons in the ground state of each atom. The Table gives the ionization energy for the most loosely bound electron, and the number of electrons occupying each "shell"—by which we mean states with the same n . Since the different isotopes have different

Table 19-2
The electron configurations of the first 36 elements

Z	Element	IP (eV)	n	Electron Configurations									
				1s	2s	2p	3s	3p	3d	4s	3p	4d	5s
1	H: hydrogen	13.6	1										
2	He: helium	24.6	2										
3	Li: lithium	5.3											
4	Be: beryllium	9.3											
5	B: boron	11.2											
6	C: carbon	11.2		FILLED	2	2

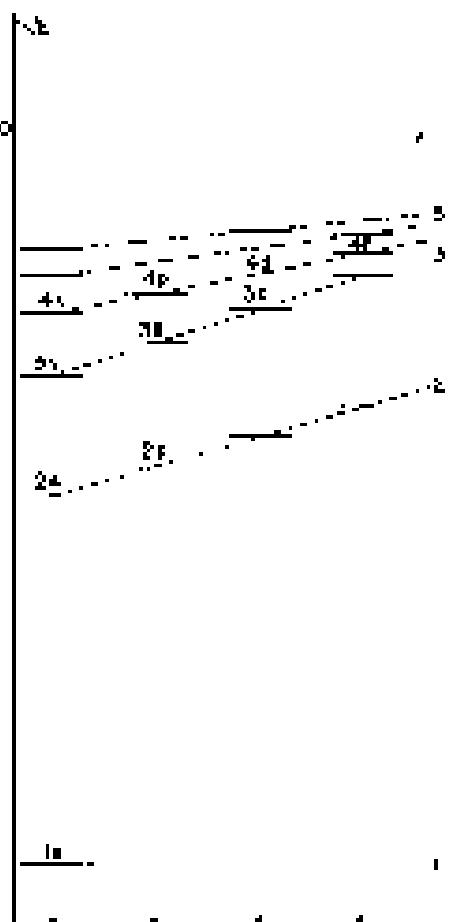

Fig. 19-8. Schematic energy-level diagram for an atomic electron with other electron shells present. The scale is not the same as in Fig. 19-7.

strength, and Rydberg corresponds to a value of 1 of 2021. It provides the same different radial electron orbitals, though all have the same energy—except for some very small effects we are neglecting.

B

"B" can be like A from except that it has two electrons in the $2p_{z}$ state, as well as two in the $2p_{x,y}$ states.

B vs. A

Boron has 3 valence. The lithium ground-state state. The case $1 \times 1 = 1$ is a different type state, so we can keep adding electrons until we get more than one. This does not happen. As we add these electrons we get an increasing Z, so the ψ_{1s} is electron distribution is pushed closer and closer to the nucleus and the energy of the $1s$ state goes down. By hydrogen example, the ionization energy goes to $11 + 9 + 8 + \dots$. Boron does not easily give up an electron. Also there are no two lone-pair electrons to be filled, so it's unlikely to gain an extra electron. Boron is thermally inert. On the other hand, due to how strongly one electron can drop into a state of low energy, so it is quite active in chemical reactions.

N vs. A

With nitrogen, the electron must start a new shell—going into a $2p$ state. The energy level of this state is much higher; the ionization energy, 102.5 kJ/mol, and so it can't easily be filled. From sodium to oxygen the $n=1$ states with $m_l = 0$ are occupied in exactly the same sequence as for lithium— $1s^2$. Angular configurations of the electrons in the outermost valence shell have the same sequence, and the progression of ionization energies is quite similar. You can see why the chemical properties repeat with increasing atomic number. Magnesium is very chemically much like boron, nitrogen, silicon, and chlorine like oxygen. Argon is inert like neon.

You may have noticed that there is a slight irregularity in the sequence of ionization energies between nitrogen and oxygen, and a similar one between sulfur and oxygen. The last electron is bound to the oxygen atom somewhat less than we might expect. And sulfur is similar. Why should that be? We can understand—if we put in just a little bit of the effects of the interactions between individual electrons. Think of what happens when we put the last electron onto the oxygen atom. It has six possibilities—three possible parities, each with two spins. Imagine that the electron goes with spin up into the $n=2$ state, which we have described as the $2p_z$ state because it looks "vertical." Now what will happen to carbon—which has two $2p$ electrons? One of them goes into the $2p_z$ state, where will the second one go? It will want lower energy if it stays away from the first electron, which it can do by going into, say, the $2p_x$ state of the $2p$ shell. (The electron, however, gets three numbers: $l=1$, $m_l = +1$ and $m_s = -1$ states.) Next, when we go to nitrogen, the three $2p$ electrons will have the lowest energy if mutual repulsion if they join the each into the $2p_x$, $2p_y$ and $2p_z$ configurations. For oxygen, however, the j_1 is 2π . The $2p_x$ and $2p_y$ configurations are at the $2p_z$ state—with opposite spins—but strongly repelled by the electron already in that state, so its energy will not be as low as it might otherwise be, and it is more easily removed. That explains the break in the sequence of binding energies which appears between nitrogen and oxygen, and between phosphorus and silicon.

N vs. Zn

After oxygen, you would expect, there's that the next electrons would start to fill up the $3d$ states. But they don't. As we described earlier—and illustrated in Fig. 19.7—the higher angular momentum states get pushed out in energy. By the time we get to the $3d_{10}$ state, they are pushed to an energy a little bit above the energy of the $4s$ state. So it's possible in the last electron, just like the $4s$ state. After zinc, 30, 31.

well as had two electrons or valence, the $3d$ shells begin to be filled for scandium, titanium, and vanadium.

The energies of the $3p$, $3d$, and $4s$ states are so close together that small changes can shift the balance either way. By the time we get to full four electrons in the $3d$ states, their repulsion raises the energy of the $4s$ state just enough that its energy is slightly lower than the $3d$ energy, and it stays in that order. For chromium we don't get a $3+4$ combination because we don't have a $4s$ electron, but instead a $3d$. In combination the other electrons tend to get "cooperative fills" and the shell capacities of the $3d$ -shell are then increased one by one in this way, with copper.

Since the outermost shell of magnesium, iron, cobalt, and nickel have the same configurations, however, they all tend to have similar electron properties. This effect is much more pronounced in the second transition which adds the $3d$ outer shell but a progressively filling outer shell which has such less influence on their electrical properties.

In copper the electron is pulled from the $3d$ shell, finally completing the $3d$ shell. The energy of the $3d$ configuration, however, is closer to the $3s$ configuration for copper than for the previous elements nearby, which is the balance. For this reason the two last electrons of copper are easily removable, and copper has a valence of either $+1$ or $+2$ (it sometimes acts as though its electrons were in the $3d$ configuration). Similar things happen at other places and account for the fact that other metals, such as iron, combine chemically with either of two valences. By now both the $3d$ and $4s$ shells are fully filled and empty.

Group 12

From gallium to krypton the sequence becomes increasingly regular. Thus the $4s-4f$ shell contains double the energy, and the chemical properties repeat themselves from boron to neon and aluminum to argon.

Boron, like arsenic and selenium, is known as "tribond" gas. All three are electronically "inert". This means only that, by using filled shells of electrons for energy storage and for covalence in which there is no energy exchange for them to join in a single combination with other atoms. Having a filled shell is not enough. Boron has a dimensionless core filled s shell, but the energy of these shells is not quite enough to stabilize. Similarly, one would have expected another "noble" element to make $\frac{1}{2}$ the energy of the $4s$ shell (the best ever for the $4s$ light). On the other hand, boron is not completely inert; it will form weak diatomic compounds with fluorine.

Since our simple tree-like approach of the main features of the periodic table, we stop our examination at element number 36. There are 36 elements so far numbered.

We would like to bring up only one more point. Let us not only examine the valence, but also see why something about the determining properties of the chemical bonds. Take an atom like oxygen. Oxygen has four $2s$ electrons. The first three go into the " x ", " y ", and " z " shells and the fourth will eventually fit in the $2p$ shells having between " x " and " y "—except consider how xy happens in that! Each of the two hydrogens are willing to share an electron with the oxygen, helping the oxygen to fill a shell. These electrons will tend to occupy the " x " and " y " positions. So the water molecule holds the two oxygens close making a right angle with respect to the center of the oxygen. The angle is actually 107° . We can now understand why the angle is large, almost 100° , indicating the electrons are occupying the x and y directions. The electron repulsion "shame" has made "water" molecules push the angle out to less than the covalent radius of H_2S . But because the sulfur atom is larger, the two hydrogen atoms are forced apart, there is less repulsion, and the angle is only pushed out to about 92° . Sulfur has been larger, so in H_2Se the angle is very close to 97° .

We can use the same arguments to understand the geometry of ammonia, H_3N . Nitrogen has four $2s$ plus three more " x ," " y ," and " z " type shells. The three hydrogens spend time in a right angle to each other. The angles are about 100° —again from the electron repul-

son, but at least we see why the molecule of H_2N is not flat. The angles in phosphine, H_3P , are close to 90° , and in H_3As are still closer. We assumed that H_3N was not flat when we described it as a two-state system. And the nonflatness is what makes the ammonia more polarizable. Now we see that also that shape can be inferred from our quantum mechanics.

The Schrödinger equation has been one of the great triumphs of physics. By providing the key to the underlying machinery of atoms in nature it has given an explanation for atomic spectra, for chemistry, and for the nature of matter.

Operations

20-1 Operations and operators

All the things we have seen so far in quantum mechanics could be handled with ordinary algebra, although we did from time to time ‘borrow’ some features of working quantum mechanics, quantities and equations. We would like now to look some more closely, since it is useful and useful mathematical ways of describing quantum-mechanical things. There are many ways of approaching the subject of quantum mechanics, and other books use a different approach from the one we have taken. As you go on to read other books you might not see right away the connection of what you will find in them with what we have been doing. Although we will also be able to get a few useful results, the main purpose of this chapter is to tell you about some of the different ways of writing the same physics because then you should be able to understand better what other people are saying. When people were first working out classical mechanics they always wrote all the equations in terms of x , y , and z components. Then someone decided to work with just one vector, but all of the writing would be made much simpler by inventing the vector calculus. This is true, but when you come down to figuring something out, you often have to convert the vector back to their components. But it's generally much easier to just start writing out what you work with vectors and also easier to do many of the calculations. In quantum mechanics we want this to write many things in a simpler way by using the basis of the quantum system. The wave vector $|\psi\rangle$ has, of course, according to the wave mechanics vectors in three dimensions but is an abstract symbol that stands for a physical state, identified by the ‘label’, or ‘name’, ψ . The label is used because the laws of quantum mechanics can be written as algebraic equations in terms of these symbols. For instance, the fundamental law that any state can be made up from a linear combination of other states is written as

$$|\psi\rangle = \sum_i C_i |i\rangle, \quad (20.1)$$

where the C_i are real or complex numbers and anything $|i\rangle = |i_1 i_2 i_3\rangle$ means $|1\rangle |2\rangle |3\rangle$, and so on. I stand for the three digits in some base, or object, whatever.

If you take some physical state and do something to it, like rotating it, or idle waiting for the time Δt , you get a different state. We say ‘performing an operation on a state produces a new state.’ We can express the same idea by an equation:

$$|x\rangle = A |\psi\rangle. \quad (20.2)$$

An operation makes something another state. The operator stands for some particular operation. When the operation is performed on the state, say, $|\psi\rangle$, ... produces some state $|x\rangle$.

What does Eq. (20.2) mean? We think it this way. If you multiply the equation by $\langle x|$ and expand $|\psi\rangle$ according to Eq. (20.1), you get

$$\langle x|\psi\rangle = \sum_i C_i \langle x|i\rangle. \quad (20.3)$$

(The states $|i\rangle$ are from the same basis as $|\psi\rangle$). This is now just an algebraic equation. The numbers $\langle x|i\rangle$ give the measure of each basis state you will find in $|x\rangle$, and this is given in terms of a linear superposition of basis amplitudes (C_i) that sum fine

20-1 Operators and operations

20-2 Average energies

20-3 The average energy of an atom

20-4 The position operator

20-5 The momentum operator

20-6 Angular momentum

20-7 The change of averages with time

$|\psi\rangle$ is each base state. The numbers a_1, a_2, \dots are just the coefficients which tell how much of $|\psi\rangle$ goes in each sum. The operator A is referred to as *mixed* by the set of numbers, or "coefficients".

$$A_{ij} = a_i \cdot A_j |\psi\rangle \quad (20.2)$$

So Eq. (20.2) is a slight class way of writing Eq. (20.3). Actually it is a little more than that: something more is implied. In Eq. (20.3) we did not make any reference to a set $\{j\}$; however, implicitly, all j is an image of Eq. (20.3) in terms of some set of base states. But if you know, you may take any set you want. And this idea is implied in Eq. (20.2). The operator way of writing avoids making any particular choice. Of course, when you want to specify, you have infinite sets. When you take your choice, you use Eq. (20.2). So the operator equation (20.3) is a more abstract way of writing the algebraic equation (20.3). It's similar to Fermi's way of *overwriting*.

$$c = a \propto b$$

instead of

$$c_1 = a_1 b_1 - a_2 b_2$$

$$c_2 = a_2 b_1 + a_1 b_2$$

$$c_3 = a_3 b_1 - a_4 b_2$$

The "new way" is much handier. The convenient results however, you will eventually have to give the components with respect to some set of bases. Similarly, if you want to be able to say what you really mean by A , you will have to be ready to give the matrix A_{ij} , i.e. basis of some set of base states. So long as you don't do it, most sensible. E.g., Eq. (20.2) may be just the same as Fig. (20.3). (You should remember also that *unless* you know a matrix for this particular set of base states you can always calculate the corresponding matrix that goes with any other basis. You can re-form the matrix from the "projection operator" in another.)

The operator version in (20.2) is to allow a new way of thinking. If we imagine some operator A , we can use it with any states $|\psi\rangle$ to create a new state $A|\psi\rangle$. Sometimes a "state" we get. It's won't be very familiar; it may not represent any physical situation we are likely to encounter in nature. (For instance, we may get a state that is not normalized to represent one electron.) In other words, we may at times get "states" that don't make much sense. Such artificial "states" may not be useful, perhaps to the point of being irrelevant.

We have already shown you many examples of quantum-mechanical operators. We have the rotation operator $R(\theta)$ which takes a state $|\psi\rangle$ and produces a new state, which is the old state as seen in a rotated coordinate system. We have had the parity operator P , which makes a new state by reversing x -coordinates. We have had the operators σ_x , σ_y , and σ_z for spin one-half particles.

The operator \hat{J}_z was defined in Sec. 17 as one of the rotation operators for small angles:

$$\hat{R}(\theta) = 1 + \frac{i}{\hbar} \int d\mathbf{r} J_z \quad (20.3)$$

In just minutes, of course, that

$$\hat{R}(\theta)|\psi\rangle = |\psi\rangle + \frac{i}{\hbar} \int d\mathbf{r} J_z |\psi\rangle \quad (20.4)$$

In this expression J_z is to be found the value you get from $\sin(\theta/\hbar)$ for the small angle θ and then subtract the original value. This represents a "state" $|\psi'\rangle$ which is the difference of two states.

One more example. We can an operator \hat{p}_x , called the momentum operator (one-component defined in an equation like (20.6)). In (20.6) is the operator which does

displace a state along \hat{q} by the distance b , then \hat{q} is defined by

$$\hat{q}|\psi\rangle = b|\psi\rangle + \frac{i}{\hbar}\hat{p}|\psi\rangle \quad (20.3)$$

where b is a real displacement. Displacing the state $|\psi\rangle$ along \hat{q} by a small amount b gives a new state $|\psi'\rangle$. We can say that the new state is obtained with plus a small kick:

$$\int_b^B V_{\hat{q}}(q) dq$$

For example we are talking about work on a state vector like $|\psi\rangle$, which is an abstract description of a physical situation. They are quite different from algebraic operators which work on mathematical functions. For instance, \hat{q} is an operator that works on $|\psi\rangle$ by changing it to a new function just $\hat{q}|\psi\rangle$. Another example is the momentum operator \hat{p}^2 . You can see that the same word is used in both cases, but you should keep in mind that the two kinds of operators are different. As a measurement operator others can work on an algebraic function, our on a state vector like $|\psi\rangle$. Both kinds of operators are used in quantum mechanics and one is in other kinds of equations. As you will see in the later chapters you are free to name the object it is well to be sure the definition always remains the same. Later on, when you are more familiar with the subject, you will find that it is less important to keep the distinction between the two kinds of operators. You will usually find that they both generally require some notation for both!

We'll go on now and look at some useful things you can do with operators. But first, one special chapter. Suppose we have a state $|\psi\rangle$ whose number in some basis $|\psi\rangle = a_1|\psi_1\rangle + a_2|\psi_2\rangle$. The amplitude for a state $|\psi\rangle$ to obtain some other state $|\phi\rangle$ is $a_1 \langle \psi_1 | \phi \rangle$. Is there some relation to the complex conjugate of this amplitude? You should be able to show that

$$a_1 \langle \psi_1 | \phi \rangle^* = \langle \psi_1 | \phi^\dagger | \psi \rangle \quad (20.4)$$

where \cdot^* (read "A dagger") is an operator whose matrix elements are

$$a_\phi = \langle \phi | \psi^* \rangle \quad (20.5)$$

To get the element $\langle \phi | \psi^* \rangle$ for any $|\phi\rangle$, elements of ψ^* are given and take its complex conjugate. This implies that the state $\hat{q}^\dagger |\psi\rangle$ is in $|\psi\rangle$ the complex conjugate of the amplitude $\langle \psi | \hat{q}^\dagger | \psi \rangle$. The operator \hat{q}^\dagger is called the "Hermitian adjoint" of \hat{q} . Many important operators of quantum mechanics have the special property that when you take the Hermitian adjoint, you get the same operator back. It's called an operator. I am

$$\hat{q}^\dagger = \hat{q}$$

and it is called a "self-adjoint" or "Hermitian" operator.

20.2 Average energies

So far we have learned how to calculate expectation values. Now we would like to calculate an average value. How would you find the average energy of a system—say, in atom i ? In atom i in a particular state of definite energy, and you measure the energy, you will find a certain energy E_i . If you keep repeat the measurement on each one of a whole series of atoms, if all atoms are in the same state, all the measurements will give E_i , and the "average" to your measurement will, of course, be E_i .

Now, however, what happens if you take the atom which is state $|\psi\rangle$ which is not a stationary state? Since the system does not have a definite energy, any measurement would give energy, the same measurement on another atom in the same state would give a different energy, and so on. What would you get for the average of a whole series of energy measurement results?

We can answer the question by projecting the wavefunction onto the set of states of definite energy. To remember that this is a special reason, we'll use the symbol $\langle \psi |$. Then if the state $|\psi\rangle$ has a definite energy E_1 , in the representation,

$$\langle \psi | = \sum_i C_i |\psi_i\rangle \quad (20.13)$$

When you make an energy measurement, and get some value E_1 , you have found that the system was in the state $|\psi_1\rangle$. But you may get a different number for next measurement. Sometimes you will get E_2 , sometimes E_3 , sometimes E_4 , and so on. Let's probability that you observe the energy E_i is just the probability of finding the system in the state $|\psi_i\rangle$, which is, of course, just the magnitude of the amplitude $C_i = \langle \psi_i | \psi \rangle$. The probability of finding each of the possible energies E_i is

$$P_i = |C_i|^2 \quad (20.14)$$

How are these probabilities related to the mean value of a whole sequence of energy measurements? Let's imagine that we get a series of energy reads like this: $E_1, E_2, E_3, \dots, E_N$. The E_i 's are $E_1, E_2, E_3, E_4, E_5, E_6, E_7, E_8, \dots, E_N$ and so on. We continue for, say, a thousand measurements. When we've finished we add all the energies and divide by one thousand. That's what we mean by the average. That's also called the expectation value of the number. You can count up how many times you get E_1 , say n_1 , in N , and then count n_2 the number of times you get E_2 , or n_3 the E_3 , and so on. The sum of all the energies is certainly just

$$n_1 E_1 + n_2 E_2 + n_3 E_3 + \dots + n_N E_N$$

The average energy is this sum divided by the total number of measurements which is just the sum of all the n_i 's, which we can call N :

$$\langle E \rangle = \frac{1}{N} \sum_i n_i E_i \quad (20.15)$$

We are almost there. When we replace the probability of something happening by just the number of times we expect it to happen divided by the total number of tries, the ratio n_i/N should, for large N , be very close to P_i , the probability of finding the state $|\psi_i\rangle$, although we'll never exactly P_i because of the statistical fluctuations. So it's very reasonable to replace probability by P_i and then we can say that

$$\langle E \rangle = \sum_i P_i E_i \quad (20.16)$$

The equals sign is being liberal, but that's what it means. The average value of a measured quantity A should be $\langle A \rangle$:

$$\langle A \rangle_A = \sum_i P_i A_i$$

where A_i are the various possible values of the measured quantity, and P_i is the probability of getting that value.

Let's go back to our question. Statistical state (by 1.3 average energy is

$$\langle E \rangle_E = \sum_i C_i^* E_i C_i = \sum_i C_i^* E_i C_i \quad (20.17)$$

Now since the identity $\langle \psi |$ is 1, we write the same:

$$\sum_i (C_i - \langle \psi |) C_i^* (\psi | - \langle \psi |) \quad (20.18)$$

Now we treat the left-hand $\langle \psi |$ as a constant "factor". We can then this factor out of the sum, and write it as

$$\langle \psi | \left[\sum_i (C_i - \langle \psi |) C_i^* (\psi | - \langle \psi |) \right] \psi \rangle$$

This expression has the form

$$|\psi\rangle = \sum_i c_i |i\rangle,$$

where $|i\rangle$ is some “number-up” state defined by

$$|i\rangle = \sum_j e^{iE_j t/\hbar} |j\rangle. \quad (20.16)$$

In fact, it’s otherwise, that’s why $\langle\psi|\psi\rangle$ if you expand two such states $|i\rangle$, it becomes $\langle i|i\rangle$.

Now remember what we know of the states $|i\rangle$. They are supposed to be **orthonormal** states—by which we mean that for each one

$$\delta(i,j) = \langle i|j\rangle.$$

Since δ_{ij} is just a number (an **integer**), this is equivalent to $\langle i|i\rangle = 1$, and the right in Eq. (20.16) is the same as

$$\sum_j e^{iE_j t/\hbar} |j\rangle |\psi\rangle.$$

Now compare this to the former combination and we’re led to $\langle\psi|\psi\rangle = \infty$.

$$\sum_i R(i,i) |\psi\rangle = R \sum_i c_i c_i |\psi\rangle = R |\psi\rangle.$$

Magic! Equation (20.16) is the same as

$$|\psi\rangle = R |\psi\rangle. \quad (20.17)$$

The average energy of the state $|\psi\rangle$ can be written very easily as

$$\langle E_{\text{av}} \rangle = \langle \psi | \hat{H} | \psi \rangle. \quad (20.18)$$

To get the average energy, you’d multiply $|\psi\rangle$ with \hat{H} , and then multiply by $\langle\psi|\hat{H}|\psi\rangle$. It should result

Our one formula for the average energy is not fully pretty. It’s also useful, because now we don’t need to say anything about the probabilities of two states. We don’t even have to know all of the possible energy levels. When we go to calculate, we’ll need to decompose our state in terms of states $|i\rangle$ of those states, but if we know the Hamiltonian matrix H_{ij} , for that we can use the average energy. Equation (20.18) says that for any set of basis states $|i\rangle$, the average energy can be calculated from

$$\langle E_{\text{av}} \rangle = \sum_i \delta_{ii} \langle \psi | H | \psi \rangle / \langle \psi | \psi \rangle, \quad (20.19)$$

where the components δ_{ii} ($i=0$) are just the elements of the matrix H_{ii} .

Let’s check this result. For the special case that the states $|i\rangle$ are the **atomic energy states**, for example, $H_{ii} = E_i \delta_{ii}$, or $\langle i|H|j\rangle = E_i \delta_{ij}$, and

$$\langle E_{\text{av}} \rangle = \sum_i \delta_{ii} \langle \psi | H | \psi \rangle / \langle \psi | \psi \rangle = \sum_i \delta_{ii} E_i \langle \psi | \psi \rangle,$$

which is right.

Equation (20.19) can, incidentally, be extended to other physical measurements which you can express as an operator. For instance, \hat{L}_z is the operator of the **z-component** of the **angular momentum** L . The average of the z-component for the state $|\psi\rangle$ is

$$\langle L_z \rangle_{\psi} = \langle \psi | \hat{L}_z | \psi \rangle.$$

One way to prove it is to think of some situation in which the energy is proportional to the angular momentum. Then all the arguments go through in the same way.

In summary, "if a physical observable A is related to a suitable quantum-mechanical operator \hat{A} , the average value of A for the state $|\psi\rangle$ is given by

$$\langle A \rangle_{\psi} = \langle \psi | \hat{A} | \psi \rangle. \quad (20.22)$$

This can be written as

$$A_{\psi} = \langle \psi | \hat{A} | \psi \rangle. \quad (20.23)$$

with

$$A_{\psi} = \langle \psi | \hat{A} | \psi \rangle. \quad (20.24)$$

20.3 The average energy of an atom

Suppose we want the average energy of an atom in a state described by a wave function $\psi(x)$. How do we find it? Let's first think of a one-dimensional situation with a state $|k\rangle$ defined by the amplitude or $|\psi\rangle = \psi(x)$. We are looking for the quantity $\langle \psi | \hat{H} | \psi \rangle$. This is applied to the momentum representation. Following our usual procedure, we replace the states $|\psi\rangle$ and $|\phi\rangle$ by $|\psi\rangle$ and $|\phi\rangle$, and change the sum to an integral. We get

$$\langle \psi | \hat{H} | \psi \rangle = \int \langle \psi | \psi(x) \hat{H} | \psi(x) \rangle dx. \quad (20.25)$$

This integral can, if we wish, be written in the following way:

$$\int \langle \psi | \psi(x) \hat{H} | \psi(x) \rangle dx, \quad (20.26)$$

with

$$\langle \psi | \psi \rangle = \int (\psi - \bar{\psi}) \psi^* dx. \quad (20.27)$$

The integral over ψ is nothing but the same one you had in Chapter 16—see Eq. (16.20) and Eq. (16.52)—and is equal to

$$-\frac{\hbar^2}{2m} \frac{d^2}{dx^2} \psi(x) = -\nabla^2 \psi(x).$$

We can therefore write

$$\langle \psi | \psi \rangle = \int \frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V(x) \psi(x) \psi^* dx. \quad (20.28)$$

Remember that $\langle \psi | \psi \rangle = \langle \psi | \psi^* \rangle = \psi^*(x)$; using this identity, the average energy in Eq. (20.27) can be written as

$$\langle \psi | \hat{H} | \psi \rangle = \int \psi^*(x) \left(-\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V(x) \right) \psi(x) dx. \quad (20.29)$$

Given a wave function $\psi(x)$, you can get the total energy by doing this integral. You can begin to see how we can go back and forth from the state vector $|\psi\rangle$ to the wave function $\psi(x)$.

The quantity in the braces of Eq. (20.27) is an *operator*†. We will write it as \hat{E}

$$\hat{E} = -\frac{\hbar^2}{2m} \frac{d^2}{dx^2} + V.$$

With the notation Eq. (20.24) becomes

$$\langle \psi | \hat{H} | \psi \rangle = \int \psi^*(x) \hat{E} \psi(x) dx. \quad (20.30)$$

The *classical* operator \hat{E} defined here is, of course, not identical to the quantum-mechanical operator \hat{H} . The new operator works on a function of position, $f(x) = \langle x | \psi \rangle$, to give a new function of x , $\hat{E}(x) = \langle x | \hat{E} | \psi \rangle$, while \hat{H}

† The “operator” \hat{E} is not “multiplied by $\psi(x)$ ”

dependence on ϕ , the scalar field. By doing so, we can state $\psi = \phi$, without mentioning the coordinate representation or any particular representation at all. Since \hat{A}^\dagger is the same as \hat{R} even in the coordinate representation, if we choose to work in the coordinate representation, we avoid inserting \hat{R} in terms of ϕ . Instead $\hat{\psi}^\dagger$, which depends on ϕ , can be written in terms of ψ and ϕ ; that is, we expect, according to Eq. (20.25), that $\hat{\psi}^\dagger$ as ψ is related to ϕ , the amplitude of ϕ at my position. On the other hand, notice that \hat{R} is a differential operator. We have already worked on, in Section 18.2, the connection between $(\hat{R}\psi)$ and the adjoint operator \hat{R}^\dagger .

We should make one qualification on our results. We have been assuming that the amplitude $\psi(x)$ — x is measured. As this is assumed, the wave has been chosen to be

$$\int \psi^*(x') dx' = 1$$

so the probability of finding the particle somewhere is unity. If you don't choose to work with a $\psi(x)$ which is not normalized, you should write

$$\langle \hat{R} \rangle_{\psi} = \frac{\int \psi^*(x) \hat{R} \psi(x)}{\int \psi^*(x) \psi(x)}, \quad (20.27)$$

It's the same thing.

Remember, however, in between Eq. (20.26) and Eq. (20.28), there are two ways of writing the successive \hat{R} -operator after you work with the ψ -representation. You can either use first form to the second wave royal, which is a local operator, where local operator is one which acts along!

$$\int \psi(x) \hat{R}(x') \psi(x') dx'$$

or in writing as it is in, where \hat{R} is a differential algebraic operator. There are, however, operators for which this is not true. For them you must work with the basic equations, i.e. (20.21) and (20.22).

You can easily extend the derivation to three dimensions. The result is just

$$\langle \hat{R} \rangle_{\psi} = \int d^3x \hat{R}(x) \psi(x), \quad (20.29)$$

and

$$\hat{R} = -\frac{\partial^2}{\partial x^2} Y^2 + V(x), \quad (20.30)$$

the wave function being ψ .

$$\int \psi^* \hat{R} \psi = 1 \quad (20.31)$$

The last equations can be extended to systems with several electrons in a fairly obvious way, but we won't bother to write down the results.

With Eq. (20.29) we can calculate the average energy of an atomic system even without knowing its energy levels. All we need is the wave function. It's an important idea. We'll tell you about a few interesting applications. Suppose you want to know the ground-state energy of some atom—say the helium atom, for instance. It's too hard to solve Schrödinger's equation for the wave function, because there are too many variables. Suppose, however, that you take a guess at the wave function—pick one function you like—and calculate the average energy. That is, you use Eq. (20.29)—generalize to three dimensions—to find what the average energy would be if the atom were really in the state described by this wave function. This energy will certainly be higher than the ground-state energy, which is the lowest

* We write $\psi(x)$ for the element of ψ at point x , but $\psi(x)$ is also the whole function $\psi(x)$ in x and t these coordinates.

possible energy the atom can have.) Now pick another function and calculate its average energy. If it is lower than your first choice you are getting closer to the true ground-state energy. If you keep on trying all sorts of different states you will be able to get lower and lower energies, which were closer and closer to the ground-state energy. If you're clever, you will try some functions which have a few adjustable parameters. When you calculate the energy it will be expressed in terms of these numbers. By varying the parameters to give the lowest enealile energy, you are trying out a whole range of functions of course. Eventually you will find that it is harder and harder to get lower energies and you will begin to suspect that you are finally close to the lowest possible energy. The parameters have been adusted in this way—not by solving a differential equation, but by making up a specific function with a lot of adjustable parameters which are eventually chosen to give the lowest possible value for the average energy.

20.4 The position operator

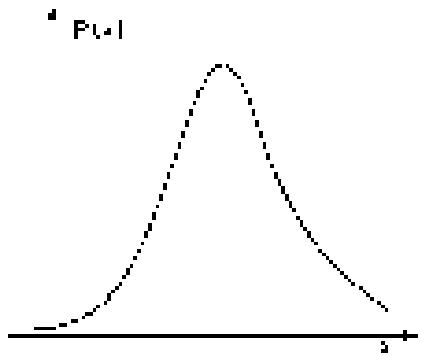

Fig. 20.1. A curve of probability density representing a localized particle

What's the average value of the position of an electron in an atom? For any particular state ψ what is the average value of the coordinate x ? Well it works in one dimension only if you extend the idea to three dimensions in 3D systems with more than one particle. We have a gauge quantum mechanics problem and we keep re-solving it over and over again. What is the average? It is

$$\int x P(x) dx,$$

where $P(x)$ is the probability of finding the electron in a little element dx . Suppose the probability density $P(x)$ looks like x as shown in Fig. 20.1. The electron is most likely to be found near the peak of the curve. The average value of x is also somewhere near the peak. It is, in fact, just the centre of gravity of the area under the curve.

We have seen earlier that $P(x) \propto |\psi(x)|^2$, $|\psi(x)|^2 = \psi^*(x)\psi(x)$, so we can write the average of x as

$$\langle x \rangle_{\psi} = \int x |\psi(x)|^2 dx \quad (20.31)$$

Our equation for $\langle x \rangle_{\psi}$ has the same form as Eq. (20.30). For the average energy, the energy operator lies somewhere between the identity operator and the position operator. (If you wish you can consider x to be the algebraic operator "imparted by x ".) We can carry the calculation still further, expressing the average position in a form which corresponds to Eq. (20.30). So suppose we are to write

$$\langle x \rangle_{\psi} = \langle \psi | x | \psi \rangle \quad (20.32)$$

with

$$|a\rangle = |x-a\rangle \quad (20.33)$$

and then see if we can find an operator A which generates the state $|a\rangle$, which will make Eq. (20.32) agree with Eq. (20.30). That is, we must find A such that

$$\langle x-a \rangle = \langle \psi | A | \psi \rangle = \int x - a |\psi(x)|^2 dx \quad (20.34)$$

First, let's expand ψ in its wave representation. It is

$$\psi |x\rangle = \int \psi(x) |x\rangle dx \quad (20.35)$$

Now compare the integrals in the last two equations. You see that in the wave representation

$$\langle x-a \rangle = \langle \psi | A | \psi \rangle \quad (20.36)$$

³ You may also look at it this way. Any function (that is, wavefunction) you choose can be written as a linear combination of the basis states which are definite energy levels. Since in this combination there is a mixture of independent states with the lowest energy states, the average energy will be higher than the ground-state energy.

Operating on $|\psi\rangle$ with \hat{x} to get $\langle\hat{x}\rangle$ is equivalent to multiplying $\psi(x) = \langle x|\psi\rangle$ by a factor of $\hat{x} = x|x\rangle$. We have a definition of \hat{x} in the coordinate representation:

[We have not bothered to try to get the x representation of the matrix of the operator \hat{x} . I leave it as an exercise you can try to show that]

$$\langle x' | \hat{x} | x \rangle = x' \delta(x - x') \quad (20.14)$$

You can then work out the coupling result that

$$\hat{x} |x\rangle = x |x\rangle \quad (20.15)$$

The operator \hat{x}^2 has the interesting property that when it works on the basis states $|x\rangle$, it is equivalent to multiplying by x^2 :

Do you want to know the average value of x^2 ? It is

$$\langle x^2 \rangle_{\psi} = \int x^2 \psi(x)^2 \delta(x) dx. \quad (20.16)$$

Or, if you prefer you can write

$$\langle x^2 \rangle_{\psi} = \langle \hat{x}^2 | \psi \rangle$$

where

$$|\hat{x}^2| = \hat{x}^2 |\psi\rangle. \quad (20.17)$$

By \hat{x}^2 we mean $\hat{x}\hat{x}$, the two operators are used one after the other. With the second form you can calculate $\langle x^2 \rangle_{\psi}$ using the representation (does anyone you what? If you want the average of x^n or of any polynomial in x , you can see how to get it).

20-5 The momentum operator

Now we would like to calculate the mean momentum of an electron again. We'll stick to one dimension – x . We might as well probability p (a measurement will give a momentum between p and $p + dp$). Then

$$\langle p_{\psi} \rangle = \int p F(p) d\psi. \quad (20.18)$$

Now we let $\langle p | \psi \rangle$ be the amplitude that the state $|\psi\rangle$ is in a definite momentum state $|p\rangle$. This is the same amplitude we called $\langle \text{pos} | p | \psi \rangle$ in Section 16.1 and is a function $\psi(p)$ just as $\langle x | \psi \rangle$ is a function of x . Let's go ahead to normalize the amplitude so that

$$F(p) = \sum_{\psi} \langle p | \psi \rangle^2. \quad (20.19)$$

We have then

$$\langle p | \psi \rangle = \left(\frac{1}{2\pi\hbar} \delta(p - k) \right) \frac{d\psi}{dk}. \quad (20.20)$$

This form is quite similar to what we had for $\langle x | \psi \rangle$.

If we want we can do exactly the same game we did with $\langle x | \psi \rangle$. First, we can write the integral above as

$$\int (p - k) \delta(p - k) \frac{d\psi}{dk}. \quad (20.21)$$

You should now recognize this equation as just the re-written form of the amplitude $\langle \psi | \psi \rangle$, expressed in terms of the new states of definite momentum. From Eq.

16.10 (in the notes we have that $\langle \psi | \psi \rangle = \langle \psi | \psi \rangle^*$). You see the "state ψ " has $\langle \psi |$, because the multiplier ψ is not in $\langle \psi | \psi \rangle$; it is a number which is different for each value of $|k\rangle$. It is not part of the construction of the state $|\psi\rangle$. See Eq. 16.10.

With the state $|\psi\rangle$ we define a ψ -representation by

$$\langle \psi | \phi \rangle = \phi_{\psi} |\psi\rangle \quad (20.47)$$

That is, we can now write

$$(\psi)_{\psi} = \langle \psi | \phi \rangle \quad (20.48)$$

$$\psi | \phi \rangle = \phi_{\psi} |\psi\rangle \quad (20.49)$$

Since the operator ϕ is defined in terms of the ψ -representation by Eq. (20.47),

Eq. (20.49) you can if you wish show that the matrix form of ϕ is

$$\langle \phi' | \phi | \phi \rangle = \phi' \phi^* \phi = \phi'^*, \quad (20.50)$$

and thus

$$\phi' \phi^* = \phi | \phi' \rangle. \quad (20.51)$$

It would not be smart to do this.

Now comes an interesting question. We can write ϕ_{ψ} , as we have done in Eqs. (20.48) and (20.49), and we know the meaning of the operator ϕ in the ψ -representation. But how specific are we about ϕ in the absolute representation? That is what we will need to know. One has some sort of function of ϕ , and we want to compute its average in quantum mechanics. Let's consider what we mean. I'll start by saying that $\langle \phi \rangle_{\psi}$ is given by Eq. (20.48), or in other words, it is equal to the expectation value of ϕ given in Eq. (20.49). If we are given the absolute value of the state $|\psi\rangle$ and the amplitude $\langle \psi | \phi \rangle$, which is an algebraic fraction of the momentum p , we can get $\langle \phi \rangle_{\psi}$ from Eq. (20.49) and proceed to evaluate the integral. The question is, what do we do if we are given a description of the state in the ψ -representation, namely the wave function $\psi(x) = \langle x | \psi \rangle$?

Well, let's start by expanding Eq. (20.48) in the ψ -representation. In a

$$\langle \psi | \phi \rangle = \int \phi(x) \psi(x) dx. \quad (20.52)$$

Now, however, we need to know what the state $|\psi\rangle$ is in the ψ -representation. If we can find it, we can carry out the integral. So our problem is to find the function ϕ_{ψ} of $x = p - \theta$.

We can find it in the following way. In Section 16-2 we saw how $\langle p | n \rangle$ was related to $\langle x | \phi \rangle$. According to Eq. (16-14),

$$\langle x | \phi \rangle = \int e^{-ipx/\hbar} \phi(x) | x \rangle dx. \quad (20.53)$$

If we know $\langle p | n \rangle$ we can use this equation for $\langle x | \phi \rangle$. Now we want, of course, to express ϕ_{ψ} in absolute form somehow in terms of $\langle x | \phi \rangle$, or $\langle x | \psi \rangle$, which we are given, and to do so we can. Start by writing Eq. (20.47) and then, using Eq. (1.6.24) to write it

$$\langle \psi | \phi \rangle = \langle \psi | \phi | x \rangle = \int e^{-ipx/\hbar} \phi(x) | x \rangle dx. \quad (20.54)$$

Since the integral is over x we can put the x outside the integral and write

$$\langle \psi | \phi \rangle = \int e^{-ipx/\hbar} \phi(x) | x \rangle dx. \quad (20.55)$$

Compare this with (20.53). You could say that ϕ is equal to $\phi(x)$. But that the wave function $\langle x | \phi \rangle = \phi(x)$ can depend only on x , not on y . That's the whole problem.

However, some ingenuity below discovered that the integral in (20.55) could be interpreted by parts. The derivative $d e^{-ipx/\hbar} / dx$ with respect to x is $-ip/\hbar e^{-ipx/\hbar}$, so the integral in (20.55) is equivalent to

$$= \frac{h}{i} \int_{-\infty}^{+\infty} \frac{d}{dx} (e^{-ipx/\hbar} \phi(x)) dx$$

If we integrate by parts we have since

$$= \frac{\hbar^2}{2} e^{-\imath kx^2} \psi(x) - \frac{\hbar}{i} \int e^{-\imath kx^2} \frac{\partial \psi}{\partial x} dx.$$

So if we consider a constant state $\psi = \psi_0$ with $\psi'(x)$ equal to zero, i.e. $\psi = \psi_0$, the derivative is zero and we have

$$\langle \psi_0 | \hat{H} \rangle = \frac{\hbar^2}{2} \int e^{-\imath kx^2} \frac{\partial \psi_0}{\partial x} dx. \quad (20.55)$$

Now compare this result with Eq. (20.54). You see that

$$\langle \psi_0 | \hat{H} \rangle = \frac{\hbar}{i} \frac{\partial}{\partial x} \langle \psi_0 | \hat{p} \rangle. \quad (20.56)$$

We have the necessary piece to be able to complete Eq. (20.52). The answer is

$$\langle \psi_0 | \hat{H} \rangle = \frac{1}{2} \langle \psi_0 | \hat{p} | \hat{p} \rangle + \frac{\hbar^2}{2} \int \psi_0(x) dx. \quad (20.57)$$

We have found that Eq. (20.57) looks like the coordinate representation.

Now we should begin to see a "natural" path to developing. When we account for the average energy of a state ψ we find it was

$$\langle \hat{E}_{\psi} \rangle = \langle \psi | \hat{E}_{\psi} | \psi \rangle \text{ with } \langle \hat{E}_{\psi} \rangle = \hat{p}^2 / 2m.$$

The same thing is written in the coordinates would be

$$\langle \hat{E}_{\psi} \rangle = \frac{1}{2} \langle \psi | \hat{p}^2 | \psi \rangle \text{ with } \langle \hat{p}^2 \rangle = \hat{p}^2 \langle \psi | \psi \rangle.$$

Here \hat{p}^2 is an algebraic operator which works as a function of x . When we take the average value of x , we found that it could also be written

$$\langle \hat{x}_{\psi} \rangle = \langle \psi | \hat{x}_{\psi} | \psi \rangle \text{ with } \langle \hat{x} \rangle = \hat{x} \langle \psi | \psi \rangle.$$

In the equivalent way the corresponding equation are

$$\langle \hat{x}_{\psi} \rangle = \int x^2 \langle \psi | \psi(x) \rangle dx \text{ with } \langle x \rangle = \langle \psi | \hat{x} | \psi \rangle.$$

When we looked about the average value of \hat{p} , we wrote

$$\langle \hat{p}_{\psi} \rangle = \langle \psi | \hat{p}_{\psi} | \psi \rangle \text{ with } \langle \hat{p} \rangle = \hat{p} \langle \psi | \psi \rangle.$$

In the coordinates words the equivalent equations were

$$\langle \hat{p}_{\psi} \rangle = \int p_{\psi}(x) \delta(x) dx \text{ with } \langle \hat{p}_{\psi} \rangle = \frac{\hbar}{i} \frac{d}{dx} \langle \psi | \psi \rangle.$$

In view of our first example we start with the state ψ and produce another (hyperoperator) with by a "coordinate-representation" operator. In the coordinate representation the generator has corresponding wave function by operating on the wave function $\psi(x)$ with an algebraic operator. There are the following approximate correspondences for one-dimensional problems:

$$\begin{aligned} \hat{H} &= \hat{p}^2 = -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2} = F(x), \\ x &\mapsto x, \\ \hat{p}_x &\mapsto \hat{p}_x = \frac{\hbar}{i} \frac{\partial}{\partial x}. \end{aligned} \quad (20.58)$$

Table 20.1

Physical Quantity	Operator	Coordinate Form
Position	\hat{r}	$\hat{r}_i = -\frac{\hbar^2}{2m} \nabla^2 + m\omega_i^2$
	\hat{x}	-
	\hat{y}	-
	\hat{z}	-
Momentum	\hat{p}_i	$\hat{p}_i = \frac{\hbar}{i} \frac{\partial}{\partial x_i}$
	\hat{p}_x	$\hat{p}_x = \frac{\hbar}{i} \frac{\partial}{\partial x}$
	\hat{p}_y	$\hat{p}_y = \frac{\hbar}{i} \frac{\partial}{\partial y}$

In this form our coordinate components are for the *general* space dimension, i.e.

$$\hat{p}_i = \frac{\hbar}{i} \frac{\partial}{\partial x_i}, \quad (20.30)$$

and we have inserted the x subscript i to remind you that we have been working only with the x -component of momentum.

You can readily extend the results to three dimensions. For the other components of the momentum,

$$\hat{p}_x = \hat{p}_i = \frac{\hbar}{i} \frac{\partial}{\partial x}$$

$$\hat{p}_y = \hat{p}_i = \frac{\hbar}{i} \frac{\partial}{\partial y}$$

If you want, you can even think of an operator of the *absolute* value and write

$$\hat{p} \rightarrow \hat{p} = \frac{\hbar}{i} \left(\hat{p}_x \frac{\partial}{\partial x} + \hat{p}_y \frac{\partial}{\partial y} + \hat{p}_z \frac{\partial}{\partial z} \right),$$

where \hat{p}_x, \hat{p}_y , and \hat{p}_z all work in the three dimensions. It looks a bit more elegant if we write

$$\hat{p} \rightarrow \hat{p} = \frac{\hbar}{i} \nabla. \quad (20.31)$$

Our general results for at least some spin-independent operators, *Cartesian coordinates*, are given by the operators in the coordinate representation. We summarize our results so far, extended to three dimensions, in Table 20.1. For each operator we list the corresponding formulae.

$$\hat{p}_i = \frac{\hbar}{i} \nabla_i \quad (20.32)$$

or

$$\hat{p}(r) = \hat{p}_i(r). \quad (20.33)$$

We will now give a few illustrations to the use of these ideas. The first one is just to point out the relation between \hat{p} and \hat{k} . If we use \hat{p} , we get

$$\hat{p}_i \hat{k}_i = -\hbar^2 \frac{\nabla^2}{m^2}.$$

In many books the same symbol is used for \hat{p} and \hat{k} , because they both stand for the same physical quantity, except it is convenient not to have to write different kinds of letters. You may usually find which one is intended by the context.

This means that we can write the equality

$$\hat{H} = \frac{1}{2m} \hat{p}_x^2 + \hat{p}_y^2 + \hat{p}_z^2 + V(r).$$

Or, using the vector notation,

$$\hat{H} = \frac{1}{2m} \hat{\vec{p}} \cdot \hat{\vec{p}} + V(r). \quad (20.64)$$

(It's an algebraic operator; any term without the operator symbol ($\hat{}$) means just a straight multiplication.) This equation is nice because it's easy to remember if you haven't forgotten your classical physics. Everyone knows that the energy is (approximately) just the kinetic energy $p^2/2m$ plus the potential energy, and \hat{H} is the operator of the total energy.

This result has impressed people so much that they try to teach students about classical physics before quantum mechanics. (We think differently.) But such parallels are often misleading. For one thing, when you have operators, the order of various factors is important; but that is not true for the factors in a classical equation.

In Chapter 17 we defined an operator A , in terms of the displacement operator δ , by [see Eq. (17.27)]

$$|\psi\rangle = A(x)|\phi\rangle = \left(1 + \frac{i}{\hbar} \Delta x\right)|\phi\rangle \quad (20.65)$$

where Δx is a small displacement. We should show you that this is equivalent to our new definition. According to what we have just worked out, this quantity should mean the same as

$$\delta(x) = \phi(x) + \frac{\partial \phi}{\partial x} x.$$

But the right-hand side is just the Taylor expansion of $\phi(x - \Delta x)$, which is certainly what you get if you displace the state to the left by Δx (or shift the coordinates to the right by the same amount). Our two definitions of δ agree!

Let's use this fact to show something else. Suppose we have a bunch of particles which we label 1, 2, 3, ..., in some complicated system. (To keep things simple we'll stick to one dimension.) The wave function describing the state is a function of all the coordinates x_1, x_2, x_3, \dots . We can write it as $\psi(x_1, x_2, x_3, \dots)$. Now displace the system (to the left) by Δ . The new wave function

$$\psi(x_1, x_2, x_3, \dots) = \psi(x_1 + \Delta, x_2 + \Delta, x_3 + \Delta, \dots)$$

can be written as

$$\begin{aligned} \psi(x_1, x_2, x_3, \dots) &= \phi(x_1, x_2, x_3, \dots) \\ &= \left[\phi \left(\frac{\partial \phi}{\partial x_1} + \frac{\partial \phi}{\partial x_2} + \frac{\partial \phi}{\partial x_3} + \dots \right) \right]. \end{aligned} \quad (20.66)$$

According to Eq. (20.64) the operator of the momentum of the state $|\psi\rangle$ (we call it the total momentum) is equal to

$$\hat{p}_{\text{total}} = \frac{1}{i} \left[\frac{\partial}{\partial x_1} + \frac{\partial}{\partial x_2} + \frac{\partial}{\partial x_3} + \dots \right].$$

But this is just the sum of

$$\hat{p}_{\text{total}} = \hat{p}_{x_1} + \hat{p}_{x_2} + \hat{p}_{x_3} + \dots. \quad (20.67)$$

The operation of momentum obey the rule that the total momentum is the sum of the momenta of all the parts. Everything hangs together nicely, and many of the things we have been saying are consistent with each other.

20-6 Antitheta notations

Let's go for fun back at another approach—the operator approach using $\hat{\theta}$ —momentum. In Chapter 1 we defined its operator $\hat{\theta}$ in terms of \hat{p} by the operator of a rotation by the angle θ around the \hat{x} -axis. We can also have a state ψ associated directly by a single wave function $\psi(\hat{x})$, which is a function of coordinate only, and does not have any reference to the fact that the electron may have its spin either up or down. That is, we want to be able to do apart from our \hat{x} -spin interpretation and think about only one orbital part. To keep the interpretation clear, we'll call the operator $\hat{\theta}$ and define it in terms of the rotation as a rotation by an infinitesimal angle $d\theta$ by

$$\hat{\theta}_x(\hat{x}, \psi) = \left(1 + \frac{i}{\hbar} \epsilon \hat{L}_x \right) \psi.$$

(Remember, this definition applies only to a state ψ which has no internal spin variables, but depends only on the coordinates $x = x_1, x_2, x_3$.) If we look at the state ψ' in a new coordinate system rotated about the \hat{x} -axis by the small angle ϵ , we have a new state

$$\psi' = \hat{\theta}_x(\hat{x}, \psi).$$

If we choose to describe the state ψ' in the coordinate representation, that is, by no wave function ψ' , we would expect to be able to write

$$\psi'(\hat{x}) = \left(1 + \frac{i}{\hbar} \epsilon \hat{L}_x \right) \psi(\hat{x}). \quad (20.65)$$

What is \hat{L}_x ? Well, again, that's a little bit of the old quantum mechanics assumed x_1 and p_1 , but we will drop the prime now formally as $x = x_1$ and $p = p_1$, so you can see in Eq. 20-2, since the strength for the electron to be at y is $S(y)$, denoted by the rotation of the coordinates we can write

$$P(x, y, z) = \delta(x + C_1 y - S_1 z) = \delta(x, y) = \delta\left(\frac{y}{S_1} - \epsilon \frac{\partial}{\partial x}\right)$$

(remembering C_1 is a constant). This means that

$$\hat{L}_x = \frac{\hbar}{i} \left(x \frac{\partial}{\partial y} - y \frac{\partial}{\partial x} \right). \quad (20.66)$$

That's not nice. But notice it is equivalent to

$$\hat{L}_x = \hat{p}_y + \epsilon \hat{p}_x. \quad (20.67)$$

Remembering our commutation relations, we can write

$$\hat{L}_x = \hat{p}_y - \epsilon \hat{p}_x. \quad (20.70)$$

This formula is easy to remember now, since it looks like the familiar form of classical mechanics; this is the x component of

$$\hat{L}_x = \hat{r} \times \hat{p}_x. \quad (20.71)$$

One of the two parts of this operator is the vector \hat{r} . They're equal, except they're not equal over the x -constant classical form. Which ones don't? There had better be some that don't come out right, because if everything p did, then there would be nothing different about quantum mechanics. There would be no new physics. Heisenberg's equation which is different. In classical physics

$$\hat{p}_x - \epsilon \hat{p}_x = 0,$$

What is the quantum mechanical?

$$\hat{p}_x - \epsilon \hat{p}_x = \hbar,$$

Let's work it out in the representation. So first we'll know what we are doing we just assume wave function $\psi(x)$. We have

$$i\partial_x \psi(x) = \hbar \omega \psi(x)$$

or

$$i \frac{\hbar}{\imath} \frac{\partial}{\partial x} \psi(x) = \frac{\hbar}{\imath} \frac{\partial}{\partial x} \psi(x)$$

Re-arrange now with the derivatives operator on everything to the right. We get

$$i \frac{\hbar}{\imath} \frac{\partial}{\partial x} + \frac{\hbar}{\imath} \psi(x) = i \frac{\hbar}{\imath} \frac{\partial \psi}{\partial x} = i \hbar \omega \psi(x) \quad (20.19)$$

The answer is now clear. The whole equation is equivalent simply to multiplication by $-i\hbar\omega$.

$$(i\hbar \omega - f(x)) \psi = -\frac{\hbar^2}{2m} \psi. \quad (20.20)$$

If Plank's constant were zero, the classical and quantum results would be the same, and there would be no quantum mechanics to be had!

Incidentally, if any two operators A and B , when taken together, act thus:

$$AB = BA$$

then we say that "the operators A and B commute." And an equation such as (20.20) is called a "commutation rule." You can see that the commutation rule for θ and φ is

$$\theta\varphi - \varphi\theta = 0.$$

There is another very important commutation rule that has to do with angular momenta. It is

$$L_x L_y = L_y L_x - i \hbar I_z. \quad (20.21)$$

You can get some practice with θ and φ up to me by proving it for yourself.

It is interesting to notice that operators which do not commute also occur in classical physics. We have all ready seen this when we have talked about rotation in space. If you rotate something, such as a horse, by 90° around x and then 90° around y , you get something different from rotating first by 90° around y and then by 90° around x . It is, in fact, just this property of space that is responsible for Eq. (20.21).

20.7 The change of strength with time

Now we want to show you something else. How an average changes with time. Suppose for the moment that we have an operator A , which does not itself have time in it in any obvious way. We have an operator like $\theta(x, t)$. (We exclude things like, say, the potential of some external potential the wave being varied with time, such as $V(x, t)$). Now suppose we take the average, in some time $\langle \cdot \rangle_t$, which is

$$\langle A \rangle_t = \langle \psi | \hat{A} | \psi \rangle_t. \quad (20.22)$$

How $\langle A \rangle_t$ depends on time? Why should it? One reason might be that the operator itself depends explicitly on time. For instance, if it had a time-dependent time-varying potential like $V(x, t)$. But even if the operator does not depend on t , say, for example, the operator $\hat{A} = \hat{x} + \hat{y}$, the time averaging may depend on time. Certainly the average position of a particle could be moving. How does such a motion come out of Eq. (20.22) if \hat{A} has no time dependence? Well, the state $|\psi\rangle$ might be changing with time. For nonstationary states we have often shown a time-dependence explicitly by writing a state as $|\chi(t)\rangle$. We want to show that the rate of change of $\langle A \rangle_t$ is given by a new operator we will call \dot{A} . Recall that \dot{A} is an operator, so that perhaps a dot over the A does not look clear to you,

the time-dependent \hat{A} , but we just a way of writing a new operator \tilde{A} which is defined by

$$\frac{d}{dt} \langle \hat{A} \rangle_{\psi_0} = \langle \hat{B} \cdot \tilde{A} \rangle_{\psi_0}. \quad (20.77)$$

Our problem is to find the operator \tilde{A} .

First, we know that the rate of change of a state is given by the Hamiltonian. Specifically,

$$i\hbar \frac{d}{dt} \langle \psi(t) \rangle = \hat{H} \langle \psi(t) \rangle. \quad (20.78)$$

This is just the direct way of writing our original definition of the “imposition”.

$$\frac{d}{dt} \frac{\partial C}{\partial t} = \sum_k H_k C_k. \quad (20.79)$$

If we take the complex conjugate of the equation, it is equivalent to

$$-i\hbar \frac{d}{dt} \langle \psi(t) \rangle^* = \langle \psi(t) | \hat{H} | \psi(t) \rangle. \quad (20.80)$$

Now, we will compare if we take the derivative $\langle \psi(t) | \hat{H} | \psi(t) \rangle$ instead of $\langle \hat{H} | \psi(t) \rangle$. Since $\langle \psi(t) | \hat{H} | \psi(t) \rangle$ depends on t , we have

$$\frac{d}{dt} \langle \hat{H} \rangle_{\psi_0} = \left(\frac{d}{dt} \langle \psi(t) | \right) \hat{H} \langle \psi(t) | + \langle \psi(t) | \hat{H} \left(\frac{d}{dt} \langle \psi(t) | \right). \quad (20.81)$$

Finally, using the two equations in (20.79) and (20.81) to replace the derivatives we get

$$\frac{d}{dt} \langle \hat{H} \rangle_{\psi_0} = \frac{i}{\hbar} \langle \psi(t) | \hat{H} | \psi(t) \rangle - \langle \psi(t) | \hat{H}' | \psi(t) \rangle.$$

This equation is the same as

$$\frac{d}{dt} \langle \hat{H} \rangle_{\psi_0} = \frac{i}{\hbar} \langle \psi(t) | \hat{H} \hat{A} - \hat{A} \hat{H} | \psi(t) \rangle.$$

Comparing this equation with Eq. (20.77), you see that

$$\hat{A} = \frac{i}{\hbar} (\hat{H} \hat{A} - \hat{A} \hat{H}). \quad (20.82)$$

This is an interesting observation, and it is true for any operator \hat{A} .

Technically, “the operator \hat{A} does not modify the time-dependent wavefunction ψ_0 ”

$$\hat{A} = \frac{i}{\hbar} (\hat{H} \hat{A} - \hat{A} \hat{H}) = \frac{d \hat{A}}{dt}. \quad (20.83)$$

Let us try out Eq. (20.83) on some example to see whether it really makes sense. For instance, what operator corresponds to \hat{x} ? We can find it:

$$\hat{x} = \frac{i}{\hbar} (\hat{H} \hat{x} - \hat{x} \hat{H}). \quad (20.84)$$

What is this? One way to do the work is to work it through in the coordinate representation using the algebraic approach to \hat{x} . In this approach, you’ll commutate \hat{x} :

$$\hat{x}\hat{x} - \hat{x}\hat{x} = \left[\frac{\hbar^2}{m} \frac{d^2}{dx^2} + V(x) \right] \hat{x} - \left[\frac{\hbar^2}{m} \frac{d^2}{dx^2} + V(x) \right] \hat{x}.$$

If you operate with this on any wave function $\psi(x)$ and work out all of the d/dx terms where you can, you’ll end up after a lot of work with

$$\frac{\hbar^2}{m} \frac{d\hat{x}^2}{dx^2}.$$

But C is just the unit cell

$$C = \frac{\hbar}{m} \partial_{\theta} \psi$$

so we find that

$$\partial_{\theta} \psi + p\theta = -i \frac{\hbar}{m} \partial_{\theta} \psi \quad (20.56)$$

or C61

$$\psi = \frac{A}{\theta}. \quad (20.57)$$

A priori result. It means that if the mean value of ω is changing with time (result of the center of gravity is not zero), the mean momentum divided by m , **Energy-like classical mechanics**

Another result. What's the rate of change of the average momentum of a system? Same goes. The operator is

$$\hat{A} = \frac{i}{\hbar} (\partial_{\theta} \psi - \partial_{\theta} \psi). \quad (20.57)$$

Again you can write it out in the x -representation. Remember that ψ becomes $A(x)$. And this means that you will be taking the derivative of the potential energy V (in Eq. 22)—but only in the second term. That means that it is the only term which does not vanish, and you find that

$$\hat{A}\hat{p} = \hat{p}\hat{A} = -i\hbar \frac{\partial V}{\partial x}$$

or C62

$$\hat{p} = -i\hbar \frac{\partial}{\partial x} \quad (20.58)$$

Again the classical result. The right-hand side is the one we have derived Newton's law! But remember: these are the laws of the **system** which give the **energy equations**. They do not determine what happens in detail inside ψ alone.

Quantum mechanics has the essential difference that ψ is not equal to ψ_0 . These differences will be the small quantum \hbar . But the whole world quantum dynamics or interference waves, and all, result from the fact that $\hat{p} \neq 0$: it is not equal zero.

The history of this idea is also interesting. Within a period of a few months in 1925, Heisenberg and Schrödinger independently found correct laws to describe atomic mechanics. Schrödinger invented the wave function ψ (that's how he called his equation). Heisenberg, on the other hand, found that ψ must be described by classical equations, except that $p\psi = \hat{p}\psi$ should be equal to $\hbar A$, which he could make happen by defining them in terms of classical lines of curves. In fact, Heisenberg was using the **matrix representation**, with its matrices. Both Heisenberg's matrix algebra and Schrödinger's differential equation explained the hydrogen atom. A few months later Schrödinger was able to show that the two theories were equivalent, as we have seen before. But the two different mathematical forms of quantum mechanics were discovered independently.

The Schrödinger Equation in a Classical Context: A Reviewer on Superconductivity

21-1 Schrödinger's equation in a magnetic field

This lecture is only by invitation. I would like to give one lecture in a semester or two to discuss it so that, if you're part of the course —the course—that it is not supposed to be a last minute effort to teach you something new. But, rather, I imagine that I'm giving a summary or research report on superconductivity, the advanced audience, to complete what have already been available in quantum mechanics. The main difference between a seminar and a regular lecture is that the seminar speaker does not carry out all the steps, he just suggests. He says, "If you do such and such, this is what comes out," instead of showing all of the details. So in this lecture I'll describe the ideas of the work along, but just give you the results of the computations. You won't see them, you're not supposed to understand everything immediately, but believe (here or now) that they would come out, if you went through the steps.

All right again, this is a subject I used to talk about — it's even a modern one, and will be a very necessary topic to give in a research seminar. My subject is the Schrödinger equation in a classical setting — the case of superconductivity.

Primarily the wave function which appears in the Schrödinger equation applies to only one or two particles. And the wave function itself is not something that has a classical meaning — unlike the electric field, or the vector potential, or things of that kind. The wave function for a single particle is a "field" in the sense that it is a function of position — but it does not generally have classical significance. Nevertheless, there are some situations in which a quantum mechanical wave function does have classical significance, and they are the ones I would like to talk about. The peculiar quantum-mechanical behavior of the fermion at small scale doesn't always itself follow a large scale except in a global way that it produces Newton's laws — the laws of the so-called classical mechanics. But there are certain situations in which the peculiarities of quantum mechanics can become in a "global" way on a large scale.

At low temperatures, when the energy of a system has been reduced very, very low, instead of a large number of states being involved, only a very, very small number of states near the ground state are involved. Under these conditions the quantum-mechanical character of that ground state can appear on a macroscopic scale. It is the purpose of this lecture to show a connection between quantum mechanics and large-scale effects — the rough derivation of the very familiar quantum-mechanical Meissner effect, for example, but a special situation in which quantum mechanics will produce its own characteristic effects on a large-scale "macroscopic" level.

I will begin by reminding you of some of the properties of the Schrödinger equation. I want to discuss the behavior of particles in a magnetic field using the Schrödinger equation, because the superconducting phenomena are involved with magnetic fields. An external magnetic field is described by a vector potential, and the problem is: what are the laws of quantum mechanics in a vector potential? The principle that describes the behavior of quantum mechanics in a vector potential is very simple: The amplitude that a particle goes from one place to another along a certain path when there is a field present is the same as the ampli-

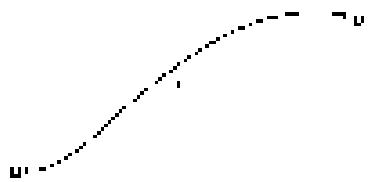

Fig. 21. The potential energy from (21.1) along the path from the origin to the point $r = R$.

more “trap-well” goes along the same route when there’s no field, multiplied by the magnitude of the line integral of the vector potential, i.e. the electric charge divided by Planck’s constant (see Chap. 11-12):

$$E_{\text{trap-well}} = \frac{q}{h} \cdot v_{\text{max}} \cdot \exp \left[\frac{q}{h} \int_{R_0}^R A \cdot dr \right]. \quad (2.11)$$

This is a short version of quantum mechanics.

Now without the vector potential the Schrödinger equation of a charged particle from classical mechanics is:

$$-\frac{\hbar^2}{2m} \nabla^2 \psi - qV = E_{\text{trap}} \left(\frac{1}{r} \cdot V \right) \left(\frac{\hbar^2}{m} \nabla^2 \psi \right) + qV. \quad (2.12)$$

Let us now include the potential V that goes to the infinite energy. Equation (21.1) is equivalent to the gradient term in a magnetized field the gradient of the Hamiltonian has reduced in value because it is a constant minus V , so that Eq. (21.12) becomes

$$\frac{\hbar^2}{m} \nabla^2 \psi = E_{\text{trap}} - \frac{q}{2m} \left(\frac{1}{r} \cdot V - qA \right) \left(\frac{\hbar^2}{m} \nabla^2 \psi + qV \right) + qV. \quad (2.13)$$

This is the Schrödinger equation for a particle moving in a constant magnetic field A , a problem we have not yet solved.

It is also not difficult to solve by analogy to a simple example in which (21.13) of classical mechanics is situation we have a limit of validity (the Schrödinger equation). We have a “resonance” — like an electron in an atom, but outside, in an “outer shell” where there is no binding force according to Eq. (21.12) if there is no vector potential (in the $\lambda = \infty$ case), i.e. the amplitude of current will be altered (so what it was before) by a factor exp $i\omega t$, the argument with $i\omega t$ times the wave number k integrated from zero to the res. Frequency ω will affect (Eq. 21.12). The effect is not at general depend on ω , so the amplitude to find the electron in the outer shell potential is called $C(\omega) = C_0$, the factor of change of that amplitude e is given by the following expression:

$$\begin{aligned} \frac{\partial}{\partial \omega} C(\omega) &= E_F C(\omega) - E_F e^{i\omega t} \exp(i\omega t) \psi = 0 \\ &= E_F e^{i\omega t} \exp(i\omega t) (\psi - e\psi) \end{aligned} \quad (2.14)$$

The two homogeneous. First, since wave energy E_F of the electron is fixed and E_F is constant, this gives the condition $C(\omega) = 0$. Next, there is the term $= E_F (e^{i\omega t} - 1)$ which is the amplitude for the electron to take unperturbed trajectory step from atom “ $n = 1$ ” to another $n = 1$. However, in a magnetized vector potential, the phase of the amplitude must be shifted according to the rule in Fig. 1.1.1. i.e. if the electron is moving clockwise in one atomic orbit, the magnetic field A turns the magnetic moment m by 180° . Since the electron is pumping back and forth, it is clear this phase shift $w = \pi$ must be given by the total phase. In the same manner there is certain amplitude to have jumps from the other side, but this time we need the vector potential at a distance $(k/2)$ to the outer wave function (because the wave k). That is exactly the reason $\Gamma = \pi \omega / \hbar$ is the capacity for the amplitude to be at $\omega = 0$ vector potential.

Now we know that in the function $C(\omega)$ growth and goes to the long wavelength limit, and if we set the mass get closer together, i.e. $\rightarrow 0$ (in approximation of classical mechanics) the solution will split. So the next step is to expand the values of (2.14) in powers of \hbar (assuming $\hbar \ll m \text{ cm}^{-1}$). For example, if $\hbar = 10^{-30}$ the right-hand side is $\sim (E_F - 10^3 E_F)(\psi)$ to the second approximation.

¹ Chapter 11, Section 13-5

By the horizon and with consideration of a free space itself

As the same argument, but was $\omega = \pi/4$ in the transition is taken away with no magnetic field, see Chapter 18.

the energy to $E_0 = \hbar\omega$. We remove the terms in \hat{p} for because the two exponentials have no more than odd even powers of $\hbar\hat{p}/m\omega$. So if you make a Taylor expansion of $C(x)$, of $C^*(x)$, and of the exponential's, and then collect the terms in $\hbar^2/m\omega^2$ you get

$$\begin{aligned} \frac{\hbar}{\hbar}\frac{dC(x)}{dx} &= E_C(x) - 2E_0/\omega \\ &= \hbar\omega^2(C^*(x) - 2p^2(x)C(x) - p^2(x)C^*(x) - f^2(x)C(x)). \end{aligned} \quad (21.5)$$

(The “ \hbar/\hbar ” here in differentiation with respect to x)

Now the final combination of terms looks quite complicated. But mathematically it is exactly the same as

$$-\frac{\hbar}{\hbar}\frac{dC(x)}{dx} = (E_0 - 2K(x)) - \hbar^2\left[\frac{\partial}{\partial x} - Q(x)\right]\left[\frac{\partial}{\partial x} + R(x)\right]C(x). \quad (21.6)$$

The second term operating on $C(x)$ gives $C'(x) + \hbar^2Q(x)C(x)$. The first bracket multiplying on these two terms give the $K''(x)$ term and terms in the last derivative of $f(x)$ and the first derivative of $C(x)$. Now remember, $C(x)$, the solutions to ψ , are magnetic so it represent a particle with an effect we have in a given b

$$E\psi = \frac{\hbar^2}{m}\psi.$$

If you then set $b_0 = -im\omega$, and put back $p(x) = ip/\hbar$, you can easily check that Eq.(21.6) is the same as the 2nd part of Eq.(21.3). (The origin of the potential energy term is well known, so I haven't bothered to include it in this discussion.) The propagation of ψ , or in fact non-relativistic quantum theory, all the symmetries by the exponential factor is the same as the rule that the momentum operator, ψ gets replaced by

$$\frac{\hbar}{\hbar}\psi = \psi,$$

as you see in the Schrödinger equation of (21.3).

21-1 The equation of continuity for probabilities

Now I turn to a second point. Another important part of the Schrödinger equation for a single particle is the idea that the probability to find the particle at a position is given by the absolute square of the wave function. It is also characteristic of the quantum mechanics that probability is conserved in a local sense. When the probability of finding the electron somewhere decreases, while the probability of the electron being elsewhere increases (keeping the total probability unchanged), something must be going on in between. In other words, the electron has a continuity in the sense that if the probability decreases at one place and builds up at another, there must be some kind of flow between. If you can't wall, for example, in this way, it will have an infinite add the probability will not be the same. So the conservation of probability there is not the empirical statement of the conservation law, just as the conservation of energy alone is not as deep and important as the local conservation of energy.⁴ If energy is dispersed into the same, how flow of energy to compensate. In the same way, we would like to find a “current” of probability such that if there is any change in the probability density (the probability of being found in a unit volume), it can be considered as coming from an inflow or an outflow due to some current. This current would be a wave which could be represented this way. On a coordinate would be the net probability per second and per unit area for a particle passes in the direction across a plane parallel to the $y-z$ plane. Positive x -axis is considered a positive flow, and passing in the opposite direction a negative flow.

⁴ Session 13.1.

⁵ Volume II, Section 27.1.

Is there such a current? Well, you know that the probability density $P(x,t)$ is given in terms of the wave function by

$$P(x,t) = \psi^*(x,t)\psi(x,t) \quad (21.2)$$

Is it according to theory a current J such that

$$\frac{\partial P}{\partial t} = -\nabla \cdot J \quad (21.3)$$

With the considerations of Eq. (21.2), I get two terms

$$\frac{\partial P}{\partial t} = \psi^* \frac{\partial \psi}{\partial t} + \psi \frac{\partial \psi^*}{\partial t}. \quad (21.4)$$

Now use the Schrödinger equation, Eq. (21.3); the ψ 's, and take the complex conjugate of it to get $\psi^*\psi^*$, and I get the following result. You get

$$\begin{aligned} \frac{\partial P}{\partial t} &= -\frac{i}{\hbar} \nabla \cdot \frac{1}{2m} \left(\frac{\hbar^2}{c} \nabla - i\epsilon \right) \cdot \left(\frac{c}{\hbar} \nabla - i\epsilon \right) \psi + c \exp \psi \\ &+ \frac{e}{2mc} \left(\frac{c}{\hbar} \nabla + i\epsilon \right) \cdot \left(\frac{\hbar^2}{c} \nabla + i\epsilon \right) \psi - c \exp \psi \end{aligned} \quad (21.5)$$

The potential ψ contains a lot of other stuff around in it. And it is the cut that makes it difficult indeed to express it as a perfect convergence. The whole equation is equivalent to

$$\frac{dP}{dt} = -\nabla \cdot \left[\frac{1}{2mc} \psi^* \left(\frac{\hbar^2}{c} \nabla + i\epsilon \right) \psi + e \left(-\frac{\hbar^2}{c} \nabla - i\epsilon \right) \psi^* \right]. \quad (21.6)$$

It is really not so cumbersome as it seems. It is a symmetrized combination of ψ^* times a certain operator on ψ , plus ψ^* times the complex conjugate operator on ψ . It is some quantity J as its own complex conjugate. In other words it reduces to a spin to be. The upper term has no importance this way. It is just the momentum operator \hbar measured. I could write the current in Eq. (21.6) as

$$J = \frac{1}{2} \left[\left\langle \hat{p} - \frac{e\mathbf{A}}{c} \right\rangle^* \psi + \psi^* \left\langle \hat{p} - \frac{e\mathbf{A}}{c} \right\rangle \psi \right] \quad (21.7)$$

There is then a current J whose components Eq. (21.5).

Equation (21.10) shows that the probability is conserved locally. If a particle disappears from one region it cannot appear in another without conserving probability between. Imagine that our disc region is surrounded by a closed surface for enough cut. But then is zero probability to find the electron at the surface. The total probability to find the electron somewhere within the surface is the volume integral of it. By applying the volume integral theorem the volume integral of the derivative of J is equal to the surface integral of J . If J is zero at the surface Eq. (21.10) says that J is zero, so the probability to find the particle incident along. Only if some of the probability approaches the boundary can come out from it. We can say that it only goes out by passing through the surface and that is local conservation.

21-3. Two kinds of momentum

The equation for the current is rather interesting, and sometimes causes a certain amount of worry. You would think the current would be something like the density of particles times the velocity. The density should be something like $\psi\psi^*$, which is not. Another use in Eq. (21.10) calls for the typical formula the average value of the operator

$$\langle \hat{p} \rangle = \frac{1}{it} \langle \psi | \hat{p} | \psi \rangle. \quad (21.8)$$

So maybe we should think of it as an identity of time. In other words, though we don't have a suggestion for addition of velocity to momentum, because we would also think that momenta are divided by mass, \vec{p}_m , should be a velocity. The two probabilities given by the source potential:

1. It happens that these two possibly true were also discovered in classical physics, even if it was found that momentum could be defined in two ways. One of the is called "kinetic momentum," and the other is called "inertial." Well in this case it is the "inertial momentum." This is the momentum obtained by multiplying mass by velocity. The other is a more fundamental, more abstract momentum, which goes called the "dynamical momentum," which I'll call "p-momentum." The two possibilities are:

$$p_{\text{momentum}} = m v \quad (21.14)$$

$$p_{\text{inertial}} = mv - qA. \quad (21.15)$$

In quantum theory, it is again an identity with magnetic field \vec{B} with parameter q , which is connected to the greatest operator \hat{p} , so it follows that (21.14) is the operator of \vec{v} -velocity.

I'd like to make a brief digression. To show you what this is all about, whether there must be something like Eq. (21.15) in the quantum mechanics. The wave function changes with time according to the Schrödinger equation ... Eq. (21.7). If I would suddenly change the vector potential, the wave function wouldn't change in the first instance only because of changing energy. Now think of what would happen in the following circumstance. Suppose I have a long solenoid, of which I can produce a flux of magnetic field parallel to itself, as shown in Fig. 21-2. And then I change \vec{B} by suddenly turning it off. Suppose this flux nearly instantaneously goes from something ... I start with zero and suddenly, and then I turn off a vector potential. This means that I produce suddenly a discontinuity in \vec{A} . You remember that the line integral of \vec{A} around a loop is the same as the flux of \vec{B} through the loop.¹ Now what happens? I will only turn on a vector potential. According to the quantum mechanical equation the sudden change of \vec{A} does not cause a sudden change of \vec{p} , the wave function is still the same. So the packet is always unchanged.

But remember what happens electrically when I suddenly turn off a flux. During the short time that the flux is going, there's an electric field generated whose line integral is the rate of change of the flux with time:

$$\vec{E} = -\frac{\partial \vec{A}}{\partial t}. \quad (21.16)$$

That electric field is continuous. The flux is changing rapidly, and it gives a finite \vec{E} to the particle. The \vec{E} here is the change from the electric field and suddenly we could up of course not permit \vec{E} to be a real variable. Just as \vec{A} changes it might well be \vec{qA} . In other words, if you suddenly turn off a vector potential at a charge, its charge immediately picks up an "old" momentum equal to $-q\vec{A}$, but there is something that isn't changing immediately and that's the difference between \vec{p} and \vec{qA} . And so the only $\vec{p} = m\vec{v} + q\vec{A}$ concerning which is not changed when you make a sudden change in the vector potential. This $q\vec{A}$ is what we have called the "p-momentum" and is of importance in classical mechanics and the theory of dynamics, but it is an important significance in quantum mechanics. It depends on the character of the wave function, and it is the one to be identified with the equation:

$$\phi = \frac{h}{i} \nabla$$

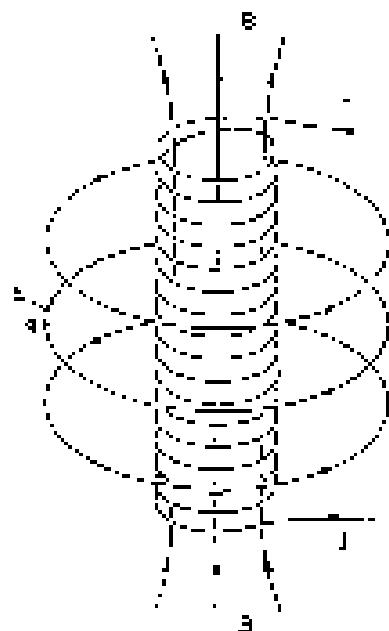

Fig. 21-2. The electric field caused by a sudden cut or increasing current.

¹ See for example, L. D. Landau and E. M. Lifshitz, *Electrodynamics, Part 1*, Pergamon Press, New York (1962), p. 181.

² Volume II, Chapter 11, Sections 11-1.

21-4 The meaning of the wave functions

When Schrödinger first discovered his equation he discovered the conservation law of $\nabla \cdot \mathbf{J}$, or, as a consequence of his equation, that he imagined necessarily that \mathbf{P} was the electric charge density of the electron and that J was the electric current density, so that though \mathbf{J} is an electromagnetic current, electromagnetism felt charges like currents. When he solved his equations for the hydrogen atom and calculated ψ , he didn't calculate the probability of finding the wave in a particular location, but from the interpretation he was completely confident. The charge density was stationary but there were magnetic moments; the charges P and currents J would switch off at electrostatical fields and the atom would radiate light. He even found, making a number of assumptions that, if this work was quite right, it was at this point too, that much more important contributions to our ideas regarding quantum mechanics. It was shown that one could go far as to know interpreted the ψ 's of Schrödinger's equations in terms of a probability amplitude—that very difficult idea is, the square of the amplitude is not the charge density, but is only the probability per unit volume of finding an electron there, and that when you divided the electron over a place the charge density is $\rho = \int \psi^2 d\tau$, where $d\tau$ is due to \mathbf{r} .

The wave function $\psi(r)$ for an electron in an atom does not, can, describe a particle—but what does it? a stationary charge density. The electron is either here or there or somewhere else, but whatever it is, it is a point charge. On the other hand, think of a situation in which there are an enormous number of particles in exactly the same state, a very large number of them will occupy the same wave function. That means that if the ψ is here and one of them is there, and the probability ρ of finding one out of them at a given place is proportional to $|\psi|^2$.

Or since there are so many particles, if it flows in any volume $d\tau$ object, we generally find a number close to zero density. So is a situation in which in the wave function for each of the enormous number of ψ 's there which is called the same state, ρ may be interpreted as the density of particles. If, under these circumstances, each particle carries the same charge, we can, in fact, go further and interpret ρ as the density of electrons. Naturally, ρ is over the dimensions of a probability density, so that it should be multiplied by $d\tau$ to give the intensities of a charge density. For our present purposes we can ignore the normal factor $1/\sqrt{d\tau}$ and take ρ as the electron charge density. With this understanding, J (the current of probability) has calculated becomes exactly the electric current density.

So in the situation in which you can have very many particles in exactly the same state, there is possible a new physical interpretation of the wave functions. The charge density and the electric current can be calculated directly from the wave functions and the wave function can take on a physical meaning which includes classical, macroscopic situations.

Something similar can happen with photons. When we have the wave function of a single photon, it is the amplitude to find a photon somewhere although we haven't ever seen it there, there is an equivalent for the theory wave function corresponding to the Schrödinger equation for the electron. The photon equation is just the same as Maxwell's equations for the electromagnetic field, and the wave function is the same as the scalar potential A . The wave function must be ψ (just the vector potential). The quantum physics in the wave theory is the classical physics because photons are noninteracting mass particles and many of them can be in the same state, as you know. They also can be in the same state. The comment that you have photons in the same state is that in the one electromagnetic theory, you can move in the wave function, which is the scalar potential, directly. Of course, it worked historically the other way. The first calculations were made directly with an amplitude in the same state, in fact associated to it either the current or the force for a single photon by comparing directly with observations on a macroscopic level the square of the wave function.

Now the picture with the electron is that you cannot pull time the ψ in the same state. Therefore, it was long believed that the wave function of the

Schrodinger equation, would never have a true one-particle approach for anything more microscopic than a hydrogen atom. The microscopic representation of the amplitude for atoms. On the other hand, it is now realized that the **standard** of superconductivity refers to a **one-particle** theory.

21-5 Superconductivity

As you know, we ordinary metals become superconducting below a certain temperature, the superconduc^ttive temperature is different for different metals. Some years ago the lowest temperature at which any metal becomes electrically without any resistance. This phenomenon has been observed for a very large number of metals but not for all of them. The reason for its absence has caused a great deal of difficulty. I used to try to understand what was going on in the crystal structure, and I will only describe enough of it for the present purpose. It has a fault due to the irregularities of the arrangement with the vibrations of the atoms in the lattice, here is a small net vibration even between the electrons. They ought to hold the electrons held together, if they speak very curiously and suddenly, bound pairs.

Now you know that a single electron is a Fermi particle. This is the first pair weak, not as a three-particle, because two electrons have paired charge, because it is twice "unpaired," and the mass is only slightly increasing, 4 parts to three per MeV .

The energy of pairing—that is, the attraction energy—is very, very weak. Only at low temperatures is needed to allow the electrons split by thermal agitation, and remain bound back to "unpair" electrons. But when you take the temperature sufficiently low, but they have to be in very regular get into the same very weak state; even may be called in pairs.

I don't wish you to imagine that the pairs are always held together very closely like a point pair etc. As a matter of fact, one of the most difficult problems in understanding the phenomena originally was that there is no one single pair. The two electrons which form the pair can easily spread over a considerable distance, and their relative velocity, which is directly smaller than the size of a μm , several pairs are occupying the same space at the same time. That's why electrons in a metal form pairs and in forming of the energy given up to binding can have been a problem of recent times. This problem, which is the theory of superconductivity was first explained by the class of Bardeen, Cooper and Schrieffer. There is an interesting historical note with every known pair, the idea that the electrons do, in some manner or other, were in place, then we can think of these pairs as being more or less like molecules and that's where we find talk about the wave function for a pair.

Now the Schrodinger equation for the wave function looks like (21.1). There will be one difference in the way the charge of the electron. Also, we don't know the wave—*i.e.* effective mass—for the Co in the solid lattice, so we don't know what number to put in front. We should see that this is going to be very high frequency, for a or something like, to be exactly right. Since the single energy that corresponds to very rapidly varying wave functions that is to say, to break up the pair, at high temperatures, there are always a few pairs which are broken up according to the usual Boltzmann theory. The probability that a pair is broken is proportional to $e^{-E_{\text{Co}}/kT}$. The electrons will be not bound in pairs and other "normal" electrons and will move around in the crystal in the ordinary way. I will, however, want to end my discussion at essentially zero temperature. At any low enough energy of the compass one pair will be broken by these electrons which are not in pairs.

* First discovered by Onnes in 1911. H. K. Onnes, Comm. Roy. Lab., Leiden, Proc. Kon. Akad. Wet. (Amsterdam), Vol. 45, p. 731 (1911). You will find a more detailed discussion of the subject in E. A. Lee, *Superconductivity*, John Wiley and Sons, Inc., New York, 1967.

¹ J. R. Allen, L. M. Cooper, and J. R. Schrieffer, Phys. Rev. 108, 1125 (1957).

Since electrons go in one direction, when there are a lot of them, they will want there is an especially large amplitude for other paths to go in the same direction. So nearly all of the paths will be locked down at the lowest energy, in which the wave function won't be easy to get away from the other paths. That's more angle to go into the same path than it was, quantified also by the Fermi factor, which reflects on the oscillatory nature of the lowest state. So we would expect all the paths to be moving in the same way.

What does this mean for the very last term, $\langle \psi | \hat{p} | \psi \rangle$, the wave function of a particle in the lowest energy state. However, since \hat{p} is going to be proportional to the charge density ρ , I can just as well write $\langle \psi | \hat{p} | \psi \rangle$ as the current density of the superconductor times some physical factor:

$$\langle \psi | \hat{p} | \psi \rangle = \rho \langle \psi | \hat{v} | \psi \rangle^2, \quad (21.17)$$

where ρ and \hat{v} are real functions of x . They complex functions, of course, so we'll do this work. It's clear what we mean when we talk about the charge density, but what is the physical meaning of the product of the wave function? Well, let's see what happens if we substitute $\langle \psi | \hat{v} | \psi \rangle$ Eq. (21.12), and express the current density in terms of basic variables v and A . It's just a lot of numbers and I won't go through it—the algebra, but it's nontrivial.

$$J = -\frac{\hbar}{m} \left(v_3 - \frac{e}{c} A_3 \right) \rho. \quad (21.18)$$

Since both the current density and the charge density have a direct physical meaning, it's the source due to the motion speed both ρ and \hat{v} are real things. The phase is just ignored because it is a phase of the current density J . The situation probably not observable, until the greatest of the phases known everywhere, the phase is known except, for a constant. And can define the phase of the particle, and then its phase contribution is definitely.

Incidentally, the expression for the current has an analytical form, since, when you do it, the current density J is in fact the charge density times the velocity. Current of the fluid of electrons, in fact. Equation (21.17) is then equivalent to

$$J\rho = \rho \hat{v} \hat{v} - \hat{v} \rho. \quad (21.19)$$

Notice that there are two pieces in the current density, one from \hat{v} and one from the vector potential, and the other is coming from from the behavior of the wave function. In other words, the quantity \hat{v} is just what we need to take into account.

21-6 The Meissner effect

Now we can state the sense of the phenomena of superconductivity. First, there is no electrical resistance. There's no resistance because all the electrons are collectively in the same state. In the ordinary flow of current you break one electron or the other out of the regular system, gradually deteriorating the general momentum. But how to get out electrical energy from what is the other is stable is very hard because of the tendency of all these particles to stay in the same state. A current, unfortunately, you always going forward.

It's also easy to understand that if you have a piece of metal in the superconducting state and then put a magnetic field which isn't too strong (We won't go into the details of how strong), the magnetic field can't penetrate the metal. If as you built up the magnetic field, any of it were to build up inside the metal, there would be a flow of charge of flux which would produce an electric field, and unless the field would immediately generate a current itself, by Faraday's law, would oppose the flux. Since all the electrons will move together, and this current also the field will generate enough current to oppose completely any applied magnetic field. So if you turn the field on after you've cooled a metal to the superconducting state, it will be excluded.

Electromagnetic screening is a related phenomenon discussed experimentally by Meissner.⁸ If you heat a piece of the metal to a high temperature so that it is a normal conductor and establish a magnetic field through it, and then you lower the temperature below the critical temperature (below the metal's transition temperature), the field is expelled. In other words, it stores up its own energy—and if you heat it up again until it just reaches the transition, the field exits.

We can see the reason for this in the equations and I'd like to explain how. Suppose that we take a piece of superconducting material which is at zero temperature. Then in a steady situation there would be divergence of the current must be zero because there's no place for it to go. It is easier to do this in terms of the divergence of the electric current. I should explain why choosing the current over charge density makes any loss of generality but I don't want to take the time. Taking the divergence of Eq. (21.28), then gives that the divergence of \mathbf{J} is equal to zero. This is correct. What about the variation of μ^2 ? If you consider a superconductor, there is a regular limit of zero for charge density due to the cosmic law of the force. If the charge density ρ is uniform there is no net electric field in the metal. If there would be an accumulation of charge in one region, the charge wouldn't be free to move and there would have to be negative polarization charge density $\pm \delta$. So in reality it turns out the charge density of the electrons in the superconductor is almost perfectly uniform. I can take $\rho = \text{constant}$. Now the \mathbf{J} is very likely to be zero everywhere. So if one lump of metal is far from another, then \mathbf{J} is zero there. And that means that there is no contribution to J from μ non-uniform. Equation (21.28) then says that no current is generated at point A . So everywhere in a lump of superconducting material the current is necessarily zero; that's in the same potential.

$$J = -\rho \frac{\partial}{\partial r} A. \quad (21.29)$$

Since ρ and dA/dr (in some meaningful sense) are constant, then J is zero again. — (from another) that

$$J = \text{some constant}. \quad (21.30)$$

This equation was originally proposed by London and London⁹ to explain the experimental observations of superconductivity. (See before the quantum-mechanical origin of the effect, see introduction.)

Now we can use Eq. (21.29) in the equations of electromagnetism to solve for the fields. The vector potential is related to the current density by

$$\nabla^2 A + \frac{1}{c^2 \epsilon_0} J = 0. \quad (21.29)$$

If I use Eq. (21.29) for J , then

$$\nabla^2 A = \frac{1}{c^2 \epsilon_0} J. \quad (21.29)$$

where J^2 is just a new constant,

$$J^2 = \rho \frac{q^2}{m_e c^2}. \quad (21.29)$$

We can try to solve this equation for A and see what happens. I do. For example, in the situation Eq. (21.29) has constant, but $c^2 \epsilon_0$ times, of the form $e^{-r/a}$ and $a \ll \lambda$. These solutions mean that the vector potential must decrease exponentially as you go from the surface into the material. (It can't increase

⁸ W. Meissner and R. Ochsenfeld, Naturwiss. 20, 261 (1933).

⁹ H. London and F. London, Proc. Roy. Soc. (London) A149, 1 (1934); Physica 2, 341 (1935).

Actually if the electric field were too strong, plus would be broken up and the "fermion" electron is created to reduce it to help stabilize any excess of positive charge still in there trying to make the system more stable. So the plus point is that a nearly uniform density is rapidly turned non-uniformly.

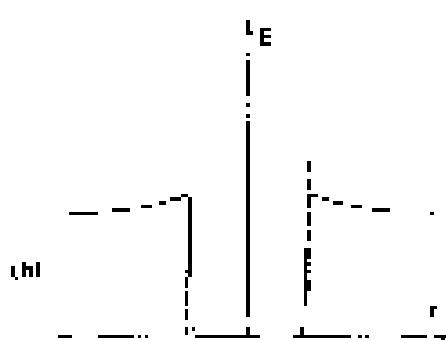

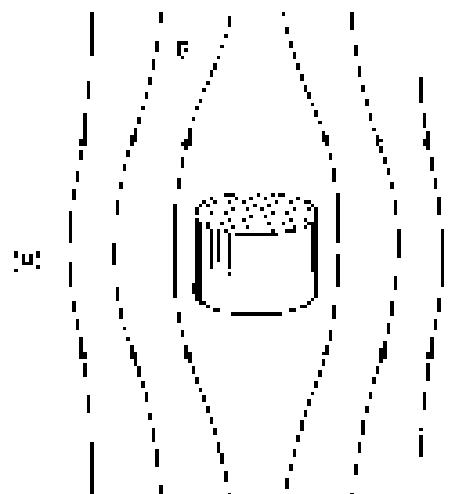

Fig. 21-2(a) (left) A superconducting cylindrical ring (noted in Fig. 21-1b), the resistance $R = 0$. (Right) A sketch of it.

resistance there would be a flow and if the Alice current is very large or equal to 1.5, the field only penetrates about 1/3 of the surface, leaving about 2/3 of the ring free of field, as sketched in Fig. 21-3. This is the explanation of the Meissner effect.

How big is the distance a^2 ? Well, remember that $\mu_0 I$, the total magnetic current in the ring, $1.3 \times 10^{-13} \text{ A}$, is given by

$$\mu_0 I = \frac{q^2}{4\pi R^2},$$

Also, remember that q in Eq. (21-24) is twice the charge on an electron, so

$$\frac{q}{2eR^2} = \frac{\mu_0 I}{4\pi},$$

which gives qR^2 , where R is the radius of the ring, in cm. So we have

$$R^2 = \frac{q^2}{8\pi\mu_0 I}, \quad (21-25)$$

For a small radius like 1 cm about $3 \times 10^{22} \text{ e}$, a current of 1.3 A and a ring with only one wound-on turn, R^2 would be about $7 \times 10^{-10} \text{ cm}^2$. This gives you the order of magnitude.

21-7 Flux quantization

The Faraday equation (21-9) is not enough to account for the anomalies of superconductivity including the Meissner effect. In recent years, however, there have been some extremely accurate predictions. One prediction made by London was so peculiar that nobody paid much attention to it until recently with new experiments. This time instead of taking a single turn, imagine we take a few turns of thickness Δz centered to the ring. Let's start with the simplest of all cases with a magnetic field B and the ring then turned so the external magnetic field is parallel to the axis of the ring. A sketch of this configuration of space is sketched in Fig. 21-4. Once again I say there will be a field in the body of the ring as indicated in part (a) of the figure. When the ring is made superconducting, the field is forced outside of the ring, as we have just seen. There will then be some flux through the body of the ring as shown in part (b). If the external field is now removed, the lines of field going through the ring are "trapped" as shown in part (c). The flux Φ through the center can't decrease because $\partial\Phi/\partial t$ has to equal to the $\partial\phi/\partial t$ integral of E around the ring which is zero in a superconductor. As the external field is removed the permanent flux is flowing through the ring to keep the flux through the ring a constant. This the old south-pole idea, it is with a twist! These currents will, however, all flow near the surface in concentric layers caused by the result of Ohm's law that I made for the static field: these currents can trap the magnetic field out of the body of the ring and part of the permanently trapped magnetic field as well.

Now, however, the ϕ is not constant in B since, and the equations involve a surprising effect. The argument is based on the fact that $\mu_0 I$ is constant in a disk with a current going around it you can see from the following argument.

Well inside the body of the ring the current density J is zero. As Eq. (21-18) gives

$$\nabla \cdot \mathbf{B} = \mu_0 J. \quad (21-26)$$

Now consider what we get if we take the line integral of \mathbf{B} around a circle C , which goes around the ring but the center of its cross-section so that it does not cross the surface, as shown in Fig. 21-5. From Eq. (21-26),

$$\oint_C \nabla \cdot \mathbf{B} d\ell = \oint_C \mu_0 J d\ell. \quad (21-27)$$

Now you know that the line integral of \mathbf{A} around any loop is equal to the flux of \mathbf{B} through the loop:

$$\oint \mathbf{A} \cdot d\mathbf{l} = \Phi.$$

Equation (21.27) now becomes

$$\oint \nabla \psi \cdot d\mathbf{l} = \oint \mathbf{A} \cdot d\mathbf{l}. \quad (21.28)$$

The line integral of a gradient from one point to another goes from point 1 to point 2 is the difference of the values of the function at the two points. Namely,

$$\int_{l_1}^{l_2} \nabla \psi \cdot dl = \psi_2 - \psi_1.$$

If we let the two end points l_1 and l_2 come together to make a closed loop you might first think that Φ would equal $\psi_1 - \psi_1$, so that the integral in Eq. (21.28) would be zero. That would be true for a closed loop in a single-connected piece of superconductor, but it is *not* necessarily true for a ring-shaped piece. The only physical measure that we can make is Φ . There can be only one value of the flux function for each point. What has happened is you have closed the ring when you just have at the starting point the ψ you get must give the same value for the new function

$$\psi = \sqrt{\Phi^2}.$$

This will happen if Φ changes by $2\pi n$, where n is any integer. So if we make one complete turn around the ring the left hand side of Eq. (21.27) must be $n \cdot 2\pi n$. Using Eq. (21.28) this gives that

$$2\pi n = \Phi. \quad (21.29)$$

The magnetic flux always has to change like $2\pi n/\psi$. If you would think of the ring as a classical object with an identity persist (that is, "lived") consistently, you would think that whatever flux was actually found through it would just stay there—any amount of flux at all could be trapped. But the quantum-mechanical theory of superconductivity says that the flux can be zero, or $2\pi/4\pi\hbar/e$, or $4\pi/4\pi\hbar/e$, or $6\pi/4\pi\hbar/e$, and so on, but no value in between. It must be a multiple of a basic quantum-mechanical unit.

London¹² postulated that the flux through a superconductor during a gap would be quantized and said that the possible values of the flux would be given by Eq. (21.29) with Φ equal to the electronic charge. According to London the basic unit of flux should be $2\pi/4\pi\hbar/e$, which is about 1.8×10^{-16} gauss \cdot cm². It should be just a flux, think of a tiny cylinder with a миллиметров diameter, the magnetic field inside it when it carries the amount of flux without any penetration of the coil's magnetic field. It should be possible to observe such a flux by a sensitive magnetometer measurement.

In 1931 such a specimen flux was looked for and found by Deaver and Fairbank¹³ at Stanford University and at about the same time by Dau and Schäfer¹⁴ in Germany.

In the experiment of Deaver and Fairbank, a tiny cylinder of superconductor was made by glistering a thin layer of tin on a one-centimeter length of No. 50 (1.3 \times 10⁻³ cm diameter) copper wire—the tin remains superconducting below 3.87K, while the copper remains a normal metal. The wire was bent in a small cylindrical magnetic field, and the temperature reduced until the tin became superconducting. Then the external source of field was removed. You would

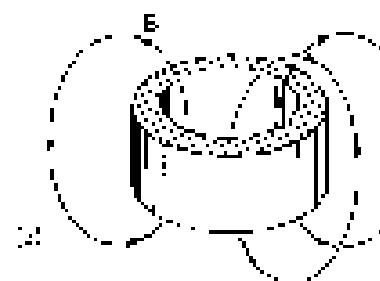

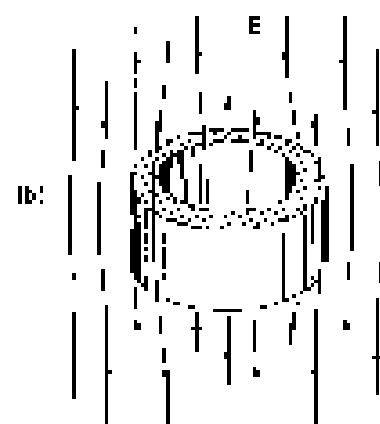

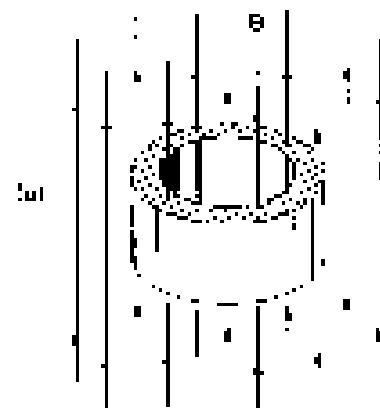

Fig. 21.4. A ring in a magnetic field. (a) in the normal state; (b) in the superconducting state; (c) after the value of field is reversed.

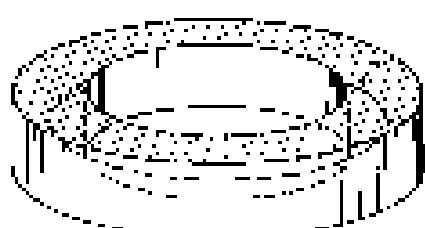

Fig. 21.5. The current in a ring in a superconducting ring.

¹² F. London, *Superfluidity*, Interscience Inc., New York, 1950, Vol. I, p. 152.

¹³ B. S. Deaver, Jr., and W. M. Fairbank, *Nature*, **189**, 740 (1931).

¹⁴ S. Dau and M. Schäfer, *Naturwissenschaften*, **31**, 11 (1940).

expect this to generate a current by Lenz's law so that the flux value would not change. The solenoid would now have magnetic moment proportional to the flux value. The magnetic moment was measured by jiggling the wire up and down like the handle of a screwing machine, but at the rate of 100 cycles per second (about a turn of cable coils at the ends of the air cylinder). The induced voltage in the coils was used a measure of the magnetic moment.

When the experiment was done by Debye and Polderman, they found that the flux was quantized, but this did not seem very remarkable since it was known that magnetism was quantized. Debye and Polderman got the same result. At first this was quite mysterious, but we now understand why it should be so. According to the Bardeev, Debye, and Semenoff theory of superconductivity, the q which appears in Eq. (21.28) is the charge of a pair of electrons and is equal to e_0 . The result is

$$q_0 = \frac{e_0 h}{c} = 1.8 \times 10^{-17} \text{ coulombs} \quad (21.30)$$

which is 11 the amount predicted by London. Everything now fits together, and the measurements show the existence of superconductivity purely quantum-mechanical effect on a large scale.

21-8 The dynamics of superconductivity

The Meissner effect and the flux quantization are two manifestations of our general theory, so far the task of completeness I would like to leave you with. The complete equations of a superconducting fluid would be from this point of view—it is rather interesting. Up to this point I have only put the expression for ψ into equations for charge density and current. If I put ψ into the complete Schrödinger equation, I get equations for ψ and ψ^* . It should be interesting to see what happens, because here we have a "fluid" of electron pairs with a charge density $\rho = e_0 n$ and a current $\mathbf{j} = \mathbf{e}_0 \nabla \psi^* \times \mathbf{B}$. We can try to see what kind of equations we get for such a "fluid". By substituting the wave function of Eq. (21.17) into the Schrödinger equation (21.3) and remembering that ϕ and ψ depend functions of x , y , and z . If we ignore the self and inductive parts we obtain these two equations. To write them in a shorter form I will be leaving Eq. (21.18) with

$$\frac{\partial}{\partial t} \nabla \psi = \frac{i}{\hbar} \mathbf{A} - \sigma \quad (21.31)$$

The first one you might get is then

$$\frac{\partial \psi}{\partial t} = \mathbf{T} \cdot \nabla \psi \quad (21.32)$$

Since ψ is first A , this is just the continuity equation again. The other equation I obtain tells now ψ how it is

$$i \frac{\partial \psi}{\partial t} = -\frac{e_0}{2} \nabla^2 \psi + \sigma \psi - \frac{e^2}{2m} \left\{ \frac{1}{\sqrt{\rho}} \nabla^2 (\sqrt{\rho}) \right\} \quad (21.33)$$

These are thoroughly familiar ψ -hydrodynamic, of which the only difference you may well recognize that is the equation of motion for an electrically charged fluid (we identify σ with the "velocity potential") except that the σ term, which is denoted by the energy of compression of the fluid, has a linear dependence on the density ρ . In any case, one expects to say that sum of charge of the quantity $\psi^* \psi$ given by ψ , A , the energy total, σ , ψ , plus a potential energy total, ϕ_0 , that is addition of ψ , containing the factor A , which we could call a "quantum mechanical energy," we've seen that inside a superconductor $\rho \rightarrow 0$, so

¹¹ It has only been suggested by Debye that this might happen (see B. London, Ref. 1), I don't know whether it has ever been tested.

uniform by the electrostatic forces, so this term can't be zero, only, or neglected in every potential approximation provided we have only one superconducting region. If we have a boundary between two superconductors for other circumstances in which the value of ϕ may change rapidly, this term can become important.

For today, when we put the function $\phi = \phi$ in the equations of hydrodynamics, I will rewrite Eq. (21.23) in a form that makes the physics more transparent by using Eq. (21.30) to express ϕ in terms of v . Taking the gradient of the whole of Eq. (21.30) and expressing $\nabla^2\phi$ in terms of A and v using (21.11), I get

$$\frac{\partial}{\partial t} \left(\frac{q}{m} \left(-\nabla \phi - \frac{\partial A}{\partial t} \right) - v \times (\nabla \times v) - (v \times \nabla) \phi \right) + \frac{q^2}{m^2} \left(\frac{1}{\sqrt{\rho}} \nabla^2 \phi / \rho \right) = 0 \quad (21.34)$$

What does this equation mean? First, consider the

$$-\nabla \phi = \frac{qA}{m} = E \quad (21.35)$$

Next, consider the first line of Eq. (21.10). I get:

$$\nabla \times E = -\frac{i}{e} \nabla \times J_i \quad (21.36)$$

Since the curl of a gradient is always zero (for $\nabla \times A$ is the magnetic field B , all the last two terms can be written as

$$\frac{q}{m} (E - v \times B).$$

Finally, you should understand that $d\phi/dt$ stands for the time derivative of the velocity of the fluid at a point. If you concentrate on a particular point, its *gradient* is the total derivative of ϕ (in, as it is + sometimes called in "fluid dynamics, the "nowhere vanishing gradient"), which is related to v by my¹³

$$\frac{dv}{dt}_{\text{along } \nabla \phi} = \frac{\partial \phi}{\partial t} - (\nabla \cdot \nabla) \phi. \quad (21.37)$$

The extra term also appears as the third term on the right side of Eq. (21.35). Taking it to the left side, I can write Eq. (21.35) in the following form:

$$m \frac{d\phi}{dt}_{\text{along } \nabla \phi} - q(E + v \times B) = \nabla \cdot \left(\frac{1}{m\rho} \nabla^2 \phi / \rho \right). \quad (21.38)$$

We also have from Eq. (21.30) that

$$\nabla \times v = -\frac{q}{m} B. \quad (21.39)$$

These two equations are the equations of motion of an *electron* in a superconductor moving in an electromagnetic field. It says that the acceleration of each particle of the fluid whose charge q comes from the ordinary source term of $E + v \times B$ plus an additional force, which is the gradient of some physical quantity, magnetopotential, a force which is not very big except at the junction between two superconductors. The second equation says that the fluid is "ideal". The word "ideal" here means that the energy of $E + v \times B$ is conserved. That means that the velocity can be expressed in terms of scalar potential. Similarly one writes that $\nabla \times v = 0$ for a conductor, but for an ideal charged fluid in a magnetic field, this is contained in Eq. (21.30).

So, for an *electron's* motion in the first two parts of a superconductor (just as the equations of motion of an electron in a dielectric charged liquid fluid, superconductivity is the same as the problem of the hydrodynamics of a charged liquid). If you want

¹³ See Volume II, Section 10-2

in order say problem about superconductor you take these equations for the field for the superconductor, Eqs. (21.32) and (21.33), and combine them with Maxwell's equations to get the fields. (The charges and currents you use depend on the finite nature of course, include the ones from the superconductor as well as from the external sources.)

The difficulty I believe that Eq. (21.34) is not quite correct but ought to have an additional term involving the density. This new term does not depend on temperature or distance from the ordinary energy associated with temperature gradient. Just as in an ordinary fluid there would be a potential energy density proportional to the square of the variation of a function, ρ_{var} , the electron density (which is, here, also proportional to the charge density of the crystal lattice). Since there will be forces proportional to the gradient of this energy, there should be another term in Eq. (21.34) of the form, $(\nabla \rho_{\text{var}} - \rho_{\text{var}})^2$. This term did not appear from my initial calculations because from the interaction between particles which I neglected by using an independent-particle approximation. If it is, however, just the force I referred to when I made the qualitative statement the electrostatic forces would tend to bring a nearly constant insulating layer around me.

21.9 The Josephson junction

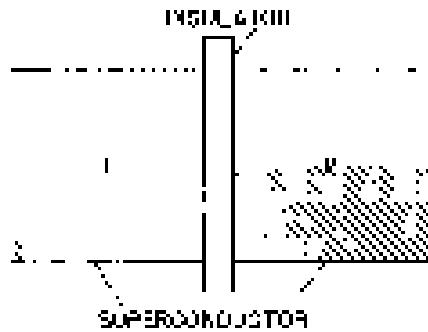

Fig. 21-6. Two superconductors connected by a thin insulator.

I would like to discuss next a very interesting situation that one method of manufacture¹⁴ while making wires might happen to join two superconductors which are separated by a thin layer of insulating material as in Fig. 21-6. Such an arrangement is now called a "Josephson junction." If the insulating layer is thick, the electrons can't go through; but if the layer is thin enough, there can be an exchange of electrons between the two superconductors. This is just another example of the quantum mechanical penetration of a barrier. Josephson analyzed this situation and discovered that a number of strange phenomena can occur.

In order to analyze such a junction I'll let the amplitude to find an electron on one side, ψ_1 , and the amplitude to find it on the other, ψ_2 . In the superconducting state the wave function ψ_1 is the same as wave function of all the electrons on one side, and ψ_2 is the corresponding function on the other side. I would do this problem for t -Fermi bands in a superconductor, but let us make a very simple situation as follows. The current is the same on both sides so that the junction is symmetrical and simple. Also, let μ_1 and μ_2 be the magnetic field. Then the two amplitudes should be related in the following way:

$$\begin{aligned} i \frac{d\psi_1}{dt} &= U_1 \psi_1 + K \psi_2, \\ i \frac{d\psi_2}{dt} &= U_2 \psi_2 + K \psi_1. \end{aligned}$$

The constant K is a characteristic of the junction. If K were zero, these two equations would just describe the lowest energy state—with energy E_0 —of an hydrogen atom—but there is coupling between the two sides by the amplitude K and there may be leakage from one side to the other. Also just the "flip-flop" amplitude of a two-state system. If the two sides are identical, U_1 would equal U_2 and I could just multiply them out. But now suppose that we connect the two superconducting regions to the two terminals of a battery so that there is a potential difference V across the junction. Then $U_1 = U_2 = qV$. Now, for convenience, let us take zero to energy to be halfway between, then the two equations are

$$\begin{aligned} i \frac{d\psi_1}{dt} - \frac{qV}{\hbar} \psi_1 &= K \psi_2, \\ i \frac{d\psi_2}{dt} - - \frac{qV}{\hbar} \psi_2 &= K \psi_1. \end{aligned} \tag{21.41}$$

¹⁴ R. D. Josephson, *Nature* Letters 2, 80 (1962).

Now we have two differential equations for two quantum mechanical states coupled together. This time, let's analyze these equations in another way. Let's make the substitutions

$$\begin{aligned} \psi_1 &= \sqrt{\rho_1} e^{i\phi_1}, \\ \psi_2 &= \sqrt{\rho_2} e^{i\phi_2}, \end{aligned} \quad (21.41)$$

where ρ_1 and ρ_2 are the masses of the two sites or the junctions and ϕ_1 and ϕ_2 are the identities of electrons at those two sites. Remember, i.e., in actual practice ρ_1 and ρ_2 are chosen exactly the same and same for ϕ_1 , the total identity of electrons in the superconducting material. Now if you substitute these equations for ψ_1 and ψ_2 into (21.39), you get two equations of equating the real and imaginary parts in reference. Letting $\theta_1 = \phi_1 - \phi_2$ for short, the result is

$$\begin{aligned} \rho_1 &= -\frac{2}{\hbar} E_V \rho_2 \rho_1 \sin \theta \\ \rho_2 &= -\frac{2}{\hbar} E_V \rho_1 \rho_2 \sin \theta \\ \theta &= +\frac{g}{\pi} \sqrt{\frac{\rho_1}{\rho_2}} \cos \theta - \frac{d\tilde{\rho}}{2\hbar} \\ \theta &= +\frac{g}{\pi} \sqrt{\frac{\rho_1}{\rho_2}} \cos \theta + \frac{d\tilde{\rho}}{2\hbar} \end{aligned} \quad (21.42)$$

The first two equations say that $\rho_1 = -\rho_2$. "But," you say, "they may both be positive, since ρ_1 and ρ_2 are both negative and equal to zero." Not quite. These equations is not the whole story. They say what ϕ_1 and ϕ_2 would be if there were no vector forces from due to the imbalance between the electron fluid and the background of positive ions. That will allow the currents to start to change, and therefore current I_1 and current I_2 would begin to flow. The current from site 1 to site 2 would be just $i_2(x - \delta_2, \omega)$.

$$I_2 = \frac{e}{\mu} \sqrt{\rho_2} i_2 \sin \theta. \quad (21.43)$$

Such a current would soon change up site 1, except that we have forgotten that the two sites are connected by wires to the rest of the circuit. The current that flows will not change \rightarrow again 2 for discrete periodicity because all sites will have the periodic component. These currents form the extra I_2 that has been included in our expression. When they are included, ρ_1 and ρ_2 are not longer charge, but the current across the junction is still given by (21.43).

Since ρ_1 and ρ_2 remain constant and equal to $\rho = kT$ set $E_V \rho_1 \Delta \theta = I_2$, and we get

$$\theta = I_2 \sin \theta. \quad (21.45)$$

$I_2 \cos \theta$ is then a constant which is characteristic of the particular junction.

The other pair of equations (21.41) is also consistent since $\theta_1 = \theta_2$. We are interested in the difference $\tilde{\theta} = \theta_2 - \theta_1$ so use Eq. (21.45) we get is

$$\tilde{\theta} = \theta_2 - \theta_1 = \frac{g^2}{\pi} \cdot \frac{\tilde{\rho}}{\rho}. \quad (21.46)$$

(21.46) means that we can write

$$\tilde{\theta}(x) = \theta_0 + \frac{g}{\pi} \int V(x) dx, \quad (21.47)$$

where θ_0 is the value of $\tilde{\theta}$ at $x = 0$. However, depending on the choice of θ_0 , we get $\tilde{\theta} = 0$. In both (21.46) and (21.47) we have the important result, the general theory of the Josephson Junction.

Now what are the consequences? First, potential voltage. If you put some dc voltage, V_0 , the current of the two junctions ($I_1 = -I_2 = V_0/R$) is a small number compared to ordinary voltage since it's passing through a diode steadily and the net current is nothing. The problem, since the bias voltage is not zero, you could say it's not due to the conduction by "normal" electrons. On the other hand if you pass over voltage, the junction you change its current! With no voltage the current can be any amount between $+I_2$ and $-I_2$ depending on the value of E_{ph} . But when you put a voltage across it and the current goes to zero, this change in behavior has been measured experimentally.¹⁸

That is another way to generate a current—by applying a voltage at a very low frequency in addition to a dc voltage, etc.

$$V = V_0 + V_{AC} \cos \omega t$$

$V_{AC} \rightarrow 0$ for $\omega \rightarrow 0$

$$I_2 = \frac{d}{dt} V_{AC} = \frac{d}{dt} V_{AC} \cos \omega t$$

Now for the small

$$\sin \omega t = \omega t \Rightarrow \sin \omega t = \omega t \cos \omega t$$

Using this approximation for $\sin \omega t$ I get

$$I = I_0 \cos \left(\phi_0 + \frac{1}{\hbar} E_{ph} \right) + \frac{V_0}{\hbar \omega} \sin \omega t \cos \left(\phi_0 + \frac{1}{\hbar} E_{ph} \right).$$

Let's first take $\omega \rightarrow 0$ at the average. In the second term I get

$$x = \frac{1}{\hbar} E_{ph}$$

The x looks like a current if we change this just a little because Chapter 3 seems to have current with a minus sign in there.

If you look up x in any subject you will find that they often write two formula for the current as

$$J = J_0 \sin \left(\phi_0 - \frac{E_{ph}}{\hbar} + \frac{1}{\hbar} \omega t - \phi \right), \quad (2.45)$$

where the integral $\rightarrow 0$ to take it across the junction. The reason for this is that there's a vector potential across the junction. The further distance is modified in such a way that we expand it out. If you do that this phase through, it comes out as given above.

Finally, I would like to describe a very dramatic and interesting experiment which has recently been made on the relationships of the variables from such a two junctions. In quantum mechanics we're used to the interaction between amplitude from two different states. Here we're going to see the interaction between two processes caused by the difference in the phase of the current of the same is through two different paths. In Fig. 21.7, I show two different junctions, "A" and "B", connected in parallel. Then the Point C is connected to a differential ammeter which measures anti-current. That is, if normal current, I_A , were to be the sum of the currents through the two junctions, $I_A = I_1 + I_2$ or the currents through the two junctions, and let their phases be ϕ_1 and ϕ_2 . Now, if a phase difference of the wave function between ϕ_1 and ϕ_2 is the same whatever you give one more to the other, along current path through junction "B", the phase difference between ϕ_1 and ϕ_2 is π , plus the last integral of the total potential along the upper diode.

$$\Delta \Phi_{B(A)}(\phi_2) = \phi_2 + \frac{e}{\hbar} \int_{\text{upper}}^{\text{lower}} A \cdot d\mathbf{r} \quad (21.46)$$

¹⁸ S. S. Antropov and J. M. Bozler, Phys. Rev. Letters 11, 1011 (1963).

¹⁹ R. Stoenescu, Rev. Roum. Phys. 10, 391 (1965).

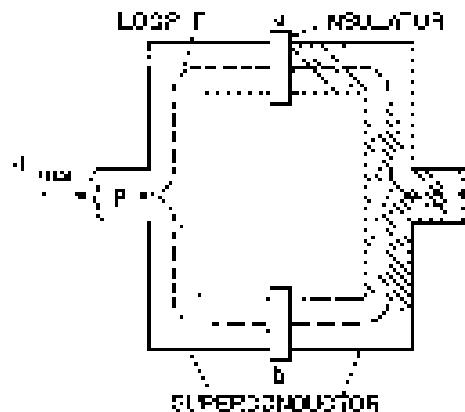

Fig. 21-7. Two-probe junctions in parallel.

Why? Because the phase is related to ϕ by Eq. (21-6). If you integrate this equation along some path, the left-hand side gives the phase change, which is then just proportional to the line integral of A , as we have written here. The phase change along each loop can then be written similarly:

$$\Delta\phi_{\text{loop}C} = \phi_C + \frac{ie}{\hbar} \int_{\text{loop}C} d\ell \cdot A_\ell. \quad (21-20)$$

There are two to be equal, and I estimate them to get the difference of the loops first at the 20 integrals, or a few π 's of the period:

$$\phi_1 - \phi_2 = \frac{2e}{\hbar} \int_{\text{loop}C} d\ell \cdot A_\ell.$$

Now the integral is around the closed loop C in Fig. 21-7. Most curves through both branches. The integral over A is the magnetic flux Φ through the loop. So the two ϕ 's are going to differ by $2\pi/\hbar$ times. In magnetic flux Φ when placed between the two branches of the circuit:

$$\phi_1 - \phi_2 = \frac{2\pi}{\hbar} \Phi. \quad (21-21)$$

I can control this phase difference by changing the magnetic field B on the circuit, and I can adjust the difference in phase and see whether it makes total current and I_c flow through the two junctions above one another of not. Let's do it. The resistance R is proportional to ϕ_1 and ϕ_2 . For convenience, I will write

$$I_1 = J_1 - \frac{2\pi}{\hbar} \Phi, \quad I_2 = J_2 - \frac{2\pi}{\hbar} \Phi.$$

Then,

$$\begin{aligned} I_{\text{total}} &= J_1 [\sin(\phi_1 - \frac{2\pi}{\hbar} \Phi) + \cos(\phi_1 - \frac{2\pi}{\hbar} \Phi)] \\ &= J_1 \sin \phi_1 \cos \frac{2\pi}{\hbar} \Phi. \end{aligned} \quad (21-22)$$

Now we don't know anything about ϕ_1 , we have to adjust that anyway she wants depending on the circumstances. In particular, it will depend on the forward voltage applied to the junction. No matter what we do, however, I_{total} is definitely not going to be zero. So the current I_{total} for any given Φ is given by

$$I_{\text{total}} = J_1 \sin \left| \frac{2\pi}{\hbar} \Phi \right|$$

This maximum current will vary with the total voltage V because whenever

$$\Phi = \frac{q}{\hbar} V$$

with q some integer. This is to say, the current takes on its maximum value whenever the magnetic flux just reaches quantum values $(21-22)$: 1.7×10^{-19} Wb.

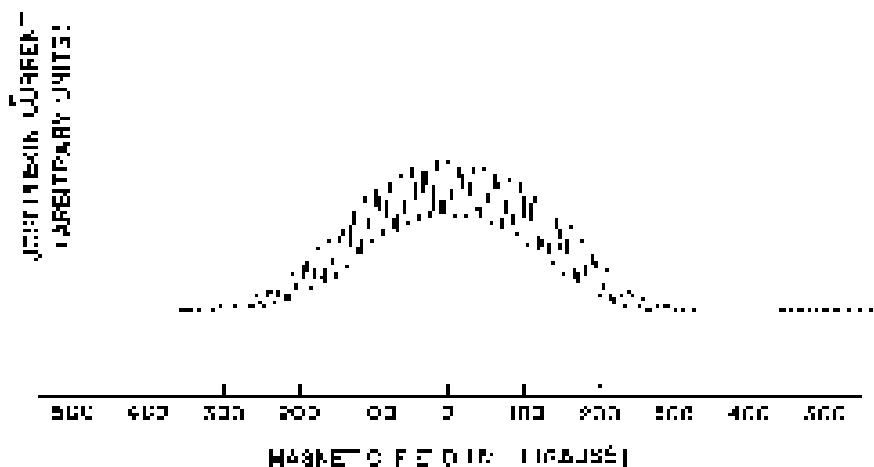

Fig. 21-5. A recording of the current through pairs of 10-ohm resistors in a portion of the magnetic field in the region between the two junctions, see Fig. 21-7. [The recording was made by R. C. Johnson, J. Lamb, A. H. Silver, and J. E. Goss, of the Bell Telephone Laboratories, New Haven, Connecticut.]

The Josephson current can be simply given by the relation of the magnetic field in the area between the two junctions. The results are shown in Fig. 21-6. There is a series of blocks, and of course, from various effects we have neglected, will be a great number of steps in the current with changes in the magnetic field due to the interference term as given by Eq. (21-1).

One of the big questions in solid quantum mechanics is the question of whether the wave potential exists in a phase wave function or not.¹¹ This aspect of wave theory just described has also been done with a very similar between the two junctions so that the only significant magnetic field is inside the junctions and a negligibly small it is outside superconducting rings themselves. Yet it is remarkable that the amount of current depends nonlinearly on the flux of magnetic field outside the solenoid even though that field never crosses the wire—an important demonstration of the "potential reality" of the vector potential.¹²

I don't know what will come next. But look what can be done. First, notice that the interference between two junctions can be used to make a sensitive magnetometer. If a set of junctions is made with an encoder gear set, say, with the max in the cause of Fig. 21-5 which is separated by 2×10^{-4} cm/cm², at room temperature to be 10° K, then you are 1000° K away from zero peaks, and it should be possible to use such a gear to measure magnetic field as small as 2×10^{-7} gauss, or to me is no longer nothing to such a precision. They should be able to go even farther. Suppose for example we put a set of 10 or 20 junctions close together and equally spaced. Then we will have the difference between the currents due to something like a magnetic field as well as temperature and distance. Instead of a field measurement we compare a 30, or perhaps even 100-bit instead of the 10, measuring the magnetic field. Perhaps we can make the measurement of a synapse. This will be a great technique of communications equipment—especially assuming more as power as the measurement of wavelength of light.

These then are some illustrations of some of the things that are happening in modern electronics. The last and new three months, where 20 more junctions appear, have not yet shown. The quantum mechanics which was the norm 10 years ago and nearly 10 years of development along rather systematically has begun to be exploited in many practical and cool ways. We are truly getting control of nature on a very delicate and basic fundamental.

I am sorry to say, gentlemen, that as participants in this seminar you will probably not participate and you will not be granted a Nobel Prize if possible. If you do have time in the future we would like a way to make an application so you at the earliest possible moment, the inventor of this part of physics.

Feymann's Epilogue

Well, I've been talking to you for two years and now I'm going to quit. In some ways I would like to apologize and in other ways not. I chose an feet. I know—
that 1990 is three years off your own birth date so follow everything were given
exclusion, and last had a good time with it. But I also know that "the powers of
intuition are of very little effect except in those tragic circumstances in which
they are powerfully exercised." So far, however, he unknown who has
reduced exclusion, only I say I have done nothing but show you the camp. For
the others, if I have made you like the subject I'm sorry. I have taught the history
payoffs before, and I apologize. I just hope that I haven't caused any trouble
to you... and that you do not leave this exciting process. I hope that someone else
can teach it to you in a way that doesn't give you information, and that you will
find something that, while all is not as horrific as I believe.

Finally, since I said that the total purpose of my teaching has not been to
prepare you for war or exclusion. It was not the. To perhaps you to serve in
it, stay in the military. I have chosen to give you some appreciation of the understand-
ing work and the payment way of working at it which, I believe, is a major part
of the true culture of modern times. (There are probably processes of other sub-
jects where one might feel that there is no. They are still, I think, working.)

Perhaps you will not only have some appreciation of this as well; it is even
possible that you may want to join in the greatest adventure that the human mind
has ever begun.
