

Feynman's Preface

These are the lectures in physics that I gave last year and the year before to the freshman and sophomore classes at Caltech. The lectures are, of course, not verbatim—they have been edited, sometimes extensively and sometimes less so. The lectures form only part of the complete course. The whole group of 180 students gathered in a big lecture room twice a week to hear these lectures and then they broke up into small groups of 15 to 20 students in recitation sections under the guidance of a teaching assistant. In addition, there was a laboratory session once a week.

The special problem we tried to get at with these lectures was to maintain the interest of the very enthusiastic and rather smart students coming out of the high schools and into Caltech. They have heard a lot about how interesting and exciting physics is—the theory of relativity, quantum mechanics, and other modern ideas. By the end of two years of our previous course, many would be very discouraged because there were really very few grand, new, modern ideas presented to them. They were made to study inclined planes, electrostatics, and so forth, and after two years it was quite stultifying. The problem was whether or not we could make a course which would save the more advanced and excited student by maintaining his enthusiasm.

The lectures here are not in any way meant to be a survey course, but are very serious. I thought to address them to the most intelligent in the class and to make sure, if possible, that even the most intelligent student was unable to completely encompass everything that was in the lectures—by putting in suggestions of applications of the ideas and concepts in various directions outside the main line of attack. For this reason, though, I tried very hard to make all the statements as accurate as possible, to point out in every case where the equations and ideas fitted into the body of physics, and how—when they learned more—things would be modified. I also felt that for such students it is important to indicate what it is that they should—if they are sufficiently clever—be able to understand by deduction from what has been said before, and what is being put in as something new. When new ideas came in, I would try either to deduce them if they were deducible, or to explain that it *was* a new idea which hadn't any basis in terms of things they had already learned and which was not supposed to be provable—but was just added in.

At the start of these lectures, I assumed that the students knew something when they came out of high school—such things as geometrical optics, simple chemistry ideas, and so on. I also didn't see that there was any reason to make the lectures

in a definite order, in the sense that I would not be allowed to mention something until I was ready to discuss it in detail. There was a great deal of mention of things **to** come, without complete discussions. These more complete discussions would come later when the preparation became more advanced. Examples are the discussions of inductance, and of energy levels, which are at first brought in in a very qualitative way and are later developed more completely.

At the same time that I was aiming at the more active student, I also wanted to take care of the fellow for whom the extra fireworks and side applications are merely disquieting and who cannot be expected to learn most of the material in the lecture at all. For such students I wanted there to be at least a central core or backbone of material which he *could* get. Even if he didn't understand everything in a lecture, I hoped he wouldn't get nervous. I didn't expect him to understand everything, but only the central and most direct features. It takes, of course, a certain intelligence on his part to see which are the central theorems and central ideas, and which are the more advanced side issues and applications which he may understand only in later years.

In giving these lectures there was one serious difficulty: in the way the course was given, there wasn't any feedback from the students to the lecturer to indicate how well the lectures were going over. This is indeed a very serious difficulty, and I don't know how good the lectures really are. The whole thing was essentially an experiment. And if I did it again I wouldn't do it the same way—I hope I ~~don't~~ have to do it again! I think, though, that things worked out—so far as the physics is concerned—quite satisfactorily in the first year.

In the second year I was not so satisfied. In the first part of the course, dealing with electricity and magnetism, I couldn't think of any really unique or different way of doing it—of any way that would be particularly more exciting than the usual way of presenting it. So I don't think I did very much in the lectures on electricity and magnetism. At the end of the second year I had originally intended to go on, after the electricity and magnetism, by giving some more lectures on the properties of materials, but mainly to take up things like fundamental modes, solutions of the diffusion equation, vibrating systems, orthogonal functions,... developing the first stages of what are usually called "the mathematical methods of physics." In retrospect, I think that if I were doing it again I would go back to that original idea. But since it was not planned that I would be giving these lectures again, it was suggested that it might be a good idea to try to give an introduction to the quantum mechanics—what you will find in Volume III.

It is perfectly clear that students who will major in physics can wait until their third year for quantum mechanics. On the other hand, the argument was made that many of the students in our course study physics as a background for their primary interest in other fields. And the usual way of dealing with quantum mechanics makes that subject almost unavailable for the great majority of students because they have to take so long to learn it. Yet, in its real applications—especially in its more complex applications, such as in electrical engineering and chemistry—the full machinery of the differential equation approach is not actually used. So I tried to describe the principles of quantum mechanics in a way which wouldn't require that one first know the mathematics of partial differential equations. Even for a physicist I think that is an interesting thing to try to do—to present quantum mechanics in this reverse fashion—for several reasons which may be apparent in the lectures themselves. However, I think that the experiment in the quantum mechanics part was not completely successful—in large part because I really did not have enough time at the end (I should, for instance, have had three or four more lectures in order to deal more completely with such matters as energy bands and the spatial dependence of amplitudes). Also, I had never presented the subject this way before, so the lack of feedback was particularly serious. I now believe the quantum mechanics should be given at a later time. Maybe I'll have a chance to do it again someday. Then I'll do it right.

The reason there are no lectures on how to solve problems is because there **were** recitation sections. Although I did put in three lectures in the first year on how to solve problems, they are not included here. Also there was a lecture on inertial

guidance which certainly belongs after the lecture on rotating systems, but which was, unfortunately, omitted. The fifth and sixth lectures are actually due to Matthew Sands, as I was out of town.

The question, of course, is how well this experiment has succeeded. My own point of view—which, however, does not seem to be shared by most of the people who worked with the students—is pessimistic. I don't think I did very well by the students. When I look at the way the majority of the students handled the problems on the examinations, I think that the system is a failure. Of course, my friends point out to me that there were one or two dozen students who—very surprisingly—understood almost everything in all of the lectures, and who were quite active in working with the material and worrying about the many points in an excited and interested way. These people have now, I believe, a first-rate background in physics—and they are, after all, the ones I was trying to get at. But then, "The power of instruction is seldom of much efficacy except in those happy dispositions where it is almost superfluous." (Gibbon)

Still, I didn't want to leave any student completely behind, as perhaps I did. I think one way we could help the students more would be by putting more hard work into developing a set of problems which would elucidate some of the ideas in the lectures. Problems give a good opportunity to fill out the material of the lectures and make more realistic, more complete, and more settled in the mind the ideas that have been exposed.

I think, however, that there isn't any solution to this problem of education other than to realize that the best teaching can be done only when there is a direct individual relationship between a student and a good teacher—a situation in which the student discusses the ideas, thinks about the things, and talks about the things. It's impossible to learn very much by simply sitting in a lecture, or even by simply doing problems that are assigned. But in our modern times we have so many students to teach that we have to try to find some substitute for the ideal. Perhaps my lectures can make some contribution. Perhaps in some small place where there are individual teachers and students, they may get some inspiration or some ideas from the lectures. Perhaps they will have fun thinking them through—or going on to develop some of the ideas further.

RICHARD P. FEYNMAN

June, 1963

Foreword

This book is based upon a course of lectures in introductory physics given by Prof. R. P. Feynman at the California Institute of Technology during the academic year 1961-62; it covers the first year of the two-year introductory course taken by all Caltech freshmen and sophomores, and was followed in 1962-63 by a similar series covering the second year. The lectures constitute a major part of a fundamental revision of the introductory course, carried out over a four-year period.

The need for a basic revision arose both from the rapid development of physics in recent decades and from the fact that entering freshmen have shown a steady increase in mathematical ability as a result of improvements in high school mathematics course content. We hoped to take advantage of this improved mathematical background, and also to introduce enough modern subject matter to make the course challenging, interesting, and more representative of present-day physics.

In order to generate a variety of ideas on what material to include and how to present it, a substantial number of the physics faculty were encouraged to offer their ideas in the form of topical outlines for a revised course. Several of these were presented and were thoroughly and critically discussed. It was agreed almost at once that a basic revision of the course could not be accomplished either by merely adopting a different textbook, or even by writing one *ab initio*, but that the new course should be centered about a set of lectures, to be presented at the rate of two or three per week; the appropriate text material would then be produced as a secondary operation as the course developed, and suitable laboratory experiments would also be arranged to fit the lecture material. Accordingly, a rough outline of the course was established, but this was recognized as being incomplete, tentative, and subject to considerable modification by whoever was to bear the responsibility for actually preparing the lectures.

Concerning the mechanism by which the course would finally be brought to life, several plans were considered. These plans were mostly rather similar, involving a cooperative effort by N staff members who would share the total burden symmetrically and equally: each man would take responsibility for $1/N$ of the material, deliver the lectures, and write text material for his part. However, the unavailability of sufficient staff, and the difficulty of maintaining a uniform point of view because of differences in personality and philosophy of individual participants, made such plans seem unworkable.

The realization that we actually possessed the means to create not just a new and different physics course, but possibly a unique one, came as a happy inspiration to Professor Sands. He suggested that Professor R. P. Feynman prepare and deliver the lectures, and that these be tape-recorded. When transcribed and edited, they would then become the textbook for the new course. This is essentially the plan that was adopted.

It was expected that the necessary editing would be minor, mainly consisting of supplying figures, and checking punctuation and grammar; it was to be done by one or two graduate students on a part-time basis. Unfortunately, this expectation was short-lived. It was, in fact, a major editorial operation to transform the verbatim transcript into readable form, even without the reorganization or revision of the subject matter that was sometimes required. Furthermore, it was not a job for a technical editor or for a graduate student, but one that required the close attention of a professional physicist for from ten to twenty hours per lecture!

The difficulty of the editorial task, together with the need to place the material in the hands of the students as soon as possible, set a strict limit upon the amount of "polishing" of the material that could be accomplished, and thus we were forced to aim toward a preliminary but technically correct product that could be used immediately, rather than one that might be considered final or finished. Because of an urgent need for more copies for our students, and a heartening interest on the part of instructors and students at several other institutions, we decided to publish the material in its preliminary form rather than wait for a further major revision which might never occur. We have no illusions as to the completeness, smoothness, or logical organization of the material; in fact, we plan several minor modifications in the course in the immediate future, and we hope that it will not become static in form or content.

In addition to the lectures, which constitute a centrally important part of the course, it was necessary also to provide suitable exercises to develop the students' experience and ability, and suitable experiments to provide first-hand contact with the lecture material in the laboratory. Neither of these aspects is in as advanced a state as the lecture material, but considerable progress has been made. Some exercises were made up as the lectures progressed, and these were expanded and amplified for use in the following year. However, because we are not yet satisfied that the exercises provide sufficient variety and depth of application of the lecture material to make the student fully aware of the tremendous power being placed at his disposal, the exercises are published separately in a less permanent form in order to encourage frequent revision.

A number of new experiments for the new course have been devised by Professor H. V. Neher. Among these are several which utilize the extremely low friction exhibited by a gas bearing: a novel linear air trough, with which quantitative measurements of one-dimensional motion, impacts, and harmonic motion can be made, and an air-supported, air-driven Maxwell top, with which accelerated rotational motion and gyroscopic precession and nutation can be studied. The development of new laboratory experiments is expected to continue **for a** considerable period of time.

The revision program was under the direction of Professors R. B. Leighton, H. V. Neher, and M. Sands. Officially participating in the program were Professors R. P. Feynman, G. Neugebauer, R. M. Sutton, H. P. Stabler,* F. Strong, and R. Vogt, from the division of Physics, Mathematics and Astronomy, and Professors T. Caughey, M. Plesset, and C. H. Wilts from the division of Engineering Science. The valuable assistance of all those contributing to the revision program is gratefully acknowledged. We are particularly indebted to the Ford Foundation, without whose financial assistance this program could not have been carried out.

ROBERT B. LEIGHTON

* 1961-62, while on leave from Williams College, Williamstown, Mass.

Contents

CHAPTER 1. ATOMS IN MOTION

- 1-1 Introduction 1-1
- 1-2 Matter is made of atoms 1-2
- 1-3 Atomic processes 1-5
- 1-4 Chemical reactions 1-6

CHAPTER 2. BASIC PHYSICS

- 2-1 Introduction 2-1
- 2-2 Physics before 1920 2-3
- 2-3 Quantum physics 2-6
- 2-4 Nuclei and particles 2-8

CHAPTER 3. THE RELATION OF PHYSICS TO OTHER SCIENCES

- 3-1 Introduction 3-1
- 3-2 Chemistry 3-1
- 3-3 Biology 3-2
- 3-4 Astronomy 3-6
- 3-5 Geology 3-7
- 3-6 Psychology 3-8
- 3-7 How did it get that way? 3-9

CHAPTER 4. CONSERVATION OF ENERGY

- 4-1 What is energy? 4-1
- 4-2 Gravitational potential energy 4-2
- 4-3 Kinetic energy 4-5
- 4-4 Other forms of energy 4-6

CHAPTER 5. TIME AND DISTANCE

- 5-1 Motion 5-1
- 5-2 Time 5-1
- 5-3 Short times 5-2
- 5-4 Long times 5-3
- 5-5 Units and standards of time 5-5
- 5-6 Large distances 5-5
- 5-7 Short distances 5-8

CHAPTER 6. PROBABILITY

- 6-1 Chance and likelihood 6-1
- 6-2 Fluctuations 6-3
- 6-3 The random walk 6-5
- 6-4 A probability distribution 6-7
- 6-5 The uncertainty principle 6-10

CHAPTER 7. THE THEORY OF GRAVITATION

- 7-1 Planetary motions 7-1
- 7-2 Kepler's laws 7-1
- 7-3 Development of dynamics 7-2
- 7-4 Newton's law of gravitation 7-3
- 7-5 Universal gravitation 7-5
- 7-6 Cavendish's experiment 7-9
- 7-7 What is gravity? 7-9
- 7-8 Gravity and relativity 7-11

CHAPTER 8. MOTION

- 8-1 Description of motion 8-1
- 8-2 Speed 8-2
- 8-3 Speed as a derivative 8-5
- 8-4 Distance as an integral 8-7
- 8-5 Acceleration 8-8

CHAPTER 9. NEWTON'S LAWS OF DYNAMICS

- 9-1 Momentum and force 9-1
- 9-2 Speed and velocity 9-2
- 9-3 Components of velocity, **acceleration, and force** 9-3
- 9-4 What is the force? 9-3
- 9-5 Meaning of the dynamical equations 9-4
- 9-6 Numerical solution of the equations 9-5
- 9-7 Planetary motions 9-6

CHAPTER 10. CONSERVATION OF MOMENTUM

- 10-1 Newton's Third Law 10-1
- 10-2 Conservation of momentum 10-2
- 10-3 Momentum *is* conserved! 10-5
- 10-4 Momentum and energy 10-7
- 10-5 Relativistic momentum 10-8

CHAPTER 11. VECTORS

- 11-1 Symmetry in physics **11-1**
- 11-2 Translations 11-1
- 11-3 Rotations 11-3
- 11-4 Vectors 11-5
- 11-5** Vector algebra **11-6**
- 11-6 Newton's laws in vector notation **11-7**
- 11-7 Scalar product of vectors 11-8

CHAPTER 12. CHARACTERISTICS OF FORCE

- 12-1 What is a force? 12-1
- 12-2 Friction 12-3
- 12-3 Molecular forces 12-6
- 12-4 Fundamental forces. Fields 12-7
- 12-5 Pseudo forces 12-10
- 12-6 Nuclear forces 12-12

CHAPTER 13. WORK AND POTENTIAL ENERGY (A)

- 13-1 Energy of a falling body 13-1
- 13-2 Work done by gravity 13-3
- 13-3 Summation of energy 13-6
- 13-4 Gravitational field of large objects 13-8

CHAPTER 14. WORK AND POTENTIAL ENERGY (conclusion)

- 14-1 Work 14-1
- 14-2 Constrained motion 14-3
- 14-3 Conservative forces 14-3
- 14-4 Nonconservative forces 14-6
- 14-5 Potentials and fields 14-7

CHAPTER 15. THE SPECIAL THEORY OF RELATIVITY

- 15-1** The principle of relativity 15-1
- 15-2** The Lorentz transformation 15-3
- 15-3** The Michelson-Morley experiment 15-3
- 15-4** Transformation of time 15-5
- 15-5** The Lorentz contraction 15-7
- 15-6** Simultaneity 15-7
- 15-7 Four-vectors 15-8
- 15-8 Relativistic dynamics 15-9
- 15-9** Equivalence of mass and energy 15-10

CHAPTER 16. RELATIVISTIC ENERGY AND MOMENTUM

- 16-1** Relativity and the philosophers **16-1**
- 16-2 The twin paradox 16-3
- 16-3 Transformation of velocities 16-4
- 16-4 Relativistic mass 16-6
- 16-5 Relativistic energy 16-8

CHAPTER 17. SPACE-TIME

- 17-1 The geometry of space-time 17-1
- 17-2 Space-time intervals 17-2
- 17-3 Past, present, and future 17-4
- 17-4 More about four-vectors 17-5
- 17-5 Four-vector algebra 17-7.

CHAPTER 18. ROTATION IN Two DIMENSIONS

- 18-1 The center of mass 18-1
- 18-2 Rotation of a rigid body 18-2
- 18-3 Angular momentum 18-5
- 18-4 Conservation of angular momentum 18-6

CHAPTER 19. CENTER OF MASS; MOMENT OF INERTIA

- 19-1 Properties of the center of mass 19-1
- 19-2 Locating the center of mass 19-4
- 19-3 Finding the moment of inertia 19-5
- 19-4** Rotational kinetic energy 19-7

CHAPTER 20. ROTATION IN SPACE

- 20-1 Torques in three dimensions 20-1
- 20-2 The rotation equations using cross products **20-1**
- 20-3 The gyroscope 20-5
- 20-4 Angular momentum of a solid body 20-8

CHAPTER 21. THE HARMONIC OSCILLATOR

- 21-1 Linear differential equations 21-1
- 21-2 The harmonic oscillator 21-1
- 21-3 Harmonic motion and circular motion 21-4
- 21-4 Initial conditions 21-4
- 21-5 Forced oscillations 21-5

CHAPTER 22. ALGEBRA

- 22-1 Addition and multiplication 22-1
- 22-2 The inverse operations 22-2
- 22-3 Abstraction and generalization 22-3
- 22-4 Approximating irrational numbers 22-4
- 22-5 Complex numbers 22-7
- 22-6 Imaginary exponents 22-9

CHAPTER 23. RESONANCE

- 23-1 Complex numbers and harmonic motion 23-1
- 23-2 The forced oscillator with damping 23-3

23-3 Electrical resonance 23-5**23-4 Resonance in nature 23-7****CHAPTER 24. TRANSIENTS**

- 24-1** The energy of an oscillator 24-1
- 24-2** Damped oscillations 24-2
- 24-3** Electrical transients 24-5

CHAPTER 25. LINEAR SYSTEMS AND REVIEW

- 25-1** Linear differential equations 25-1
- 25-2** Superposition of solutions 25-2
- 25-3** Oscillations in linear systems 25-5
- 25-4** Analogs in physics 25-6
- 25-5** Series and parallel impedances 25-8

CHAPTER 26. OPTICS: THE PRINCIPLE OF LEAST TIME

- 26-1** Light 26-1
- 26-2** Reflection and refraction 26-2
- 26-3** Fermat's principle of least time 26-3
- 26-4** Applications of Fermat's principle 26-5
- 26-5** A more precise statement of Fermat's principle 26-7
- 26-6** How it works 26-8

CHAPTER 27. GEOMETRICAL OPTICS

- 27-1** Introduction 27-1
- 27-2** The focal length of a spherical surface 27-1
- 27-3** The focal length of a lens 27-4
- 27-4** Magnification 27-5
- 27-5** Compound lenses **27-6**
- 27-6** Aberrations 27-7
- 27-7** Resolving power 27-7

CHAPTER 28. ELECTROMAGNETIC RADIATION

- 28-1** Electromagnetism 28-1
- 28-2** Radiation 28-3
- 28-3** The dipole radiator 28-5
- 28-4** Interference 28-6

CHAPTER 29. INTERFERENCE

- 29-1** Electromagnetic waves 29-1
- 29-2** Energy of radiation 29-2
- 29-3** Sinusoidal waves 29-2
- 29-4** Two dipole radiators 29-3
- 29-5** The mathematics of interference 29-5

CHAPTER 30. DIFFRACTION

- 30-1** The resultant amplitude due to n equal oscillators 30-1
- 30-2** The diffraction grating 30-3
- 30-3** Resolving power of a grating **30-5**
- 30-4** The parabolic antenna 30-6
- 30-5** Colored films; crystals 30-7
- 30-6** Diffraction by opaque screens 30-8
- 30-7** The field of a plane of oscillating charges 30-10

CHAPTER 31. THE ORIGIN OF THE REFRACTIVE INDEX

- 31-1** The index of refraction 31-1
- 31-2** The field due to the material 31-4
- 31-3** Dispersion 31-6
- 31-4** Absorption 31-8
- 31-5** The energy carried by an electric wave 31-9
- 31-6** Diffraction of light by a screen 31-10

CHAPTER 32. RADIATION DAMPING. LIGHT SCATTERING

- 32-1 Radiation resistance 32-1
- 32-2 The rate of radiation of energy 32-2
- 32-3 Radiation damping 32-3
- 32-4 Independent sources 32-5
- 32-5 Scattering of light 32-6

CHAPTER 33. POLARIZATION

- 33-1 The electric vector of light 33-1
- 33-2 Polarization of scattered light 33-3
- 33-3 Birefringence 33-3
- 33-4 Polarizers 33-5
- 33-5 Optical activity 33-6
- 33-6 The intensity of reflected light 33-7
- 33-7 Anomalous refraction 33-9

CHAPTER 34. RELATIVISTIC EFFECTS IN RADIATION

- 34-1 Moving sources 34-1
- 34-2 Finding the "apparent" motion 34-2
- 34-3 Synchrotron radiation 34-3
- 34-4 Cosmic synchrotron radiation 34-6
- 34-5 Bremsstrahlung 34-6
- 34-6 The Doppler effect 34-7
- 34-7 The $\pm k$ four-vector 34-9
- 34-8 Aberration 34-10
- 34-9 The momentum of light 34-10

CHAPTER 35. COLOR VISION

- 35-1 The human eye 35-1
- 35-2 Color depends on intensity 35-2
- 35-3 Measuring the color sensation 35-3
- 35-4 The chromaticity diagram 35-6
- 35-5 The mechanism of color vision 35-7
- 35-6 Physiochemistry of color vision 35-9

CHAPTER 36. MECHANISMS OF SEEING

- 36-1 The sensation of color 36-1
- 36-2 The physiology of the eye 36-3
- 36-3 The rod cells 36-6
- 36-4 The compound (insect) eye 36-6
- 36-5 Other eyes 36-9
- 36-6 Neurology of vision 36-9

CHAPTER 37. QUANTUM BEHAVIOR

- 37-1 Atomic mechanics 37-1
- 37-2 An experiment with bullets 37-2
- 37-3 An experiment with waves 37-3
- 37-4 An experiment with electrons 37-4
- 37-5 The interference of electron waves 37-5
- 37-6 Watching the electrons 37-7
- 37-7 First principles of quantum mechanics 37-10
- 37-8 The uncertainty principle 37-11

CHAPTER 38. THE RELATION OF WAVE AND PARTICLE VIEWPOINTS

- 38-1 Probability wave amplitudes 38-1
- 38-2 Measurement of position and momentum 38-2
- 38-3 Crystal diffraction 38-4
- 38-4 The size of an atom 38-5

- 38-5 Energy levels 38-7
- 38-6 Philosophical implications 38-8

CHAPTER 39. THE KINETIC THEORY OF GASES

- 39-1 Properties of matter 39-1
- 39-2 The pressure of a gas 39-2
- 39-3 Compressibility of radiation 39-6
- 39-4 Temperature and kinetic energy 39-6
- 39-5 The ideal gas law 39-10

CHAPTER 40. THE PRINCIPLES OF STATISTICAL MECHANICS

- 40-1 The exponential atmosphere 40-1
- 40-2 The Boltzmann law 40-2
- 40-3 Evaporation of a liquid 40-3
- 40-4 The distribution of molecular speeds 40-4
- 40-5 The specific heats of gases 40-7
- 40-6 The failure of classical physics 40-8

CHAPTER 41. THE BROWNIAN MOVEMENT

- 41-1 Equipartition of energy 41-1
- 41-2 Thermal equilibrium of radiation 41-3
- 41-3 Equipartition and the quantum oscillator 41-6
- 41-4 The random walk 41-8

CHAPTER 42. APPLICATIONS OF KINETIC THEORY

- 42-1 Evaporation 42-1
- 42-2 Thermionic emission 42-4
- 42-3 Thermal ionization 42-5
- 42-4 Chemical kinetics 42-7
- 42-5 Einstein's laws of radiation 42-8

CHAPTER 43. DIFFUSION

- 43-1 Collisions between molecules 43-1
- 43-2 The mean free path 43-3
- 43-3 The drift speed 43-4
- 43-4 Ionic conductivity 43-6
- 43-5 Molecular diffusion 43-7
- 43-6 Thermal conductivity 43-9

CHAPTER 44. THE LAWS OF THERMODYNAMICS

- 44-1 Heat engines; the first law 44-1
- 44-2 The second law 44-3
- 44-3 Reversible engines 44-4
- 44-4 The efficiency of an ideal engine 44-7
- 44-5 The thermodynamic temperature 44-9
- 44-6 Entropy 44-10

CHAPTER 45. ILLUSTRATIONS OF THERMODYNAMICS

- 45-1 Internal energy 45-1
- 45-2 Applications 45-4
- 45-3 The Clausius-Clapeyron equation 45-6

CHAPTER 46. RATCHET AND PAWL

- 46-1 How a ratchet works 46-1
- 46-2 The ratchet as an engine 46-2
- 46-3 Reversibility in mechanics 46-4

Atoms in Motion

1-1 Introduction

This two-year course in physics is presented from the point of view that you, the reader, are going to be a physicist. This is not necessarily the case of course, but that is what every professor in every subject assumes! If you are going to be a physicist, you will have a lot to study: two hundred years of the most rapidly developing field of knowledge that there is. So much knowledge, in fact, that you might think that you cannot learn all of it in four years, and truly you cannot; you will have to go to graduate school too!

Surprisingly enough, in spite of the tremendous amount of work that has been done for all this time it is possible to condense the enormous mass of results to a large extent—that is, to find *laws* which summarize all our knowledge. Even so, the laws are so hard to grasp that it is unfair to you to start exploring this tremendous subject without some kind of map or outline of the relationship of one part of the subject of science to another. Following these preliminary remarks, the first three chapters will therefore outline the relation of physics to the rest of the sciences, the relations of the sciences to each other, and the meaning of science, to help us develop a "feel" for the subject.

You might ask why we cannot teach physics by just giving the basic laws on page one and then showing how they work in all possible circumstances, as we do in Euclidean geometry, where we state the axioms and then make all sorts of deductions. (So, not satisfied to learn physics in four years, you want to learn it in four minutes?) We cannot do it in this way for two reasons. First, we do not yet know all the basic laws: there is an expanding frontier of ignorance. Second, the correct statement of the laws of physics involves some very unfamiliar ideas which require advanced mathematics for their description. Therefore, one needs a considerable amount of preparatory training even to learn what the *words* mean. No, it is not possible to do it that way. We can only do it piece by piece.

Each piece, or part, of the whole of nature is always merely an *approximation to the complete truth*, or the complete truth so far as we know it. In fact, everything we know is only some kind of approximation, because *we know that we do not know all the laws* as yet. Therefore, things must be learned only to be unlearned again or, more likely, to be corrected.

The principle of science, the definition, almost, is the following: *The test of all knowledge is experiment*. Experiment is the *sole judge* of scientific "truth." But what is the source of knowledge? Where do the laws that are to be tested come from? Experiment, itself, helps to produce these laws, in the sense that it gives us hints. But also needed is *imagination* to create from these hints the great generalizations—to guess at the wonderful, simple, but very strange patterns beneath them all, and then to experiment to check again whether we have made the right guess. This imagining process is so difficult that there is a division of labor in physics: there are *theoretical* physicists who imagine, deduce, and guess at new laws, but do not experiment; and then there are *experimental* physicists who experiment, imagine, deduce, and guess.

We said that the laws of nature are approximate: that we first find the "wrong" ones, and then we find the "right" ones. Now, how can an experiment be "wrong"? First, in a trivial way: if something is wrong with the apparatus that you did not notice. But these things are easily fixed, and checked back and forth. So without snatching at such minor things, how *can* the results of an experiment be wrong? Only by being inaccurate. For example, the mass of an object never seems to

1-1 Introduction

1-2 Matter is made of atoms

1-3 Atomic processes

1-4 Chemical reactions

change; a spinning top has the same weight as a still one. So a "law" was invented: mass is constant, independent of speed. That "law" is now found to be incorrect. Mass is found to increase with velocity, but appreciable increases require velocities near that of light. A *true* law is: if an object moves with a speed of less than one hundred miles a second the mass is constant to within one part in a million. In some such approximate form this is a correct law. So in practice one might think that the new law makes no significant difference. Well, yes and no. For ordinary speeds we can certainly forget it and use the simple constant-mass law as a good approximation. But for high speeds we are wrong, and the higher the speed, the more wrong we are.

Finally, and most interesting, *philosophically we are completely wrong* with the approximate law. Our entire picture of the world has to be altered even though the mass changes only by a little bit. This is a very peculiar thing about the philosophy, or the ideas, behind the laws. Even a very small effect sometimes requires profound changes in our ideas.

Now, what should we teach first? Should we teach the *correct* but unfamiliar law with its strange and difficult conceptual ideas, for example the theory of relativity, four-dimensional space-time, and so on? Or should we first teach the simple "constant-mass" law, which is only approximate, but does not involve such difficult ideas? The first is more exciting, more wonderful, and more fun, but the second is easier to get at first, and is a first step to a real understanding of the second idea. This point arises again and again in teaching physics. At different times we shall have to resolve it in different ways, but at each stage it is worth learning what is now known, how accurate it is, how it fits into everything else, and how it may be changed when we learn more.

Let us now proceed with our outline, or general map, of our understanding of science today (in particular, physics, but also of other sciences on the periphery), so that when we later concentrate on some particular point we will have some idea of the background, why that particular point is interesting, and how it fits into the big structure. So, what *is* our over-all picture of the world?

1-2 Matter is made of atoms

If, in some cataclysm, all of scientific knowledge were to be destroyed, and only one sentence passed on to the next generations of creatures, what statement would contain the most information in the fewest words? I believe it is the *atomic hypothesis* (or the *atomic fact*, or whatever you wish to call it) that *all things are made of atoms—little particles that move around in perpetual motion, attracting each other when they are a little distance apart, but repelling upon being squeezed into one another*. In that one sentence, you will see, there is an *enormous* amount of information about the world, if just a little imagination and thinking are applied.

To illustrate the power of the atomic idea, suppose that we have a drop of water a quarter of an inch on the side. If we look at it very closely we see nothing but water—smooth, continuous water. Even if we magnify it with the best optical microscope available—roughly two thousand times—then the water drop will be roughly forty feet across, about as big as a large room, and if we looked rather closely, we would *still* see relatively smooth water—but here and there small football-shaped things swimming back and forth. Very interesting. These are paramecia. You may stop at this point and get so curious about the paramecia with their wiggling cilia and twisting bodies that you go no further, except perhaps to magnify the paramecia still more and see inside. This, of course, is a subject for biology, but for the present we pass on and look still more closely at the water material itself, magnifying it two thousand times again. Now the drop of water extends about fifteen miles across, and if we look very closely at it we see a kind of teeming, something which no longer has a smooth appearance—it looks something like a crowd at a football game as seen from a very great distance. In order to see what this teeming is about, we will magnify it another two hundred and fifty times and we will see something similar to what is shown in Fig. 1-1. This is a picture of water magnified a billion times, but idealized in several ways.

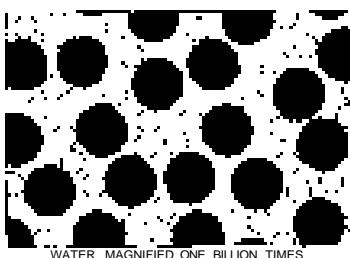

Figure 1-1

In the first place, the particles are drawn in a simple manner with sharp edges, which is inaccurate. Secondly, for simplicity, they are sketched almost schematically in a two-dimensional arrangement, but of course they are moving around in three dimensions. Notice that there are two kinds of "blobs" or circles to represent the atoms of oxygen (black) and hydrogen (white), and that each oxygen has two hydrogens tied to it. (Each little group of an oxygen with its two hydrogens is called a molecule.) The picture is idealized further in that the real particles in nature are continually jiggling and bouncing, turning and twisting around one another. You will have to imagine this as a dynamic rather than a static picture. Another thing that cannot be illustrated in a drawing is the fact that the particles are "stuck together"—that they attract each other, this one pulled by that one, etc. The whole group is "glued together," so to speak. On the other hand, the particles do not squeeze through each other. If you try to squeeze two of them too close together, they repel.

The atoms are 1 or 2×10^{-8} cm in radius. Now 10^{-8} cm is called an *angstrom* (just as another name), so we say they are 1 or 2 angstroms (\AA) in radius. Another way to remember their size is this: if an apple is magnified to the size of the earth, then the atoms in the apple are approximately the size of the original apple.

Now imagine this great drop of water with all of these jiggling particles stuck together and tagging along with each other. The water keeps its volume; it does not fall apart, because of the attraction of the molecules for each other. If the drop is on a slope, where it can move from one place to another, the water will flow, but it does not just disappear—things do not just fly apart—because of the molecular attraction. Now the jiggling motion is what we represent as *heat*: when we increase the temperature, we increase the motion. If we heat the water, the jiggling increases and the volume between the atoms increases, and if the heating continues there comes a time when the pull between the molecules is not enough to hold them together and they *do* fly apart and become separated from one another. Of course, this is how we manufacture steam out of water—by increasing the temperature; the particles fly apart because of the increased motion.

In Fig. 1-2 we have a picture of steam. This picture of steam fails in one respect: at ordinary atmospheric pressure there might be only a few molecules in a whole room, and there certainly would not be as many as three in this figure. Most squares this size would contain none—but we accidentally have two and a half or three in the picture (just so it would not be completely blank). Now in the case of steam we see the characteristic molecules more clearly than in the case of water. For simplicity, the molecules are drawn so that there is a 120° angle between them. In actual fact the angle is $105^\circ 3'$, and the distance between the center of a hydrogen and the center of the oxygen is 0.957 \AA , so we know this molecule very well.

Let us see what some of the properties of steam vapor or any other gas are. The molecules, being separated from one another, will bounce against the walls. Imagine a room with a number of tennis balls (a hundred or so) bouncing around in perpetual motion. When they bombard the wall, this pushes the wall away. (Of course we would have to push the wall back.) This means that the gas exerts a jittery force which our coarse senses (not being ourselves magnified a billion times) feels only as an *average push*. In order to confine a gas we must apply a pressure. Figure 1-3 shows a standard vessel for holding gases (used in all textbooks), a cylinder with a piston in it. Now, it makes no difference what the shapes of water molecules are, so for simplicity we shall draw them as tennis balls or little dots. These things are in perpetual motion in all directions. So many of them are hitting the top piston all the time that to keep it from being patiently knocked out of the tank by this continuous banging, we shall have to hold the piston down by a certain force, which we call the *pressure* (really, the pressure times the area is the force). Clearly, the force is proportional to the area, for if we increase the area but keep the number of molecules per cubic centimeter the same, we increase the number of collisions with the piston in the same proportion as the area was increased.

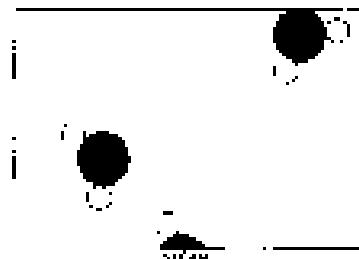

Figure 1-2

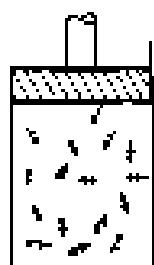

Figure 1-3

Now let us put twice as many molecules in this tank, so as to double the density, and let them have the same speed, i.e., the same temperature. Then, to a close approximation, the number of collisions will be doubled, and since each will be just as "energetic" as before, the pressure is proportional to the density. If we consider the true nature of the forces between the atoms, we would expect a slight decrease in pressure because of the attraction between the atoms, and a slight increase because of the finite volume they occupy. Nevertheless, to an excellent approximation, if the density is low enough that there are not many atoms, *the pressure is proportional to the density*.

We can also see something else: If we increase the temperature without changing the density of the gas, i.e., if we increase the speed of the atoms, what is going to happen to the pressure? Well, the atoms hit harder because they are moving faster, and in addition they hit more often, so the pressure increases. You see how simple the ideas of atomic theory are.

Let us consider another situation. Suppose that the piston moves inward, so that the atoms are slowly compressed into a smaller space. What happens when an atom hits the moving piston? Evidently it picks up speed from the collision. You can try it by bouncing a ping-pong ball from a forward-moving paddle, for example, and you will find that it comes off with more speed than that with which it struck. (Special example: if an atom happens to be standing still and the piston hits it, it will certainly move.) So the atoms are "hotter" when they come away from the piston than they were before they struck it. Therefore all the atoms which are in the vessel will have picked up speed. This means that *when we compress a gas slowly, the temperature of the gas increases*. So, under slow compression, a gas will increase in temperature, and under slow expansion it will decrease in temperature.

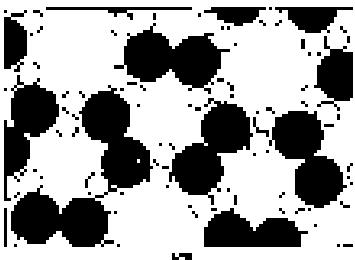

Figure 1-4

We now return to our drop of water and look in another direction. Suppose that we decrease the temperature of our drop of water. Suppose that the jiggling of the molecules of the atoms in the water is steadily decreasing. We know that there are forces of attraction between the atoms, so that after a while they will not be able to jiggle so well. What will happen at very low temperatures is indicated in Fig. 1-4: the molecules lock into a new pattern which is *ice*. This particular schematic diagram of ice is wrong because it is in two dimensions, but it is right qualitatively. The interesting point is that the material has a *definite place for every atom*, and you can easily appreciate that if somehow or other we were to hold all the atoms at one end of the drop in a certain arrangement, each atom in a certain place, then because of the structure of interconnections, which is rigid, the other end miles away (at our magnified scale) will have a definite location. So if we hold a needle of ice at one end, the other end resists our pushing it aside, unlike the case of water, in which the structure is broken down because of the increased jiggling so that the atoms all move around in different ways. The difference between solids and liquids is, then, that in a solid the atoms are arranged in some kind of an array, called a *crystalline array*, and they do not have a random position at long distances; the position of the atoms on one side of the crystal is determined by that of other atoms millions of atoms away on the other side of the crystal. Figure 1-4 is an invented arrangement for ice, and although it contains many of the correct features of ice, it is not the true arrangement. One of the correct features is that there is a part of the symmetry that is hexagonal. You can see that if we turn the picture around an axis by 120° , the picture returns to itself. So there is a *symmetry* in the ice which accounts for the six-sided appearance of snowflakes. Another thing we can see from Fig. 1-4 is why ice shrinks when it melts. The particular crystal pattern of ice shown here has many "holes" in it, as does the true ice structure. When the organization breaks down, these holes can be occupied by molecules. Most simple substances, with the exception of water and type metal, *expand* upon melting, because the atoms are closely packed in the solid crystal and upon melting need more room to jiggle around, but an open structure collapses, as in the case of water.

Now although ice has a "rigid" crystalline form, its temperature can change—ice has heat. If we wish, we can change the amount of heat. What is the heat in

the case of ice? The atoms are not standing still. They are jiggling and vibrating. So even though there is a definite order to the crystal—a definite structure—all of the atoms are vibrating "in place." As we increase the temperature, they vibrate with greater and greater amplitude, until they shake themselves out of place. We call this *melting*. As we decrease the temperature, the vibration decreases and decreases until, at absolute zero, there is a minimum amount of vibration that the atoms can have, but *not zero*. This minimum amount of motion that atoms can have is not enough to melt a substance, with one exception: helium. Helium merely decreases the atomic motions as much as it can, but even at absolute zero there is still enough motion to keep it from freezing. Helium, even at absolute zero, does not freeze, unless the pressure is made so great as to make the atoms squash together. If we increase the pressure, we *can* make it solidify.

1-3 Atomic processes

So much for the description of solids, liquids, and gases from the atomic point of view. However, the atomic hypothesis also describes *processes*, and so we shall now look at a number of processes from an atomic standpoint. The first process that we shall look at is associated with the surface of the water. What happens at the surface of the water? We shall now make the picture more complicated—and more realistic—by imagining that the surface is in air. Figure 1-5 shows the surface of water in air. We see the water molecules as before, forming a body of liquid water, but now we also see the surface of the water. Above the surface we find a number of things: First of all there are water molecules, as in steam. This is *water vapor*, which is always found above liquid water. (There is an equilibrium between the steam vapor and the water which will be described later.) In addition we find some other molecules—here two oxygen atoms stuck together by themselves, forming an *oxygen molecule*; there two nitrogen atoms also stuck together to make a nitrogen molecule. Air consists almost entirely of nitrogen, oxygen, some water vapor, and lesser amounts of carbon dioxide, argon, and other things. So above the water surface is the air, a gas, containing some water vapor. Now what is happening in this picture? The molecules in the water are always jiggling around. From time to time, one on the surface happens to be hit a little harder than usual, and gets knocked away. It is hard to see that happening in the picture because it is a *still* picture. But we can imagine that one molecule near the surface has just been hit and is flying out, or perhaps another one has been hit and is flying out. Thus, molecule by molecule, the water disappears—it evaporates. But if we *close* the vessel above, after a while we shall find a large number of molecules of water amongst the air molecules. From time to time, one of these vapor molecules comes flying down to the water and gets stuck again. So we see that what looks like a dead, uninteresting thing—a glass of water with a cover, that has been sitting there for perhaps twenty years—really contains a dynamic and interesting phenomenon which is going on all the time. To our eyes, our crude eyes, nothing is changing, but if we could see it a billion times magnified, we would see that from its own point of view it is always changing: molecules are leaving the surface, molecules are coming back.

Why do we see *no change*? Because just as many molecules are leaving as are coming back! In the long run "nothing happens." If we then take the top of the vessel off and blow the moist air away, replacing it with dry air, then the number of molecules leaving is just the same as it was before, because this depends on the jiggling of the water, but the number coming back is greatly reduced because there are so many fewer water molecules above the water. Therefore there are more going out than coming in, and the water evaporates. Hence, if you wish to evaporate water turn on the fan!

Here is something else: Which molecules leave? When a molecule leaves it is due to an accidental, extra accumulation of a little bit more than ordinary energy, which it needs if it is to break away from the attractions of its neighbors. Therefore, since those that leave have more energy than the average, the ones that are left have *less* average motion than they had before. So the liquid gradually

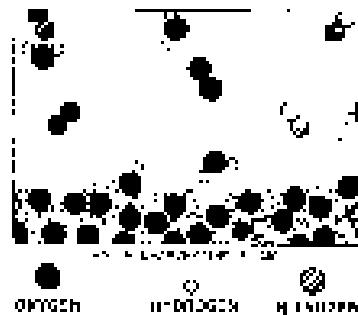

Figure 1-5

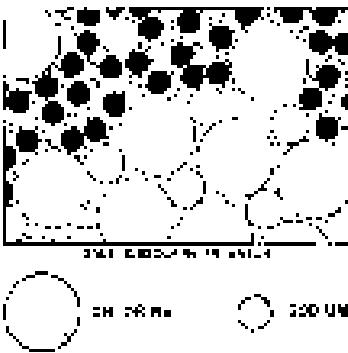

Figure 1-6

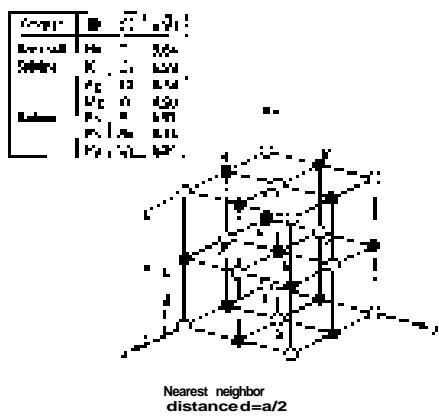

Figure 1-7

cools if it evaporates. Of course, when a molecule of vapor comes from the air to the water below there is a sudden great attraction as the molecule approaches the surface. This speeds up the incoming molecule and results in generation of heat. So when they leave they take away heat; when they come back they generate heat. Of course when there is no net evaporation the result is nothing—the water is not changing temperature. If we blow on the water so as to maintain a continuous preponderance in the number evaporating, then the water is cooled. Hence, blow on soup to cool it!

Of course you should realize that the processes just described are more complicated than we have indicated. Not only does the water go into the air, but also, from time to time, one of the oxygen or nitrogen molecules will come in and "get lost" in the mass of water molecules, and work its way into the water. Thus the air dissolves in the water; oxygen and nitrogen molecules will work their way into the water and the water will contain air. If we suddenly take the air away from the vessel, then the air molecules will leave more rapidly than they come in, and in doing so will make bubbles. This is very bad for divers, as you may know.

Now we go on to another process. In Fig. 1-6 we see, from an atomic point of view, a solid dissolving in water. If we put a crystal of salt in the water, what will happen? Salt is a solid, a crystal, an organized arrangement of "salt atoms." Figure 1-7 is an illustration of the three-dimensional structure of common salt, sodium chloride. Strictly speaking, the crystal is not made of atoms, but of what we call *ions*. An ion is an atom which either has a few extra electrons or has lost a few electrons. In a salt crystal we find chlorine ions (chlorine atoms with an extra electron) and sodium ions (sodium atoms with one electron missing). The ions all stick together by electrical attraction in the solid salt, but when we put them in the water we find, because of the attractions of the negative oxygen and positive hydrogen for the ions, that some of the ions jiggle loose. In Fig. 1-6 we see a chlorine ion getting loose, and other atoms floating in the water in the form of ions. This picture was made with some care. Notice, for example, that the hydrogen ends of the water molecules are more likely to be near the chlorine ion, while near the sodium ion we are more likely to find the oxygen end, because the sodium is positive and the oxygen end of the water is negative, and they attract electrically. Can we tell from this picture whether the salt is *dissolving in water* or *crystallizing out of water*? Of course we *cannot* tell, because while some of the atoms are leaving the crystal other atoms are rejoining it. The process is a *dynamic* one, just as in the case of evaporation, and it depends on whether there is more or less salt in the water than the amount needed for equilibrium. By equilibrium we mean that situation in which the rate at which atoms are leaving just matches the rate at which they are coming back. If there is almost no salt in the water, more atoms leave than return, and the salt dissolves. If, on the other hand, there are too many "salt atoms," more return than leave, and the salt is crystallizing.

In passing, we mention that the concept of a *molecule* of a substance is only approximate and exists only for a certain class of substances. It is clear in the case of water that the three atoms are actually stuck together. It is not so clear in the case of sodium chloride in the solid. There is just an arrangement of sodium and chlorine ions in a cubic pattern. There is no natural way to group them as "molecules of salt."

Returning to our discussion of solution and precipitation, if we increase the temperature of the salt solution, then the rate at which atoms are taken away is increased, and so is the rate at which atoms are brought back. It turns out to be very difficult, in general, to predict which way it is going to go, whether more or less of the solid will dissolve. Most substances dissolve more, but some substances dissolve less, as the temperature increases.

1-4 Chemical reactions

In all of the processes which have been described so far, the atoms and the ions have not changed partners, but of course there are circumstances in which the atoms do change combinations, forming new molecules. This is illustrated in

Fig. 1-8. A process in which the rearrangement of the atomic partners occurs is what we call a *chemical reaction*. The other processes so far described are called physical processes, but there is no sharp distinction between the two. (Nature does not care what we call it, she just keeps on doing it.) This figure is supposed to represent carbon burning in oxygen. In the case of oxygen, *two* oxygen atoms stick together very strongly. (Why do not *three* or *even four* stick together? That is one of the very peculiar characteristics of such atomic processes. Atoms are very special: they like certain particular partners, certain particular directions, and so on. It is the job of physics to analyze why each one wants what it wants. At any rate, two oxygen atoms form, saturated and happy, a molecule.)

The carbon atoms are supposed to be in a solid crystal (which could be graphite or diamond*). Now, for example, one of the oxygen molecules can come over to the carbon, and each atom can pick up a carbon atom and go flying off in a new combination—"carbon-oxygen"—which is a molecule of the gas called carbon monoxide. It is given the chemical name CO. It is very simple: the letters "CO" are practically a picture of that molecule. But carbon attracts oxygen much more than oxygen attracts oxygen or carbon attracts carbon. Therefore in this process the oxygen may arrive with only a little energy, but the oxygen and carbon will snap together with a tremendous vengeance and commotion, and everything near them will pick up the energy. A large amount of motion energy, kinetic energy, is thus generated. This of course is *burning*; we are getting *heat* from the combination of oxygen and carbon. The heat is ordinarily in the form of the molecular motion of the hot gas, but in certain circumstances it can be so enormous that it generates *light*. That is how one *gets flames*.

In addition, the carbon monoxide is not quite satisfied. It is possible for it to attach another oxygen, so that we might have a much more complicated reaction in which the oxygen is combining with the carbon, while at the same time there happens to be a collision with a carbon monoxide molecule. One oxygen atom could attach itself to the CO and ultimately form a molecule, composed of one carbon and two oxygens, which is designated CO₂ and called carbon dioxide. If we burn the carbon with very little oxygen in a very rapid reaction (for example, in an automobile engine, where the explosion is so fast that there is not time for it to make carbon dioxide) a considerable amount of carbon monoxide is formed. In many such rearrangements, a very large amount of energy is released, forming explosions, flames, etc., depending on the reactions. Chemists have studied these arrangements of the atoms, and found that every substance is some type of *arrangement of atoms*.

To illustrate this idea, let us consider another example. If we go into a field of small violets, we know what "that smell" is. It is some kind of *molecule*, or arrangement of atoms, that has worked its way into our noses. First of all, *how* did it work its way in? That is rather easy. If the smell is some kind of molecule in the air, jiggling around and being knocked every which way, it might have *accidentally* worked its way into the nose. Certainly it has no particular desire to get into our nose. It is merely one helpless part of a jostling crowd of molecules, and in its aimless wanderings this particular chunk of matter happens to find itself in the nose.

Now chemists can take special molecules like the odor of violets, and analyze them and tell us the *exact arrangement* of the atoms in space. We know that the carbon dioxide molecule is straight and symmetrical: O—C—O. (That can be determined easily, too, by physical methods.) However, even for the vastly more complicated arrangements of atoms that there are in chemistry, one can, by a long, remarkable process of detective work, find the arrangements of the atoms. Figure 1-9 is a picture of the air in the neighborhood of a violet; again we find nitrogen and oxygen in the air, and water vapor. (Why is there water vapor? Because the violet is *wet*. All plants transpire.) However, we also see a "monster" composed of carbon atoms, hydrogen atoms, and oxygen atoms, which have picked a certain particular pattern in which to be arranged. It is a much more complicated arrange-

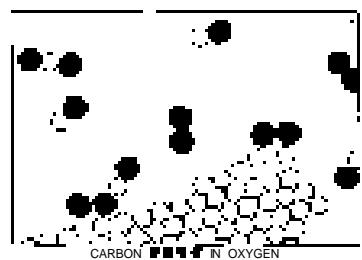

Figure 1-8

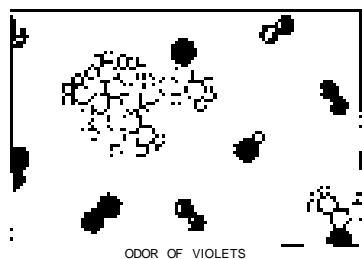

Figure 1-9

*One can burn a diamond in air.

ment than that of carbon dioxide; in fact, it is an enormously complicated arrangement. Unfortunately, we cannot picture all that is really known about it chemically, because the precise arrangement of all the atoms is actually known in three dimensions, while our picture is in only two dimensions. The six carbons which form a ring do not form a flat ring, but a kind of "puckered" ring. All of the angles and distances are known. So a chemical *formula* is merely a picture of such a molecule. When the chemist writes such a thing on the blackboard, he is trying to "draw," roughly speaking, in two dimensions. For example, we see a "ring" of six carbons, and a "chain" of carbons hanging on the end, with an oxygen second from the end, three hydrogens tied to that carbon, two carbons and three hydrogens sticking up here, etc.

How does the chemist find what the arrangement is? He mixes bottles full of stuff together, and if it turns red, it tells him that it consists of one hydrogen and two carbons tied on here; if it turns blue, on the other hand, that is not the way it is at all. This is one of the most fantastic pieces of detective work that has ever been done—organic chemistry. To discover the arrangement of the atoms in these enormously complicated arrays the chemist looks at what happens when he mixes two ~~different~~ substances together. The physicist could never quite believe that the chemist knew what he was talking about when he described the arrangement of the atoms. For about twenty years it has been possible, in some cases, to look at such molecules (not quite as complicated as this one, but some which contain parts of it) by a physical method, and it has been possible to locate every atom, not by looking at colors, but by *measuring where they are*. And lo and behold!, the chemists are almost always correct.

It turns out, in fact, that in the odor of violets there are three slightly different molecules, which differ only in the arrangement of the hydrogen atoms.

One problem of chemistry is to name a substance, so that we will know what it is. Find a name for this shape! Not only must the name tell the shape, but it must also tell that here is an oxygen atom, there a hydrogen—exactly what and where each atom is. So we can appreciate that the chemical names must be complex in order to be complete. You see that the name of this thing in the more complete form that will tell you the structure of it is 4-(2, 2, 3, 6 tetramethyl-5-cyclohexanyl)-3-buten-2-one, and that tells you that this is the arrangement. We can appreciate the difficulties that the chemists have, and also appreciate the reason for such long names. It is not that they wish to be obscure, but they have an extremely difficult problem in trying to describe the molecules in words!

How do we *know* that there are atoms? By one of the tricks mentioned earlier: we make the *hypothesis* that there are atoms, and one after the other results come out the way we predict, as they ought to if things *are* made of atoms. There is also somewhat more direct evidence, a good example of which is the following: The atoms are so small that you cannot see them with a light microscope—in fact, not even with an *electron* microscope. (With a light microscope you can only see things which are much bigger.) Now if the atoms are always in motion, say in water, and we put a big ball of something in the water, a ball much bigger than the atoms, the ball will jiggle around—much as in a push ball game, where a great big ball is pushed around by a lot of people. The people are pushing in various directions, and the ball moves around the field in an irregular fashion. So, in the same way, the "large ball" will move because of the inequalities of the collisions on one side to the other, from one moment to the next. Therefore, if we look at very tiny particles (colloids) in water through an excellent microscope, we see a perpetual jiggling of the particles, which is the result of the bombardment of the atoms. This is called the *Brownian motion*.

We can see further evidence for atoms in the structure of crystals. In many cases the structures deduced by x-ray analysis agree in their spatial "shapes" with the forms actually exhibited by crystals as they occur in nature. The angles between the various "faces" of a crystal agree, within seconds of arc, with angles deduced on the assumption that a crystal is made of many "layers" of atoms.

Everything is made of atoms. That is the key hypothesis. The most important hypothesis in all of biology, for example, is that *everything that animals do, atoms*

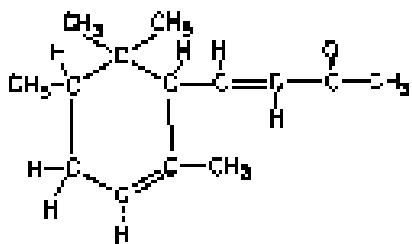

Fig. 1-10. The substance pictured is α-irone.

do. In other words, *there is nothing that living things do that cannot be understood from the point of view that they are made of atoms acting according to the laws of physics.* This was not known from the beginning: it took some experimenting and theorizing to suggest this hypothesis, but now it is accepted, and it is the most useful theory for producing new ideas in the field of biology.

If a piece of steel or a piece of salt, consisting of atoms one next to the other, can have such interesting properties; if water—which is nothing but these little blobs, mile upon mile of the same thing over the earth—can form waves and foam, and make rushing noises and strange patterns as it runs over cement; if all of this, all the life of a stream of water, can be nothing but a pile of atoms, *how much more is possible?* If instead of arranging the atoms in some definite pattern, again and again repeated, on and on, or even forming little lumps of complexity like the odor of violets, we make an arrangement which is *always different* from place to place, with different kinds of atoms arranged in many ways, continually changing, not repeating, how much more marvelously is it possible that this thing might behave? Is it possible that that "thing" walking back and forth in front of you, talking to you, is a great glob of these atoms in a very complex arrangement, such that the sheer complexity of it staggers the imagination as to what it can do? When we say we are a pile of atoms, we do not mean we are *merely* a pile of atoms, because a pile of atoms which is not repeated from one to the other might well have the possibilities which you see before you in the mirror.

Basic Physics

2-1 Introduction

In this chapter, we shall examine the most fundamental ideas that we have about physics—the nature of things as we see them at the present time. We shall not discuss the history of how we know that all these ideas are true; you will learn these details in due time.

The things with which we concern ourselves in science appear in myriad forms, and with a multitude of attributes. For example, if we stand on the shore and look at the sea, we see the water, the waves breaking, the foam, the sloshing motion of the water, the sound, the air, the winds and the clouds, the sun and the blue sky, and light; there is sand and there are rocks of various hardness and permanence, color and texture. There are animals and seaweed, hunger and disease, and the observer on the beach; there may be even happiness and thought. Any other spot in nature has a similar variety of things and influences. It is always as complicated as that, no matter where it is. Curiosity demands that we ask questions, that we try to put things together and try to understand this multitude of aspects as perhaps resulting from the action of a relatively small number of elemental things and forces acting in an infinite variety of combinations.

For example: Is the sand other than the rocks? That is, is the sand perhaps nothing but a great number of very tiny stones? Is the moon a great rock? If we understood rocks, would we also understand the sand and the moon? Is the wind a sloshing of the air analogous to the sloshing motion of the water in the sea? What common features do different movements have? What is common to different kinds of sound? How many different colors are there? And so on. In this way we try gradually to analyze all things, to put together things which at first sight look different, with the hope that we may be able to *reduce* the number of *different* things and thereby understand them better.

A few hundred years ago, a method was devised to find partial answers to such questions. *Observation, reason, and experiment* make up what we call the *scientific method*. We shall have to limit ourselves to a bare description of **our** basic view of what is sometimes called *fundamental physics*, or fundamental ideas which have arisen from the application of the scientific method.

What do we mean by "understanding" something? We can imagine that this complicated array of moving things which constitutes "the world" is something like a great chess game being played by the gods, and we are observers of the game. We do not know what the rules of the game are; all we are allowed to do is to *watch* the playing. Of course, if we watch long enough, we may eventually catch on to a few of the rules. *The rules of the game* are what we mean by *fundamental physics*. Even if we knew every rule, however, we might not be able to understand why a particular move is made in the game, merely because it is too complicated and our minds are limited. If you play chess you must know that it is easy to learn all the rules, and yet it is often very hard to select the best move or to understand why a player moves as he does. So it is in nature, only much more so; but we may be able at least to find all the rules. Actually, we do not have all the rules now. (Every once in a while something like castling is going on that we still do not understand.) Aside from not knowing all of the rules, what we really can explain in terms of those rules is very limited, because almost all situations are so enormously complicated that we cannot follow the plays of the game using the rules, much less tell what is going to happen next. We must, therefore, limit ourselves to the more basic question of the rules of the game. If we know the rules, we consider that we "understand" the world.

2-1 Introduction

2-2 Physics before 1920

2-3 Quantum physics

2-4 Nuclei and particles

How can we tell whether the rules which we "guess" at are really right if we cannot analyze the game very well? There are, roughly speaking, three ways. First, there may be situations where nature has arranged, or we arrange nature, to be simple and to have so few parts that we can predict exactly what will happen, and thus we can check how our rules work. (In one corner of the board there may be only a few chess pieces at work, and that we can figure out exactly.)

A second good way to check rules is in terms of less specific rules derived from them. For example, the rule on the move of a bishop on a chessboard is that it moves only on the diagonal. One can deduce, no matter how many moves may be made, that a certain bishop will always be on a red square. So, without being able to follow the details, we can always check our idea about the bishop's motion by finding out whether it is always on a red square. Of course it will be, for a long time, until all of a sudden we find that it is on a *black* square (what happened of course, is that in the meantime it was captured, another pawn crossed for queening, and it turned into a bishop on a black square). That is the way it is in physics. For a long time we will have a rule that works excellently in an over-all way, even when we cannot follow the details, and then some time we may discover a *new rule*. From the point of view of basic physics, the most interesting phenomena are of course in the *new* places, the places where the rules do not work—not the places where they *do* work! That is the way in which we discover new rules.

The third way to tell whether our ideas are right is relatively crude but probably the most powerful of them all. That is, by rough *approximation*. While we may not be able to tell why Alekhine moves *this particular piece*, perhaps we can *roughly* understand that he is gathering his pieces around the king to protect it, more or less, since that is the sensible thing to do in the circumstances. In the same way, we can often understand nature, more or less, without being able to see what *every little piece* is doing, in terms of our understanding of the game.

At first the phenomena of nature were roughly divided into classes, like heat, electricity, mechanics, magnetism, properties of substances, chemical phenomena, light or optics, x-rays, nuclear physics, gravitation, meson phenomena, etc. However, the aim is to see *complete nature* as different aspects of *one set* of phenomena. That is the problem in basic theoretical physics, today—to *find the laws behind experiment*; to *amalgamate these classes*. Historically, we have always been able to amalgamate them, but as time goes on new things are found. We were amalgamating very well, when all of a sudden x-rays were found. Then we amalgamated some more, and mesons were found. Therefore, at any stage of the game, it always looks rather messy. A great deal is amalgamated, but there are always many wires or threads hanging out in all directions. That is the situation today, which we shall try to describe.

Some historic examples of amalgamation are the following. First, take *heat* and *mechanics*. When atoms are in motion, the more motion, the more heat the system contains, and so *heat and all temperature effects can be represented by the laws of mechanics*. Another tremendous amalgamation was the discovery of the relation between electricity, magnetism, and light, which were found to be different aspects of the same thing, which we call today the *electromagnetic field*. Another amalgamation is the unification of chemical phenomena, the various properties of various substances, and the behavior of atomic particles, which is in the *quantum mechanics of chemistry*.

The question is, of course, is it going to be possible to amalgamate *everything*, and merely discover that this world represents different aspects of *one* thing? Nobody knows. All we know is that as we go along, we find that we can amalgamate pieces, and then we find some pieces that do not fit, and we keep trying to put the jigsaw puzzle together. Whether there are a finite number of pieces, and whether there is even a border to the puzzle, is of course unknown. It will never be known until we finish the picture, if ever. What we wish to do here is to see to what extent this amalgamation process has gone on, and what the situation is at present, in understanding basic phenomena in terms of the smallest set of principles. To express it in a simple manner, *what are things made of and how few elements are there?*

2-2 Physics before 1920

It is a little difficult to begin at once with the present view, so we shall first see how things looked in about 1920 and then take a few things out of that picture. Before 1920, our world picture was something like this: The "stage" on which the universe goes is the three-dimensional *space* of geometry, as described by Euclid, and things change in a medium called *time*. The elements on the stage are *particles*, for example the atoms, which have some *properties*. First, the property of inertia: if a particle is moving it keeps on going in the same direction unless *forces* act upon it. The second element, then, is *forces*, which were then thought to be of two varieties: First, an enormously complicated, detailed kind of interaction force which held the various atoms in different combinations in a complicated way, which determined whether salt would dissolve faster or slower when we raise the temperature. The other force that was known was a long-range interaction—a smooth and quiet attraction—which varied inversely as the square of the distance, and was called *gravitation*. This law was known and was very simple. *Why* things remain in motion when they are moving, or *why* there is a law of gravitation was, of course, not known.

A description of nature is what we are concerned with here. From this point of view, then, a gas, and indeed *all* matter, is a myriad of moving particles. Thus many of the things we saw while standing at the seashore can immediately be connected. First the pressure: this comes from the collisions of the atoms with the walls or whatever; the drift of the atoms, if they are all moving in one direction on the average, is wind; the *random* internal motions are the *heat*. There are waves of excess density, where too many particles have collected, and so as they push off they push up piles of particles farther out, and so on. This wave of excess density is *sound*. It is a tremendous achievement to be able to understand so much. Some of these things were described in the previous chapter.

What *kinds* of particles are there? There were considered to be 92 at that time: 92 different kinds of atoms were ultimately discovered. They had different names associated with their chemical properties.

The next part of the problem was, *what are the short-range forces?* Why does carbon attract one oxygen or perhaps two oxygens, but not three oxygens? What is the machinery of interaction between atoms? Is it gravitation? The answer is no. Gravity is entirely too weak. But imagine a force analogous to gravity, varying inversely with the square of the distance, but enormously more powerful and having one difference. In gravity everything attracts everything else, but now imagine that there are *two kinds* of "things," and that this new force (which is the electrical force, of course) has the property that likes *repel* but unlikes *attract*. The "thing" that carries this strong interaction is called *charge*.

Then what do we have? Suppose that we have two unlikes that attract each other, a plus and a minus, and that they stick very close together. Suppose we have another charge some distance away. Would it feel any attraction? It would feel *practically none*, because if the first two are equal in size, the attraction for the one and the repulsion for the other balance out. Therefore there is very little force at any appreciable distance. On the other hand, if we get *very close* with the extra charge, *attraction* arises, because the repulsion of likes and attraction of unlikes will tend to bring unlikes closer together and push likes farther apart. Then the repulsion will be *less* than the attraction. This is the reason why the atoms, which are constituted out of plus and minus electric charges, feel very little force when they are separated by appreciable distance (aside from gravity). When they come close together, they can "see inside" each other and rearrange their charges, with the result that they have a very strong interaction. The ultimate basis of an interaction between the atoms is *electrical*. Since this force is so enormous, all the plusses and all minuses will normally come together in as intimate a combination as they can. All things, even ourselves, are made of fine-grained, enormously strongly interacting plus and minus parts, all neatly balanced out. Once in a while, by accident, we may rub off a few minuses or a few plusses (usually it is easier to rub off minuses), and in those circumstances we find the force of electricity *unbalanced*, and we can then see the effects of these electrical attractions.

To give an idea of how much stronger electricity is than gravitation, consider two grains of sand, a millimeter across, thirty meters apart. If the force between them were not balanced, if everything attracted everything else instead of likes repelling, so that there were no cancellation, how much force would there be? There would be a force of *three million tons* between the two! You see, there is very, *very* little excess or deficit of the number of negative or positive charges necessary to produce appreciable electrical effects. This is, of course, the reason why you cannot see the difference between an electrically charged or uncharged thing—so few particles are involved that they hardly make a difference in the weight or size of an object.

With this picture the atoms were easier to understand. They were thought to have a "nucleus" at the center, which is positively electrically charged and very massive, and the nucleus is surrounded by a certain number of "electrons" which are very light and negatively charged. Now we go a little ahead in our story to remark that in the nucleus itself there were found two kinds of particles, protons and neutrons, almost of the same weight and very heavy. The protons are electrically charged and the neutrons are neutral. If we have an atom with six protons inside its nucleus, and this is surrounded by six electrons (the negative particles in the ordinary world of matter are all electrons, and these are very light compared with the protons and neutrons which make nuclei), this would be atom number six in the chemical table, and it is called carbon. Atom number eight is called oxygen, etc., because the chemical properties depend upon the electrons on the *outside*, and in fact only upon *how many* electrons there are. So the *chemical* properties of a substance depend only on a number, the number of electrons. (The whole list of elements of the chemists really could have been called 1, 2, 3, 4, 5, etc. Instead of saying "carbon," we could say "element six," meaning six electrons, but of course, when the elements were first discovered, it was not known that they could be numbered that way, and secondly, it would make everything look rather complicated. It is better to have names and symbols for these things, rather than to call everything by number.)

More was discovered about the electrical force. The natural interpretation of electrical interaction is that two objects simply attract each other: plus against minus. However, this was discovered to be an inadequate idea to represent it. A more adequate representation of the situation is to say that the existence of the positive charge, in some sense, distorts, or creates a "condition" in space, so that when we put the negative charge in, it feels a force. This potentiality for producing a force is called an *electric field*. When we put an electron in an electric field, we say it is "pulled." We then have two rules: (a) charges make a field, and (b) charges in fields have forces on them and move. The reason for this will become clear when we discuss the following phenomena: If we were to charge a body, say a comb, electrically, and then place a charged piece of paper at a distance and move the comb back and forth, the paper will respond by always pointing to the comb. If we shake it faster, it will be discovered that the paper is a little behind, *there is a delay* in the action. (At the first stage, when we move the comb rather slowly, we find a complication which is *magnetism*. Magnetic influences have to do with *charges in relative motion*, so magnetic forces and electric forces can really be attributed to one field, as two different aspects of exactly the same thing. A changing electric field cannot exist without magnetism.) If we move the charged paper farther out, the delay is greater. Then an interesting thing is observed. Although the forces between two charged objects should go inversely as the *square* of the distance, it is found, when we shake a charge, that the influence extends *very much farther out* than we would guess at first sight. That is, the effect falls off more slowly than the inverse square.

Here is an analogy: If we are in a pool of water and there is a floating cork very close by, we can move it "directly" by pushing the water with another cork. If you looked only at the two *corks*, all you would see would be that one moved immediately in response to the motion of the other—there is some kind of "*interaction*" between them. Of course, what we really do is to disturb the *water*; the *water* then disturbs the other cork. We could make up a "law" that if you pushed

the water a little bit, an object close by in the water would move. If it were farther away, of course, the second cork would scarcely move, for we move the water *locally*. On the other hand, if we jiggle the cork a new phenomenon is involved, in which the motion of the water moves the water there, etc., and *waves* travel away, so that by jiggling, there is an influence *wry much farther out*, an oscillatory influence, that cannot be understood from the direct interaction. Therefore the idea of direct interaction must be replaced with the existence of the water, or—in the electrical case, with what we call the *electromagnetic field*.

The electromagnetic field can carry waves; some of these waves are *light*, others are used in *radio broadcasts*, but the general name is *electromagnetic waves*. These oscillatory waves can have various *frequencies*. The only thing that is really different from one wave to another is the *frequency of oscillation*. If we shake a charge back and forth more and more rapidly, and look at the effects, we get a whole series of different kinds of effects, which are all unified by specifying but one number, the number of oscillations per second. The usual "pickup" that we get from electric currents in the circuits in the walls of a building have a frequency of about one hundred cycles per second. If we increase the frequency to 500 or 1000 kilocycles (1 kilocycle = 1000 cycles) per second, we are "on the air," for this is the frequency range which is used for radio broadcasts. (Of course it has nothing to do with the *air!* We can have radio broadcasts without any air.) If we again increase the frequency, we come into the range that is used for FM and TV. Going still further, we use certain short waves, for example for *radar*. Still higher, and we do not need an instrument to "see" the stuff, we can see it with the human eye. In the range of frequency from 5×10^{14} to 5×10^{15} cycles per second our eyes would see the oscillation of the charged comb, if we could shake it that fast, as red, blue, or violet light, depending on the frequency. Frequencies below this range are called infrared, and above it, ultraviolet. The fact that we can see in a particular frequency range makes that part of the electromagnetic spectrum no more impressive than the other parts from a physicist's standpoint, but from a human standpoint, of course, it *is* more interesting. If we go up even higher in frequency, we get x-rays. X-rays are nothing but very high-frequency light. If we go still higher, we get gamma rays. These two terms, x-rays and gamma rays, are used almost synonymously. Usually electromagnetic rays coming from nuclei are called gamma rays, while those of high energy from atoms are called x-rays, but at the same frequency they are indistinguishable physically, no matter what their source. If we go to still higher frequencies, say to 10^{24} cycles per second, we find that we can make those waves artificially, for example with the synchrotron here at Caltech. We can find electromagnetic waves with stupendously high frequencies—with even a thousand times more rapid oscillation—in the waves found in *cosmic rays*. These waves cannot be controlled by us.

Table 2-1
The Electromagnetic Spectrum

Freq. per sec. in oscillations/sec.	Name	Rough Example
10^2	Electrical disturbance	Wind
$5 \times 10^4 - 10^5$	Radio broadcast	
10^5	FM—TV	
10^{10}	Radar	Waves
$5 \times 10^{14} - 10^{15}$	Light	
10^{17}	X rays	
10^{20}	γ rays, nuclear	
10^{22}	γ rays, "artificial"	Particle
10^{24}	γ rays, in cosmic rays	

2-3 Quantum physics

Having described the idea of the electromagnetic field, and that this field can carry waves, we soon learn that these waves actually behave in a strange way which seems very unwavelike. At higher frequencies they behave much more like *particles!* It is *quantum mechanics*, discovered just after 1920, which explains this strange behavior. In the years before 1920, the picture of space as a three-dimensional space, and of time as a separate thing, was changed by Einstein, first into a combination which we call space-time, and then still further into a *curved* space-time to represent gravitation. So the "stage" is changed into space-time, and gravitation is presumably a modification of space-time. Then it was also found that the rules for the motions of particles were incorrect. The mechanical rules of "inertia" and "forces" are *wrong*—Newton's laws are *wrong*—in the world of atoms. Instead, it was discovered that things on a small scale behave *nothing like* things on a large scale. That is what makes physics difficult—and very interesting. It is hard because the way things behave on a small scale is so "unnatural"; we have no direct experience with it. Here things behave like nothing we know of, so that it is impossible to describe this behavior in any other than analytic ways. It is difficult, and takes a lot of imagination.

Quantum mechanics has many aspects. In the first place, the idea that a particle has a definite location and a definite speed is no longer allowed; that is wrong. To give an example of how wrong classical physics is, there is a rule in quantum mechanics that says that one cannot know both where something is and how fast it is moving. The uncertainty of the momentum and the uncertainty of the position are complementary, and the product of the two is constant. We can write the law like this: $Dx Dp \geq h/2p$, but we shall explain it in more detail later. This rule is the explanation of a very mysterious paradox: if the atoms are made out of plus and minus charges, why don't the minus charges simply sit on top of the plus charges (they attract each other) and get so close as to completely cancel them out? *Why are atoms so big?* Why is the nucleus at the center with the electrons around it? It was first thought that this was because the nucleus was so big; but no, the nucleus is *very small*. An atom has a diameter of about 10^{-8} cm. The nucleus has a diameter of about 10^{-13} cm. If we had an atom and wished to see the nucleus, we would have to magnify it until the whole atom was the size of a large room, and then the nucleus would be a bare speck which you could just about make out with the eye, but very nearly *all the weight* of the atom is in that infinitesimal *nucleus*. What keeps the electrons from simply falling in? This principle: If they were in the nucleus, we would know their position precisely, and the uncertainty principle would then require that they have a very *large* (but uncertain) momentum, i.e., a very large *kinetic energy*. With this energy they would break away from the nucleus. They make a compromise: they leave themselves a little room for this uncertainty and then jiggle with a certain amount of minimum motion in accordance with this rule. (Remember that when a crystal is cooled to absolute zero, we said that the atoms do not stop moving, they still jiggle. Why? If they stopped moving, we would know where they were and that they had zero motion, and that is against the uncertainty principle. We cannot know where they are and how fast they are moving, so they must be continually wiggling in there!)

Another most interesting change in the ideas and philosophy of science brought about by quantum mechanics is this: it is not possible to predict *exactly* what will happen in any circumstance. For example, it is possible to arrange an atom which is ready to emit light, and we can measure when it has emitted light by picking up a photon particle, which we shall describe shortly. We cannot, however, predict *when* it is going to emit the light or, with several atoms, *which one* is going to. You may say that this is because there are some internal "wheels" which we have not looked at closely enough. No, there *are* no internal wheels; nature, as we understand it today, behaves in such a way that *it is fundamentally impossible* to make a precise prediction of *exactly what will happen* in a given experiment. This is a horrible thing; in fact, philosophers have said before that one of the fundamental requisites of science is that whenever you set **up** the same

conditions, the same thing must happen. This is simply *not true*, it is *not* a fundamental condition of science. The fact is that the same thing does not happen, that we can find only an average, statistically, **as to** what happens. Nevertheless, science has not completely collapsed. Philosophers, incidentally, say a great deal about what is *absolutely necessary* for science, and it is always, so far as one can see, rather naive, and probably wrong. For example, some philosopher or other said it is fundamental to the scientific effort that if an experiment is performed in, say, Stockholm, and then the same experiment is done in, say, Quito, the *same results* must occur. That is quite false. It is not necessary that *science* do that; it may be a *fact of experience*, but it is not necessary. For example, if one of the experiments is to look out at the sky and see the aurora borealis in Stockholm, you do not see it in Quito; that is a different phenomenon. "But," you say, "that is something that has to do with the outside; can you close yourself up in a box in Stockholm and pull down the shade and get any difference?" Surely. If we take a pendulum on a universal joint, and pull it out and let go, then the pendulum will swing almost in a plane, but not quite. Slowly the plane keeps changing in Stockholm, but not in Quito. The blinds are down, too. The fact that this happened does not bring on the destruction of science. What *is* the fundamental hypothesis of science, the fundamental philosophy? We stated it in the first chapter: *the sole test of the validity of any idea is experiment*. If it turns out that most experiments work out the same in Quito as they do in Stockholm, then those "most experiments" will be used to formulate some general law, and those experiments which do not come out the same we will say were a result of the environment near Stockholm. We will invent some way to summarize the results of the experiment, and we do not have to be told ahead of time what this way will look like. If we are told that the same experiment will always produce the same result, that is all very well, but if when we try it, it does *not*, then it does *not*. We just have to take what we see, and then formulate all the rest of our ideas in terms of our actual experience.

Returning again to quantum mechanics and fundamental physics, we cannot go into details of the quantum-mechanical principles at this time, of course, because these are rather difficult to understand. We shall assume that they are there, and go on to describe what some of the consequences are. One of the consequences is that things which we used to consider as waves also behave like particles, and particles behave like waves; in fact everything behaves the same way. There is no distinction between a wave and a particle. So quantum mechanics *unifies* the idea of the field and its waves, and the particles, all into one. Now it is true that when the frequency is low, the field aspect of the phenomenon is more evident, or more useful as an approximate description in terms of everyday experiences. But as the frequency increases, the particle aspects of the phenomenon become more evident with the equipment with which we usually make the measurements. In fact, although we mentioned many frequencies, no phenomenon directly involving a frequency has yet been detected above approximately 10^{12} cycles per ~~second~~. We only *deduce* the higher frequencies from the energy of the particles, by a rule which assumes that the particle-wave idea of quantum mechanics is valid.

Thus we have a new view of electromagnetic interaction. We have a new kind of *particle* to add to the electron, the proton, and the neutron. That new particle is called a *photon*. The new view of the interaction of electrons and protons that is electromagnetic theory, but with everything quantum-mechanically correct, is called *quantum electrodynamics*. This fundamental theory of the interaction of light and matter, or electric field and charges, is our greatest success so far in physics. In this one theory we have the basic rules for all ordinary phenomena except for gravitation and nuclear processes. For example, out of quantum electrodynamics come all known electrical, mechanical, and chemical laws: the laws for the collision of billiard balls, the motions of wires in magnetic fields, the specific heat of carbon monoxide, the color of neon signs, the density of salt, and the reactions of hydrogen and oxygen to make water are all consequences of this one law. All these details can be worked out if the situation is simple enough for us to make an approximation, which is almost never, but often we can understand more

or less what is happening. At the present time no exceptions are found to the quantum-electrodynamic laws outside the nucleus, and there we do not know whether there is an exception because we simply do not know what is going on in the nucleus.

In principle, then, quantum electrodynamics is the theory of all chemistry, and of life, if life is ultimately reduced to chemistry and therefore just to physics because chemistry is already reduced (the part of physics which is involved in chemistry being already known). Furthermore, the same quantum electrodynamics, this great thing, predicts a lot of new things. In the first place, it tells the properties of very high-energy photons, gamma rays, etc. It predicted another very remarkable thing: besides the electron, there should be another particle of the same mass, but of opposite charge, called a *positron*, and these two, coming together, could annihilate each other with the emission of light or gamma rays. (After all, light and gamma rays are all the same, they are just different points on a frequency scale.) The generalization of this, that for each particle there is an antiparticle, turns out to be true. In the case of electrons, the antiparticle has another name—it is called a positron, but for most other particles, it is called anti-so-and-so, like antiproton or antineutron. In quantum electrodynamics, *two numbers* are put in and most of the other numbers in the world are supposed to come out. The two numbers that are put in are called the mass of the electron and the charge of the electron. Actually, that is not quite true, for we have a whole set of numbers for chemistry which tells how heavy the nuclei are. That leads us to the next part.

2-4 Nuclei and particles

What are the nuclei made of, and how are they held together? It is found that the nuclei are held together by enormous forces. When these are released, the energy released is tremendous compared with chemical energy, in the same ratio as the atomic bomb explosion is to a TNT explosion, because, of course, the atomic bomb has to do with changes inside the nucleus, while the explosion of TNT has to do with the changes of the electrons on the outside of the atoms. The question is, what are the forces which hold the protons and neutrons together in the nucleus? Just as the electrical interaction can be connected to a particle, a photon, Yukawa suggested that the forces between neutrons and protons also have a field of some kind, and that when this field jiggles it behaves like a particle. Thus there could be some other particles in the world besides protons and neutrons, and he was able to deduce the properties of these particles from the already known characteristics of nuclear forces. For example, he predicted they should have a mass of two or three hundred times that of an electron; and lo and behold, in cosmic rays there was discovered a particle of the right mass! But it later turned out to be the wrong particle. It was called a m-meson, or muon.

However, a little while later, in 1947 or 1948, another particle was found, the p-meson, or pion, which satisfied Yukawa's criterion. Besides the proton and the neutron, then, in order to get nuclear forces we must add the pion. Now, you say, "Oh great!, with this theory we make quantum nucleodynamics using the pions just like Yukawa wanted to do, and see if it works, and everything will be explained." Bad luck. It turns out that the calculations that are involved in this theory are so difficult that no one has ever been able to figure out what the consequences of the theory are, or to check it against experiment, and this has been going on now for almost twenty years!

So we are stuck with a theory, and we do not know whether it is right or wrong, but we do know that it is a *little* wrong, or at least incomplete. While we have been dawdling around theoretically, trying to calculate the consequences of this theory, the experimentalists have been discovering some things. For example, they had already discovered this m-meson or muon, and we do not yet know where it fits. Also, in cosmic rays, a large number of other "extra" particles were found. It turns out that today we have approximately thirty particles, and it is very difficult to understand the relationships of all these particles, and what nature

, wants them for, or what the connections are from one to another. We do not today understand these various particles as different aspects of the same thing, and the fact that we have so many unconnected particles is a representation of the fact that we have so much unconnected information without a good theory. After the great successes of quantum electrodynamics, there is a certain amount of knowledge of nuclear physics which is rough knowledge, sort of half experience and half theory, assuming a type of force between protons and neutrons and seeing what will happen, but not really understanding where the force comes from. Aside from that, we have made very little progress. We have collected an enormous number of chemical elements. In the chemical case, there suddenly appeared a relationship among these elements which was unexpected, and which is embodied in the periodic table of Mendeleev. For example, sodium and potassium are about the same in their chemical properties and are found in the same column in the Mendeleev chart. We have been seeking a Mendeleev-type chart for the new particles. One such chart of the new particles was made independently by Gell-Mann in the U.S.A. and Nishijima in Japan. The basis of their classification is a new number, like the electric charge, which can be assigned to each particle, called its "strangeness," S . This number is conserved, like the electric charge, in reactions which take place by nuclear forces.

In Table 2-2 are listed all the particles. We cannot discuss them much at this stage, but the table will at least show you how much we do not know. Underneath each particle its mass is given in a certain unit, called the Mev. One Mev is equal to 1.782×10^{-27} gram. The reason this unit was chosen is historical, and we shall not go into it now. More massive particles are put higher up on the chart; we see that a neutron and a proton have almost the same mass. In vertical columns we have put the particles with the same electrical charge, all neutral objects in one column, all positively charged ones to the right of this one, and all negatively charged objects to the left.

Particles are shown with a solid line and "resonances" with a dashed one. Several particles have been omitted from the table. These include the important zero-mass, zero-charge particles, the photon and the graviton, which do not fall into the baryon-meson-lepton classification scheme, and also some of the newer resonances (K^* , η , r). The antiparticles of the mesons are listed in the table, but the antiparticles of the leptons and baryons would have to be listed in another table which would look exactly like this one reflected on the zero-charge column. Although all of the particles except the electron, neutrino, photon, graviton, and proton are unstable, decay products have been shown only for the resonances. Strangeness assignments are not applicable for leptons, since they do not interact strongly with nuclei.

All particles which are together with the neutrons and protons are called *baryons*, and the following ones exist: There is a "lambda," with a mass of 1154 Mev, and three others, called sigmas, minus, neutral, and plus, with several masses almost the same. There are groups or multiplets with almost the same mass, within one or two percent. Each particle in a *multiplet* has the same strangeness. The first *multiplet* is the proton-neutron doublet, and then there is a singlet (the lambda) then the sigma triplet, and finally the xi doublet. Very recently, in 1961, even a few more particles were found. Or *are* they particles? They live so short a time, they disintegrate almost instantaneously, as soon as they are formed, that we do not know whether they should be considered as new particles, or some kind of "resonance" interaction of a certain definite energy between the A and T products into which they disintegrate.

In addition to the baryons the other particles which are involved in the nuclear interaction are called *mesons*. There are first the pions, which come in three varieties, positive, negative, and neutral; they form another multiplet. We have also found some new things called A' -mesons, and they occur as a doublet, π^+ and K^0 . Also, every particle has its antiparticle, unless a particle is *its own* antiparticle. For example, the π^- and the π^+ are antiparticles, but the π^0 is its own antiparticle. The K^- and K^+ are antiparticles, and the K^0 and K^0 . In addition, in 1961 we also found some more mesons or *maybe* mesons which disintegrate almost immediately.

Table 2-2. Elementary Particles

MASs	-E	CHARGE	STRANGENESS
π^-	$\frac{1}{2} -$	$\frac{1}{2} -$	$S = 0$
π^0	$\frac{1}{2} 0$	$\frac{1}{2} 0$	$S = 0$

$\Lambda^+</math$			

A thing called w which goes into three pions has a mass 780 on this scale, and somewhat less certain is an object which disintegrates into two pions. These particles, called mesons and baryons, and the antiparticles of the mesons are on the same chart, but the antiparticles of the baryons must be put on another chart, "reflected" through the charge-zero column.

Just as Mendeleev's chart was very good, except for the fact that there were a number of rare earth elements which were hanging out loose from it, so we have a number of things hanging out loose from this chart—particles which do not interact strongly in nuclei, have nothing to do with a nuclear interaction, and do not have a strong interaction (I mean the powerful kind of interaction of nuclear energy). These are called leptons, and they are the following: there is the electron, which has a very small mass on this scale, only 0.510 Mev. Then there is that other, the μ meson, the muon, which has a mass much higher, 206 times as heavy as an electron. So far as we can tell, by all experiments so far, the difference between the electron and the muon is nothing but the mass. Everything works exactly the same for the muon as for the electron, except that one is heavier than the other. Why is there another one heavier; what is the use for it? We do not know. In addition, there is a lepton which is neutral, called a neutrino, and this particle has zero mass. In fact, it is now known that there are *two* different kinds of neutrinos, one related to electrons and the other related to muons.

Finally, we have two other particles which do not interact strongly with the nuclear ones: one is a photon, and perhaps, if the field of gravity also has a quantum-mechanical analog (a quantum theory of gravitation has not yet been worked out), then there will be a particle, a graviton, which will have zero mass.

What is this "zero mass"? The masses given here are the masses of the particles *at rest*. The fact that a particle has zero mass means, in a way, that it cannot *be at rest*. A photon is never at rest, it is always moving at 186,000 miles a second. We will understand more what mass means when we understand the theory of relativity, which will come in due time.

Thus we are confronted with a large number of particles, which together seem to be the fundamental constituents of matter. Fortunately, these particles are not *all* different in their *interactions* with one another. In fact, there seem to be just *four kinds* of interaction between particles which, in the order of decreasing strength, are the nuclear force, electrical interactions, the beta-decay interaction, and gravity. The photon is coupled to all charged particles and the strength of the interaction is measured by some number, which is 1/137. The detailed law of this coupling is known, that is quantum electrodynamics. Gravity is coupled to all *energy*, but its coupling is extremely weak, much weaker than that of electricity. This law is also known. Then there are the so-called weak decays—beta decay, which causes the neutron to disintegrate into proton, electron, and neutrino, relatively slowly. This law is only partly known. The so-called strong interaction, the meson-baryon interaction, has a strength of 1 in this scale, and the law is completely unknown, although there are a number of known rules, such as that the number of baryons does not change in any reaction.

Table 2-3. Elementary Interactions

Coupling	Strength*	Law
Photon to charged particles	$\sim 10^{-4}$	Law known
Gravity to all energy	$\sim 10^{-5}$	known
Weak decays	Law $\sim 10^{-5}$	known
Mesons to baryons	~ 1	Law unknown (some rules known)

* The "strength" is a dimensionless measure of the coupling constant involved in each interaction (\sim means "approximately").

This then, is the horrible condition of our physics today. To summarize it, I would say this: outside the nucleus, we seem to know all; inside it, quantum mechanics is valid—the principles of quantum mechanics have not been found to fail. The stage on which we put all of our knowledge, we would say, is relativistic space-time; perhaps gravity is involved in space-time. We do not know how the universe got started, and we have never made experiments which check our ideas of space and time accurately, below some tiny distance, so we only *know* that our ideas work above that distance. We should also add that the rules of the game are the quantum-mechanical principles, and those principles apply, so far as we can tell, to the new particles as well as to the old. The origin of the forces in nuclei leads us to new particles, but unfortunately they appear in great profusion and we lack a complete understanding of their interrelationship, although we already know that there are some very surprising relationships among them. We seem gradually to be groping toward an understanding of the world of subatomic particles, but we really do not know how far we have yet to go in this task.

The Relation of Physics to Other Sciences

3-1 Introduction

Physics is the most fundamental and all-inclusive of the sciences, and has had a profound effect on all scientific development. In fact, physics is the present-day equivalent of what used to be called *natural philosophy*, from which most of our modern sciences arose. Students of many fields find themselves studying physics because of the basic role it plays in all phenomena. In this chapter we shall try to explain what the fundamental problems in the other sciences are, but of course it is impossible in so small a space really to deal with the complex, subtle, beautiful matters in these other fields. Lack of space also prevents our discussing the relation of physics to engineering, industry, society, and war, or even the most remarkable relationship between mathematics and physics. (Mathematics is not a science from our point of view, in the sense that it is not a *natural* science. The test of its validity is not experiment.) We must, incidentally, make it clear from the beginning that if a thing is not a science, it is not necessarily bad. For example, love is not a science. So, if something is said not to be a science, it does not mean that there is something wrong with it; it just means that it is not a science.

3-2 Chemistry

The science which is perhaps the most deeply affected by physics is chemistry. Historically, the early days of chemistry dealt almost entirely with what we now call inorganic chemistry, the chemistry of substances which are not associated with living things. Considerable analysis was required to discover the existence of the many elements and their relationships—how they make the various relatively simple compounds found in rocks, earth, etc. This early chemistry was very important for physics. The interaction between the two sciences was very great because the theory of atoms was substantiated to a large extent by experiments in chemistry. The theory of chemistry, i.e., of the reactions themselves, was summarized to a large extent in the periodic chart of Mendeleev, which brings out many strange relationships among the various elements, and it was the collection of rules as to which substance is combined with which, and how, that constituted inorganic chemistry. All these rules were ultimately explained in principle by quantum mechanics, so that theoretical chemistry is in fact physics. On the other hand, it must be emphasized that this explanation is *in principle*. We have already discussed the difference between knowing the rules of the game of chess, and being able to play. So it is that we may know the rules, but we cannot play very well. It turns out to be very difficult to predict precisely what will happen in a given chemical reaction; nevertheless, the deepest part of theoretical chemistry must end up in quantum mechanics.

There is also a branch of physics and chemistry which was developed by both sciences together, and which is extremely important. This is the method of statistics applied in a situation in which there are mechanical laws, which is aptly called *statistical mechanics*. In any chemical situation a large number of atoms are involved, and we have seen that the atoms are all jiggling around in a very random and complicated way. If we could analyze each collision, and be able to follow in detail the motion of each molecule, we might hope to figure out what would happen, but the many numbers needed to keep track of all these molecules exceeds so enormously the capacity of any computer, and certainly the capacity of

3-5 Geology

3-6 Psychology

3-7 How did it get that way?

the mind, that it was important to develop a method for dealing with such complicated situations. Statistical mechanics, then, is the science of the phenomena of heat, or thermodynamics. Inorganic chemistry is, as a science, now reduced essentially to what are called physical chemistry and quantum chemistry; physical chemistry to study the rates at which reactions occur and what is happening in detail (How do the molecules hit? Which pieces fly off first?, etc.), and quantum chemistry to help us understand what happens in terms of the physical laws.

The other branch of chemistry is *organic chemistry*, the chemistry of the substances which are associated with living things. For a time it was believed that the substances which are associated with living things were so marvelous that they could not be made by hand, from inorganic materials. This is not at all true—they are just the same as the substances made in inorganic chemistry, but more complicated arrangements of atoms are involved. Organic chemistry obviously has a very close relationship to the biology which supplies its substances, and to industry, and furthermore, much physical chemistry and quantum mechanics can be applied to organic as well as to inorganic compounds. However, the main problems of organic chemistry are not in these aspects, but rather in the analysis and synthesis of the substances which are formed in biological systems, in living things. This leads imperceptibly, in steps, toward biochemistry, and then into biology itself, or molecular biology.

3-3 Biology

Thus we come to the science of *biology*, which is the study of living things. In the early days of biology, the biologists had to deal with the purely descriptive problem of finding out *what* living things there were, and so they just had to count such things as the hairs of the limbs of fleas. After these matters were worked out with a great deal of interest, the biologists went into the *machinery* inside the living bodies, first from a gross standpoint, naturally, because it takes some effort to get into the finer details.

There was an interesting early relationship between physics and biology in which biology helped physics in the discovery of the *conservation of energy*, which was first demonstrated by Mayer in connection with the amount of heat taken in and given out by a living creature.

If we look at the processes of biology of living animals more closely, we see many physical phenomena: the circulation of blood, pumps, pressure, etc. There are nerves: we know what is happening when we step on a sharp stone, and that somehow or other the information goes from the leg up. It is interesting how that happens. In their study of nerves, the biologists have come to the conclusion that nerves are very fine tubes with a complex wall which is very thin; through this wall the cell pumps ions, so that there are positive ions on the outside and negative ions on the inside, like a capacitor. Now this membrane has an interesting property; if it "discharges" in one place, i.e., if some of the ions were able to move through one place, so that the electric voltage is reduced there, that electrical influence makes itself felt on the ions in the neighborhood, and it affects the membrane in such a way that it lets the ions through at neighboring points also. This in turn affects it farther along, etc., and so there is a wave of "penetrability" of the membrane which runs down the fiber when it is "excited" at one end by stepping on the sharp stone. This wave is somewhat analogous to a long sequence of vertical dominoes; if the end one is pushed over, that one pushes the next, etc. Of course this will transmit only one message unless the dominoes are set up again; and similarly in the nerve cell, there are processes which pump the ions slowly out again, to get the nerve ready for the next impulse. So it is that we know what we are doing (or at least where we are). Of course the electrical effects associated with this nerve impulse can be picked up with electrical instruments, and because there *are* electrical effects, obviously the physics of electrical effects has had a great deal of influence on understanding the phenomenon.

The opposite effect is that, from somewhere in the brain, a message is sent out along a nerve. What happens at the end of the nerve? There the nerve branches

out into fine little things, connected to a structure near a muscle, called an end-plate. For reasons which are not exactly understood, when the impulse reaches the end of the nerve, little packets of a chemical called acetylcholine are shot off (five or ten molecules at a time) and they affect the muscle fiber and make it contract—how simple! What makes a muscle contract? A muscle is a very large number of fibers close together, containing two different substances, myosin and actomyosin, but the machinery by which the chemical reaction induced by acetylcholine can modify the dimensions of the molecule is not yet known. Thus the fundamental processes in the muscle that make mechanical motions are not known.

Biology is such an enormously wide field that there are hosts of other problems that we cannot mention at all—problems on how vision works (what the light does in the eye), how hearing works, etc. (The way in which *thinking* works we shall discuss later under psychology.) Now, these things concerning biology which we have just discussed are, from a biological standpoint, really not fundamental, at the bottom of life, in the sense that even if we understood them we still would not understand life itself. To illustrate: the men who study nerves feel their work is very important, because after all you cannot have animals without nerves. But you *can* have *life* without nerves. Plants have neither nerves nor muscles, but they are working, they are alive, just the same. So for the fundamental problems of biology we must look deeper; when we do, we discover that all living things have a great many characteristics in common. The most common feature is that they are made of *cells*, within each of which is complex machinery for doing things chemically. In plant cells, for example, there is machinery for picking up light and generating sucrose, which is consumed in the dark to keep the plant alive. When the plant is eaten the sucrose itself generates in the animal a series of chemical reactions very closely related to photosynthesis (and its opposite effect in the dark) in plants.

In the cells of living systems there are many elaborate chemical reactions, in which one compound is changed into another and another. To give some impression of the enormous efforts that have gone into the study of biochemistry, the chart in Fig. 3-1 summarizes our knowledge to date on just one small part of the many series of reactions which occur in cells, perhaps a percent or so of it.

Here we see a whole series of molecules which change from one to another in a sequence or cycle of rather small steps. It is called the Krebs cycle, the respiratory cycle. Each of the chemicals and each of the steps is fairly simple, in terms of what change is made in the molecule, but—and this is a centrally important discovery in biochemistry—these changes are *relatively difficult to accomplish in a laboratory*. If we have one substance and another very similar substance, the one does not just turn into the other, because the two forms are usually separated by

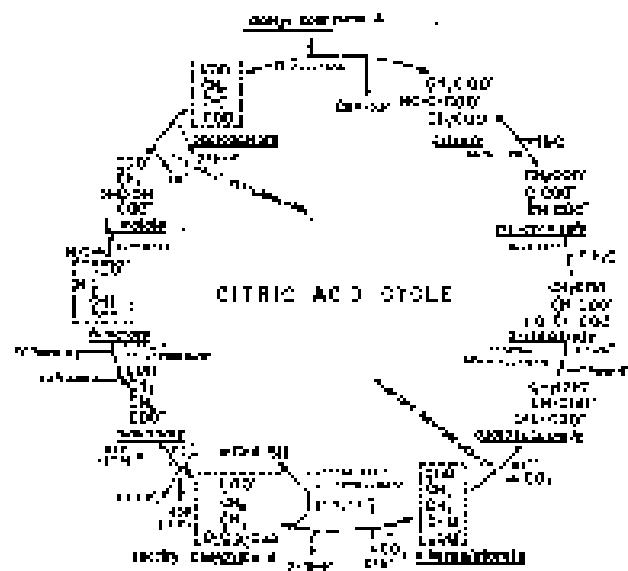

Fig. 3-1. The Krebs cycle.

an energy barrier or "hill." Consider this analogy: If we wanted to take an object from one place to another, at the same level but on the other side of a hill, we could push it over the top, but to do so requires the addition of some energy. Thus most chemical reactions do not occur, because there is what is called an *activation energy* in the way. In order to add an extra atom to our chemical requires that we get it *close* enough that some rearrangement can occur; then it will stick. But if we cannot give it enough energy to get it close enough, it will not go to completion, it will just go part way up the "hill" and back down again. However, if we could literally take the molecules in our hands and push and pull the atoms around in such a way as to open a hole to let the new atom in, and then let it snap back, we would have found another way, *around* the hill, which would not require extra energy, and the reaction would go easily. Now there actually *are*, in the cells, *very* large molecules, much larger than the ones whose changes we have been describing, which in some complicated way hold the smaller molecules just right, so that the reaction can occur easily. These very large and complicated things are called *enzymes*. (They were first called fermenters, because they were originally discovered in the fermentation of sugar. In fact, some of the first reactions in the cycle were discovered there.) In the presence of an enzyme the reaction will go.

An enzyme is made of another substance called *protein*. Enzymes are very big and complicated, and each one is different, each being built to control a certain special reaction. The names of the enzymes are written in Fig. 3-1 at each reaction. (Sometimes the same enzyme may control two reactions.) We emphasize that the enzymes themselves are not involved in the reaction directly. They do not change; they merely let an atom go from one place to another. Having done so, the enzyme is ready to do it to the next molecule, like a machine in a factory. Of course, there must be a supply of certain atoms and a way of disposing of other atoms. Take hydrogen, for example: there are enzymes which have special units on them which carry the hydrogen for all chemical reactions. For example, there are three or four hydrogen-reducing enzymes which are used all over our cycle in different places. It is interesting that the machinery which liberates some hydrogen at one place will take that hydrogen and use it somewhere else.

The most important feature of the cycle of Fig. 3-1 is the transformation from GDP to GTP (guanadine-di-phosphate to guanadine-tri-phosphate) because the one substance has much more energy in it than the other. Just as there is a "box" in certain enzymes for carrying hydrogen atoms around, there are special *energy-carrying* "boxes" which involve the triphosphate group. So, GTP has more energy than GDP and if the cycle is going one way, we are producing molecules which have extra energy and which can go drive some other cycle which *requires* energy, for example the contraction of muscle. The muscle will not contract unless there is GTP. We can take muscle fiber, put it in water, and add GTP, and the fibers contract, changing GTP to GDP if the right enzymes are present. So the real system is in the GDP-GTP transformation; in the dark the GTP which has been stored up during the day is used to run the whole cycle around the other way. An enzyme you see, does not care in which direction the reaction goes, for if it did it would violate one of the laws of physics.

Physics is of great importance in biology and other sciences for still another reason, that has to do with *experimental techniques*. In fact, if it were not for the great development of experimental physics, these biochemistry charts would not be known today. The reason is that the most useful tool of all for analyzing this fantastically complex system is to *label* the atoms which are used in the reactions. Thus, if we could introduce into the cycle some carbon dioxide which has a "green mark" on it, and then measure after three seconds where the green mark is, and again measure after ten seconds, etc., we could trace out the course of the reactions. What are the "green marks"? They are different *isotopes*. We recall that the chemical properties of atoms are determined by the number of ~~electrons~~, not by the mass of the nucleus. But there can be, for example in carbon, six neutrons or seven neutrons, together with the six protons which all carbon nuclei have. Chemically, the two atoms C₁₂ and C₁₃ are the same, but they differ in weight and they have different nuclear properties, and so they are distinguishable.

By using these isotopes of different weights, or even radioactive isotopes like C₁₄, which provide a more sensitive means for tracing very small quantities, it is possible to trace the reactions.

Now, we return to the description of enzymes and proteins. All proteins are not enzymes, but all enzymes are proteins. There are many proteins, such as the proteins in muscle, the structural proteins which are, for example, in cartilage and hair, skin, etc., that are not themselves enzymes. However, proteins are a very characteristic substance of life: first of all they make up all the enzymes, and second, they make up much of the rest of living material. Proteins have a very interesting and simple structure. They are a series, or chain, of different *amino acids*. There are twenty different amino acids, and they all can combine with each other to form chains in which the backbone is CO-NH, etc. Proteins are nothing but chains of various ones of these twenty amino acids. Each of the amino acids probably serves some special purpose. Some, for example, have a sulphur atom at a certain place; when two sulphur atoms are in the same protein, they form a bond, that is, they tie the chain together at two points and form a loop. Another has extra oxygen atoms which make it an acidic substance, another has a basic characteristic. Some of them have big groups hanging out to one side, so that they take up a lot of space. One of the amino acids, called proline, is not really an amino acid, but imino acid. There is a slight difference, with the result that when proline is in the chain, there is a kink in the chain. If we wished to manufacture a particular protein, we would give these instructions: put one of those sulphur hooks here; next, add something to take up space; then attach something to put a kink in the chain. In this way, we will get a complicated-looking chain, hooked together and having some complex structure; this is presumably just the manner in which all the various enzymes are made. One of the great triumphs in recent times (since 1960), was at last to discover the exact spatial atomic arrangement of certain proteins, which involve some fifty-six or sixty amino acids in a row. Over a thousand atoms (more nearly two thousand, if we count the hydrogen atoms) have been located in a complex pattern in two proteins. The first was hemoglobin. One of the sad aspects of this discovery is that we cannot see anything from the pattern; we do not understand why it works the way it does. Of course, that is the next problem to be attacked.

Another problem is how do the enzymes know what to be? A red-eyed fly makes a red-eyed fly baby, and so the information for the whole pattern of enzymes to make red pigment must be passed from one fly to the next. This is done by a substance in the nucleus of the cell, not a protein, called DNA (short for deoxyribose nucleic acid). This is the key substance which is passed from one cell to another (for instance, sperm cells consist mostly of DNA) and carries the information as to how to make the enzymes. DNA is the "blueprint." What does the blueprint look like and how does it work? First, the blueprint must be able to reproduce itself. Secondly, it must be able to instruct the protein. Concerning the reproduction, we might think that this proceeds like cell reproduction. Cells simply grow bigger and then divide in half. Must it be thus with DNA molecules, then, that they too grow bigger and divide in half? Every *atom* certainly does not grow bigger and divide in half! No, it is impossible to reproduce a molecule except by some more clever way.

The structure of the substance DNA was studied for a long time, first chemically to find the composition, and then with x-rays to find the pattern in space. The result was the following remarkable discovery: The DNA molecule is a pair of chains, twisted upon each other. The backbone of each of these chains, which are analogous to the chains of proteins but chemically quite different, is a series of sugar and phosphate groups, as shown in Fig. 3-2. Now we see how the chain can contain instructions, for if we could split this chain down the middle, we would have a series BAADC . . . and every living thing could have a different series. Thus perhaps, in some way, the specific *instructions* for the manufacture of proteins are contained in the specific *series* of the DNA.

Attached to each sugar along the line, and linking the two chains together, are certain pairs of cross-links. However, they are not all of the same kind; there are

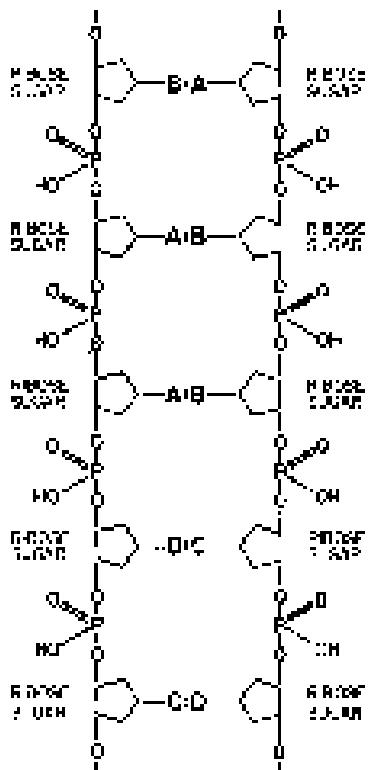

Fig. 3-2. Schematic diagram of DNA.

four kinds, called adenine, thymine, cytosine, and guanine, but let us call them *A*, *B*, *C*, and *D*. The interesting thing is that only certain pairs can sit opposite each other, for example *A* with *B* and *C* with *D*. These pairs are put on the two chains in such a way that they "fit together," and have a strong energy of interaction. However, *C* will not fit with *A*, and *B* will not fit with *C*; they will only fit in pairs, *A* against *B* and *C* against *D*. Therefore if one is *C*, the other must be *D*, etc. Whatever the letters may be in one chain, each one must have its specific complementary letter on the other chain.

What then about reproduction? Suppose we split this chain in two. How can we make another one just like it? If, in the substances of the cells, there is a manufacturing department which brings up phosphate, sugar, and *A*, *B*, *C*, *D* units not connected in a chain, the only ones which will attach to our split chain will be the correct ones, the complements of *BAADC* . . . , namely, *ABBCD* . . . Thus what happens is that the chain splits down the middle during cell division, one half ultimately to go with one cell, the other half to end up in the other cell; when separated, a new complementary chain is made by each half-chain.

Next comes the question, precisely how does the order of the *A*, *B*, *C*, *D* units determine the arrangement of the amino acids in the protein? This is the central unsolved problem in biology today. The first clues, or pieces of information, however, are these: There are in the cell tiny particles called microsomes, and it is now known that that is the place where proteins are made. But the microsomes are not in the nucleus, where the DNA and its instructions are. Something seems to be the matter. However, it is also known that little molecule pieces come off the DNA—not as long as the big DNA molecule that carries all the information itself, but like a small section of it. This is called RNA, but that is not essential. It is a kind of copy of the DNA, a short copy. The RNA, which somehow carries a message as to what kind of protein to make goes over to the microsome; that is known. When it gets there, protein is synthesized at the microsome. That is also known. However, the details of how the amino acids come in and are arranged in accordance with a code that is on the RNA are, as yet, still unknown. We do not know how to read it. If we knew, for example, the "lineup" *A*, *B*, *C*, *C*, *A*, we could not tell you what protein is to be made.

Certainly no subject or field is making more progress on so many fronts at the present moment, than biology, and if we were to name the most powerful assumption of all, which leads one on and on in an attempt to understand life, it is that *all things are made of atoms*, and that everything that living things do can be understood in terms of the jigglings and wiggles of atoms.

3-4 Astronomy

In this rapid-fire explanation of the whole world, we must now turn to astronomy. Astronomy is older than physics. In fact, it got physics started by showing the beautiful simplicity of the motion of the stars and planets, the understanding of which was the *beginning* of physics. But the most remarkable discovery in all of astronomy is that *the stars are made of atoms of the same kind as those on the earth**. How was this done? Atoms liberate light which has definite fre-

* How I'm rushing through this! How much each sentence in this brief story contains. "The stars are made of the same atoms as the earth." I usually pick one small topic like this to give a lecture on. Poets say science takes away from the beauty of the stars—mere globs of gas atoms. Nothing is "mere." I too can see the stars on a desert night, and feel them. But do I see less or more? The vastness of the heavens stretches my imagination—stuck on this carousel my little eye can catch one-million-year-old light. A vast pattern—of which I am a part—perhaps my stuff was belched from some forgotten star, as one is belching there. Or see them with the greater eye of Palomar, rushing all apart from some common starting point when they were perhaps all together. What is the pattern, or the meaning, or the *why*? It does not do harm to the mystery to know a little about it. For far more marvelous is the truth than any artists of the past imagined! Why do the poets of the present not speak of it? What men are poets who can speak of Jupiter if he were like a man, but if he is an immense spinning sphere of methane and ammonia must be silent?

quencies, something like the timbre of a musical instrument, which has definite pitches or frequencies of sound. When we are listening to several different tones we can tell them apart, but when we look with our eyes at a mixture of colors we cannot tell the parts from which it was made, because the eye is nowhere near as discerning as the ear in this connection. However, with a spectroscope we *can* analyze the frequencies of the light waves and in this way we can see the very tunes of the atoms that are in the different stars. As a matter of fact, two of the chemical elements were discovered on a star before they were discovered on the earth. Helium was discovered on the sun, whence its name, and technetium was discovered in certain cool stars. This, of course, permits us to make headway in understanding the stars, because they are made of the same kinds of atoms which are on the earth. Now we know a great deal about the atoms, especially concerning their behavior under conditions of high temperature but not very great density, so that we can analyze by statistical mechanics the behavior of the stellar substance. Even though we cannot reproduce the conditions on the earth, using the basic physical laws we often can tell precisely, or very closely, what will happen. So it is that physics aids astronomy. Strange as it may seem, we understand the distribution of matter in the interior of the sun far better than we understand the interior of the earth. What goes on *inside* a star is better understood than one might guess from the difficulty of having to look at a little dot of light through a telescope, because we can *calculate* what the atoms in the stars should do in most circumstances.

One of the most impressive discoveries was the origin of the energy of the stars, that makes them continue to burn. One of the men who discovered this was out with his girl friend the night after he realized that *nuclear reactions* must be going on in the stars in order to make them shine. She said "Look at how pretty the stars shine!" He said "Yes, and right now I am the only man in the world who knows *why* they shine." She merely laughed at him. She was not impressed with being out with the only man who, at that moment, knew why stars shine. Well, it is sad to be alone, but that is the way it is in this world.

It is the nuclear "burning" of hydrogen which supplies the energy of the sun; the hydrogen is converted into helium. Furthermore, ultimately, the manufacture of various chemical elements proceeds in the centers of the stars, from hydrogen. The stuff of which *we* are made, was "cooked" once, in a star, and spit out. How do we know? Because there is a clue. The proportion of the different isotopes—how much C¹², how much C¹³, etc., is something which is never changed by *chemical* reactions, because the chemical reactions are so much the same for the two. The proportions are purely the result of *nuclear* reactions. By looking at the proportions of the isotopes in the cold, dead ember which we are, we can discover what the *furnace* was like in which the stuff of which we are made was formed. That furnace was like the stars, and so it is very likely that our elements were "made" in the stars and spit out in the explosions which we call novae and supernovae. Astronomy is so close to physics that we shall study many astronomical things as we go along.

3-5 Geology

We turn now to what are called *earth sciences*, or *geology*. First, meteorology and the weather. Of course the *instruments* of meteorology are physical instruments, and the development of experimental physics made these instruments possible, as was explained before. However, the theory of meteorology has never been satisfactorily worked out by the physicist. "Well," you say, "there is nothing but air, and we know the equations of the motions of air." Yes we do. "So if we know the condition of air today, why can't we figure out the condition of the air tomorrow?" First, we do not *really* know what the condition is today, because the air is swirling and twisting everywhere. It turns out to be very sensitive, and even unstable. If you have ever seen water run smoothly over a dam, and then turn into a large number of blobs and drops as it falls, you will understand what I mean by unstable. You know the condition of the water before it goes over the

spillway; it is perfectly smooth; but the moment it begins to fall, where do the drops begin? What determines how big the lumps are going to be and where they will be? That is not known, because the water is unstable. Even a smooth moving mass of air, in going over a mountain turns into complex whirlpools and eddies. In many fields we find this situation of *turbulent flow* that we cannot analyze today. Quickly we leave the subject of weather, and discuss geology!

The question basic to geology is, what makes the earth the way it is? The most obvious processes are in front of your very eyes, the erosion processes of the rivers, the winds, etc. It is easy enough to understand these, but for every bit of erosion there is an equal amount of something else going on. Mountains are no lower today, on the average, than they were in the past. There must be *mountain-forming* processes. You will find, if you study geology, that there *are* mountain-forming processes and vulcanism, which nobody understands but which is half of geology. The phenomenon of volcanoes is really not understood. What makes an earthquake is, ultimately, not understood. It is understood that if something is pushing something else, it snaps and will slide—that is all right. But what pushes, and why? The theory is that there are currents inside the earth—circulating currents, due to the difference in temperature inside and outside—which, in their motion, push the surface slightly. Thus if there are two opposite circulations next to each other, the matter will collect in the region where they meet and make belts of mountains which are in unhappy stressed conditions, and so produce volcanoes and earthquakes.

What about the inside of the earth? A great deal is known about the speed of earthquake waves through the earth and the density of distribution of the earth. However, physicists have been unable to get a good theory as to how dense a substance should be at the pressures that would be expected at the center of the earth. In other words, we cannot figure out the properties of matter very well in these circumstances. We do much less well with the earth than we do with the conditions of matter in the stars. The mathematics involved seems a little too difficult, so far, but perhaps it will not be too long before someone realizes that it is an important problem, and really work it out. The other aspect, of course, is that even if we did know the density, we cannot figure out the circulating currents. Nor can we really work out the properties of rocks at high pressure. We cannot tell how fast the rocks should "give"; that must all be worked out by experiment.

3-6 Psychology

Next, we consider the science of *psychology*. Incidentally, psychoanalysis is not a science: it is at best a medical process, and perhaps even more like witch-doctoring. It has a theory as to what causes disease—lots of different "spirits," etc. The witch doctor has a theory that a disease like malaria is caused by a spirit which comes into the air; it is not cured by shaking a snake over it, but quinine does help malaria. So, if you are sick, I would advise that you go to the witch doctor because he is the man in the tribe who knows the most about the disease; on the other hand, his knowledge is not science. Psychoanalysis has not been checked carefully by experiment, and there is no way to find a list of the number of cases in which it works, the number of cases in which it does not work, etc.

The other branches of psychology, which involve things like the physiology of sensation—what happens in the eye, and what happens in the brain—are, if you wish, less interesting. But some small but real progress has been made in studying them. One of the most interesting technical problems may or may not be called psychology. The central problem of the mind, if you will, or the nervous system, is this: when an animal learns something, it can do something different than it could before, and its brain cell must have changed too, if it is made out of atoms. *In what way is it different?* We do not know where to look, or what to look for, when something is memorized. We do not know what it means, or what change there is in the nervous system, when a fact is learned. This is a very important problem which has not been solved at all. Assuming, however, that there is some kind of memory thing, the brain is such an enormous mass of interconnect-

ing wires and nerves that it probably cannot be analyzed in a straightforward manner. There is an analog of this to computing machines and computing elements, in that they also have a lot of lines, and they have some kind of element, analogous, perhaps, to the synapse, or connection of one nerve to another. This is a very interesting subject which we have not the time to discuss further—the relationship between thinking and computing machines. It must be appreciated, of course, that this subject will tell us very little about the real complexities of ordinary human behavior. All human beings are so different. It will be a long time before we get there. We must start much further back. If we could even figure out how a *dog* works, we would have gone pretty far. Dogs are easier to understand, but nobody yet knows how dogs work.

3-7 How did it get that way?

In order for physics to be useful to other sciences in a *theoretical* way, other than in the invention of instruments, the science in question must supply to the physicist a description of the object in a physicist's language. They can say "why does a frog jump?", and the physicist cannot answer. If they tell him what a frog is, that there are so many molecules, there is a nerve here, etc., that is different. If they will tell us, more or less, what the earth or the stars are like, then we can figure it out. In order for physical theory to be of any use, we must know where the atoms are located. In order to understand the chemistry, we must know exactly what atoms are present, for otherwise we cannot analyze it. That is but one limitation, of course.

There is another *kind* of problem in the sister sciences which does not exist in physics; we might call it, for lack of a better term, the historical question. How did it get that way? If we understand all about biology, we will want **to** know how all the things which are on the earth got there. There is the theory of evolution, an important part of biology. In geology, we not only want to know how the mountains are forming, but how the entire earth was formed in the beginning, the origin of the solar system, etc. That, of course, leads us to want to know what kind of matter there was in the world. How did the stars evolve? What were the initial conditions? That is the problem of astronomical history. A great deal has been found out about the formation of stars, the formation of elements from which we were made, and even a little about the origin of the universe.

There is no historical question being studied in physics at the present time. We do not have a question, "Here are the laws of physics, how did they get that way?" We do not imagine, at the moment, that the laws of physics are somehow changing with time, that they were different in the past than they are at present. Of course they *may* be, and the moment we find they *are*, the historical question of physics will be wrapped up with the rest of the history of the universe, and then the physicist will be talking about the same problems as astronomers, geologists, and biologists.

Finally, there is a physical problem that is common to many fields, that is very old, and that has not been solved. It is not the problem of finding new fundamental particles, but something left over from a long time ago—over a hundred years. Nobody in physics has really been able to analyze it mathematically satisfactorily in spite of its importance to the sister sciences. It is the analysis of *circulating or turbulent fluids*. If we watch the evolution of a star, there comes a point where we can deduce that it is going to start convection, and thereafter we can no longer deduce what should happen. A few million years later the star explodes, but we cannot figure out the reason. We cannot analyze the weather. We do not know the patterns of motions that there should be inside the earth. The simplest form of the problem is to take a pipe that is very long and push water through it at high speed. We ask: to push a given amount of water through that pipe, how much pressure is needed? No one can analyze it from first principles and the properties of water. If the water flows very slowly, or if we use a thick goo like honey, then we can do it nicely. You will find that in your textbook.

What we really cannot do is deal with actual, wet water running through a pipe. That is the central problem which we ought to solve some day, and we have not.

A poet once said, "The whole universe is in a glass of wine." We will probably never know in what sense he meant that, for poets do not write to be understood. But it is true that if we look at a glass of wine closely enough we see the entire universe. There are the things of physics: the twisting liquid which evaporates depending on the wind and weather, the reflections in the glass, and our imagination adds the atoms. The glass is a distillation of the earth's rocks, and in its composition we see the secrets of the universe's age, and the evolution of stars. What strange array of chemicals are in the wine? How did they come to be? There are the ferments, the enzymes, the substrates, and the products. There in wine is found the great generalization: all life is fermentation. Nobody can discover the chemistry of wine without discovering, as did Louis Pasteur, the cause of much disease. How vivid is the claret, pressing its existence into the consciousness that watches it! If our small minds, for some convenience, divide this glass of wine, this universe, into parts—physics, biology, geology, astronomy, psychology, and so on—remember that nature does not know it! So let us put it all back together, not forgetting ultimately what it is for. Let it give us one more final pleasure: drink it and forget it all!

Conservation of Energy

4-1 What is energy?

In this chapter, we begin our more detailed study of the different aspects of physics, having finished our description of things in general. To illustrate the ideas and the kind of reasoning that might be used in theoretical physics, we shall now examine one of the most basic laws of physics, the conservation of energy.

There is a fact, or if you wish, a *law*, governing all natural phenomena that are known to date. There is no known exception to this law—it is exact so far as we know. The law is called the *conservation of energy*. It states that there is a certain quantity, which we call energy, that does not change in the manifold changes which nature undergoes. That is a most abstract idea, because it is a mathematical principle; it says that there is a numerical quantity which does not change when something happens. It is not a description of a mechanism, or anything concrete; it is just a strange fact that we can calculate some number and when we finish watching nature go through her tricks and calculate the number again, it is the same. (Something like the bishop on a red square, and after a number of moves—details unknown—it is still on some red square. It is a law of this nature.) Since it is an abstract idea, we shall illustrate the meaning of it by an analogy.

Imagine a child, perhaps "Dennis the Menace," who has blocks which are absolutely indestructible, and cannot be divided into pieces. Each is the same as the other. Let us suppose that he has 28 blocks. His mother puts him with his 28 blocks into a room at the beginning of the day. At the end of the day, being curious, she counts the blocks very carefully, and discovers a phenomenal law—no matter what he does with the blocks, there are always 28 remaining! This continues for a number of days, until one day there are only 27 blocks, but a little investigating shows that there is one under the rug—she must look everywhere to be sure that the number of blocks has not changed. One day, however, the number appears to change—there are only 26 blocks. Careful investigation indicates that the window was open, and upon looking outside, the other two blocks are found. Another day, careful count indicates that there are 30 blocks! This causes considerable consternation, until it is realized that Bruce came to visit, bringing his blocks with him, and he left a few at Dennis' house. After she has disposed of the extra blocks, she closes the window, does not let Bruce in, and then everything is going along all right, until one time she counts and finds only 25 blocks. However, there is a box in the room, a toy box, and the mother goes to open the toy box, but the boy says "No, do not open my toy box," and screams. Mother is not allowed to open the toy box. Being extremely curious, and somewhat ingenious, she invents a scheme! She knows that a block weighs three ounces, so she weighs the box at a time when she sees 28 blocks, and it weighs 16 ounces. The next time she wishes to check, she weighs the box again, subtracts sixteen ounces and divides by three. She discovers the following:

$$\left(\begin{array}{l} \text{number of} \\ \text{blocks seen} \end{array} \right) + \frac{\text{weight of box}}{\text{A ounce}} = \text{constant.} \quad (4.1)$$

There then appear to be some new deviations, but careful study indicates that the dirty water in the bathtub is changing its level. The child is throwing blocks into the water, and she cannot see them because it is so dirty, but she can find out how many blocks are in the water by adding another term to her formula. Since the original height of the water was 6 inches and each block raises the water a quarter

4-1 What is energy?

4-2 Gravitational potential energy

4-3 Kinetic energy

4-4 Other forms of energy

of an inch, this new formula would be:

$$\begin{aligned} \left(\frac{\text{number of}}{\text{blocks seen}} \right) & - \frac{\text{(weight of box)}}{3 \text{ ounces}} = \frac{16 \text{ ounces}}{3 \text{ ounces}} \\ + \frac{\text{(height of water)}}{1/2 \text{ inch}} & = \text{constant.} \quad (4.2) \end{aligned}$$

In the gradual increase in the complexity of her world, she finds a whole series of terms representing ways of calculating how many blocks are in places where she is not allowed to look. As a result, she finds a complex formula, a quantity which *has to be computed*, which always stays the same in her situation.

What is the analogy of this to the conservation of energy? The most remarkable aspect that must be abstracted from this picture is that *there are no blocks*. Take away the first terms in (4.1) and (4.2) and we find ourselves calculating more or less abstract things. The analogy has the following points. First, when we are calculating the energy, sometimes some of it leaves the system and goes away, or sometimes some comes in. In order to verify the conservation of energy, we must be careful that we have not put any in or taken any out. Second, the energy has a large number of *different forms*, and there is a formula for each one. These are: gravitational energy, kinetic energy, heat energy, elastic energy, electrical energy, chemical energy, radiant energy, nuclear energy, mass energy. If we total up the formulas for each of these contributions, it will not change except for energy going in and out.

It is important to realize that in physics today, we have no knowledge of what energy *is*. We do not have a picture that energy comes in little blobs of a definite amount. It is not that way. However, there are formulas for calculating some numerical quantity, and when we add it all together it gives ~~"the"~~—*always*, the same number. It is an abstract thing in that it does not tell us the mechanism or the *reasons* for the various formulas.

4-2 Gravitational potential energy

Conservation of energy can be understood only if we have the formula for all of its forms. I wish to discuss the formula for gravitational energy near the surface of the Earth, and I wish to derive this formula in a way which has nothing to do with history but is simply a line of reasoning invented for this particular lecture to give you an illustration of the remarkable fact that a great deal about nature can be extracted from a few facts and close reasoning. It is an illustration of the kind of work theoretical physicists become involved in. It is patterned after a most excellent argument by Mr. Carnot on the efficiency of steam engines.*

Consider weight-lifting machines—machines which have the property that they lift one weight by lowering another. Let us also make a hypothesis: that *there is no such thing as perpetual motion* with these weight-lifting machines. (In fact, that there is no perpetual motion at all is a general statement of the law of conservation of energy.) We must be careful to define perpetual motion. First, let us do it for weight-lifting machines. If, when we have lifted and lowered a lot of weights and restored the machine to the original condition, we find that the net result is to have *lifted a weight*, then we have a perpetual motion machine because we can use that lifted weight to run something else. That is, *provided* the machine which lifted the weight is brought back to its exact *original condition*, and furthermore that it is completely *self-contained*—that it has not received the energy to lift that weight from some external source—like Bruce's blocks.

A very simple weight-lifting machine is shown in Fig. 4-1. This machine lifts weights three units "strong." We place three units on one balance pan, and one unit on the other. However, in order to get it actually to work, we must lift a little weight off the left pan. On the other hand, we could lift a one-unit weight

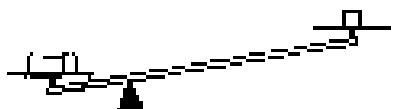

Fig. 4-1. Simple weight-lifting machine.

* Our point here is not so much the result, (4.3), which in fact you may already know, as the possibility of arriving at it by theoretical reasoning.

by lowering the three-unit weight, if we cheat a little by lifting a little weight off the other pan. Of course, we realize that with any *actual* lifting machine, we must add a little extra to get it to run. This we disregard, *temporarily*. Ideal machines, although they do not exist, do not require anything extra. A machine that we actually use can be, in a sense, *almost* reversible: that is, if it will lift the weight of three by lowering a weight of one, then it will also lift nearly the weight of one the same amount by lowering the weight of three.

We imagine that there are two classes of machines, those that are *not* reversible, which includes all real machines, and those that *are* reversible, which of course are actually not attainable no matter how careful we may be in our design of bearings, levers, etc. We suppose, however, that there is such a thing—a reversible machine—which lowers one unit of weight (a pound or any other unit) by one unit of distance, and at the same time lifts a three-unit weight. Call this reversible machine, Machine A. Suppose this particular reversible machine lifts the three-unit weight a distance X . Then suppose we have another machine, Machine B, which is not necessarily reversible, which also lowers a unit weight a unit distance, but which lifts three units a distance Y . We can now prove that Y is not higher than X ; that is, it is impossible to build a machine that will lift a weight *any higher* than it will be lifted by a reversible machine. Let us see why. Let us suppose that Y were higher than X . We take a one-unit weight and lower it one unit height with Machine B, and that lifts the three-unit weight up a distance V . Then we could lower the weight from Y to X , *obtaining free power*, and use the reversible Machine A, running backwards, to lower the three-unit weight a distance X and lift the one-unit weight by one unit height. This will put the one-unit weight back where it was before, and leave both machines ready to be used again! We would therefore have perpetual motion if Y were higher than X , which we assumed was impossible. With those assumptions, we thus deduce that **F is not higher than X**, so that of all machines that can be designed, the reversible machine is the best.

We can also see that all reversible machines must lift to *exactly the same height*. Suppose that B were really reversible also. The argument that Y is not higher than X is, of course, just as good as it was before, but we can also make our argument the other way around, using the machines in the opposite order, and prove that X is not higher than Y . This, then, is a very remarkable observation because it permits us to analyze the height to which different machines are going to lift something *without looking at the interior mechanism*. We know at once that if somebody makes an enormously elaborate series of levers that lift three units a certain distance by lowering one unit by one unit distance, and we compare it with a simple lever which does the same thing and is fundamentally reversible, his machine will lift it no higher, but perhaps less high. If his machine is reversible, we also know exactly *how* high it will lift. To summarize: every reversible machine, no matter how it operates, which drops one pound one foot and lifts a three-pound weight always lifts it the same distance, X . This is clearly a universal law of great utility. The next question is, of course, what is **T**?

Suppose we have a reversible machine which is going to lift this distance X , three for one. We set up three balls in a rack which does not move, as shown in Fig. 4-2. One ball is held on a stage at a distance one foot above the ground. The machine can lift three balls, lowering one by a distance 1. Now, we have arranged that the platform which holds three balls has a floor and two shelves, exactly spaced at distance X , and further, that the rack which holds the balls is spaced at distance X , (a). First we roll the balls horizontally from the rack to the shelves, (b), and we suppose that this takes no energy because we do not change the height. The reversible machine then operates: it lowers the single ball to the floor, and it lifts the rack a distance X , (c). Now we have ingeniously arranged the rack so that these balls are again even with the platforms. Thus we unload the balls onto the rack, (d); having unloaded the balls, we can restore the machine to its original condition. Now we have three balls on the upper three shelves and one at the bottom. But the strange thing is that, in a certain way of speaking, we have not lifted *two* of them at all because, after all, there were balls on shelves 2 ~~and 1~~.

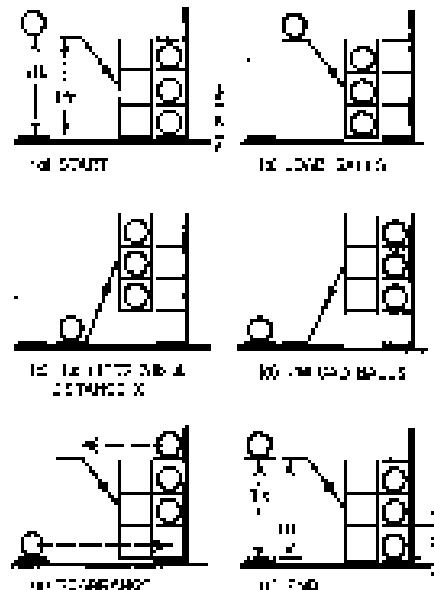

Fig. 4-2. A reversible machine.

before. The resulting effect has been to lift *one ball* a distance $3X$. Now, if $3X$ exceeds one foot, then we can *lower* the ball to return the machine to the initial condition, (f), and we can run the apparatus again. Therefore $3X$ cannot exceed one foot, for if $3X$ exceeds one foot we can make perpetual motion. Likewise, we can prove that *one foot cannot exceed $3X$* , by making the whole machine run the opposite way, since it is a reversible machine. Therefore $3X$ is neither greater nor less than a foot, and we discover then, by argument alone, the law that $X = \frac{1}{3}$ foot. The generalization is clear: one pound falls a certain distance in operating a reversible machine; then the machine can lift p pounds this distance divided by p . Another way of putting the result is that three pounds times the height lifted, which in our problem was X , is equal to one pound times the distance lowered, which is one foot in this case. If we take all the weights and multiply them by the heights at which they are now, above the floor, let the machine operate, and then multiply all the weights by all the heights again, *there will be no change*. (We have to generalize the example where we moved only one weight to the case where when we lower one we lift several different ones—but that is easy.)

We call the sum of the weights times the heights *gravitational potential energy*—the energy which an object has because of its relationship in space, relative to the earth. The formula for gravitational energy, then, so long as we are not too far from the earth (the force weakens as we go higher) is

$$\left(\begin{array}{l} \text{(gravitational} \\ \text{potential energy)} \\ \text{for one object!} \end{array} \right) = (\text{weight!}) \times (\text{height}). \quad (4.3)$$

It is a very beautiful line of reasoning. The only problem is that perhaps it is not true. (After all, nature does not *have* to go along with our reasoning.) For example, perhaps perpetual motion is, in fact, possible. Some of the assumptions may be wrong, or we may have made a mistake in reasoning, so it is always necessary to check. It turns out experimentally, in fact, to be true.

The general name of energy which has to do with location relative to something else is called *potential energy*. In this particular case, of course, we call it *gravitational potential energy*. If it is a question of electrical forces against which we are working, instead of gravitational forces, if we are "lifting" charges away from other charges with a lot of levers, then the energy content is called *electrical potential energy*. The general principle is that the change in the energy is the force times the distance that the force is pushed, and that this is a change in energy in general:

$$\left(\begin{array}{l} \text{(change in)} \\ \text{energy} \end{array} \right) = (\text{force}) \times \left(\begin{array}{l} \text{(distance force)} \\ \text{acts through} \end{array} \right). \quad (4.4)$$

We will return to many of these other kinds of energy as we continue the course.

The principle of the conservation of energy is very useful for deducing what will happen in a number of circumstances. In high school we learned a lot of laws about pulleys and levers used in different ways. We can now see that these "laws" are *all the same thing*, and that we did not have to memorize 75 rules to figure it out. A simple example is a smooth inclined plane which is, happily, a three-four-five triangle (Fig. 4-3). We hang a one-pound weight on the inclined plane with a pulley, and on the other side of the pulley, a weight W . We want to know how heavy W must be to balance the one pound on the plane. How can we figure that out? If we say it is just balanced, it is reversible and so can move up and down, and we can consider the following situation. In the initial circumstance, (a), the one pound weight is at the bottom and weight W is at the top. When W has slipped down in a reversible way, we have a one-pound weight at the top and the weight W the slant distance, (b), or five feet, from the plane in which it was before. We *lifted* the one-pound weight only *three* feet and we lowered W pounds by *five* feet. Therefore $W = \frac{5}{3}$ of a pound. Note that we deduced this from the *conservation of energy*, and not from force components. Cleverness, however, is relative. It can be deduced in a way which is even more brilliant, discovered by

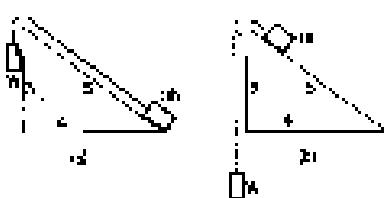

Fig. 4-3. Reversible slope.

Stevinus and inscribed on his tombstone. Figure 4-4 explains that it has to be $\frac{1}{5}$ of a pound, because the chain does not go around. It is evident that the lower part of the chain is balanced by itself, so that the pull of the five weights on one side must balance the pull of three weights on the other, or whatever the ratio of the legs. You see, by looking at this diagram, that W must be $\frac{1}{5}$ of a pound. (If you get an epitaph like that on your gravestone, you are doing fine.)

Let us now illustrate the energy principle with a more complicated problem, the screw jack shown in Fig. 4-5. A handle 20 inches long is used to turn the screw, which has 10 threads to the inch. We would like to know how much force would be needed at the handle to lift one ton (2000 pounds). If we want to lift the ton one inch, say, then we must turn the handle around ten times. When it goes around once it goes approximately 126 inches. The handle must thus travel 1260 inches, and if we used various pulleys, etc., we would be lifting our one ton with an unknown smaller weight W applied to the end of the handle. So we find out that W is about 1.6 pounds. This is a result of the conservation of energy.

Take now the somewhat more complicated example shown in Fig. 4-6. A rod or bar, 8 feet long, is supported at one end. In the middle of the bar is a weight of 60 pounds, and at a distance of two feet from the support there is a weight of 100 pounds. How hard do we have to lift the end of the bar in order to keep it balanced, disregarding the weight of the bar? Suppose we put a pulley at one end and hang a weight on the pulley. How big would the weight W have to be in order for it to balance? We imagine that the weight falls any arbitrary distance—to make it easy for ourselves suppose it goes down 4 inches—how high would the two load weights rise? The center rises 2 inches, and the point a quarter of the way from the fixed end lifts 1 inch. Therefore, the principle that the sum of the heights times the weights does not change tells us that the weight W times 4 inches down, plus 60 pounds times 2 inches up, plus 100 pounds times 1 inch has to add up to nothing:

$$-4W + (2)(60) = 11(100) = 0, \quad W = 55 \text{ lb.} \quad (4.5)$$

Thus we must have a 55-pound weight to balance the bar. In this way we can work out the laws of "balance"—the statics of complicated bridge arrangements, and so on. This approach is called *the principle of virtual work*, because in order to apply this argument we had to *imagine* that the structure moves a little—even though it is not *really* moving or even *movable*. We use the very small imagined motion to apply the principle of conservation of energy.

4-3 Kinetic energy

To illustrate another type of energy we consider a pendulum (Fig. 4-7). If we pull the mass aside and release it, it swings back and forth. In its motion, it loses height in going from either end to the center. Where does the potential energy go? ~~Gravitational~~ energy disappears when it is down at the bottom; nevertheless, it will climb up again. The gravitational energy must have gone into another form. Evidently it is by virtue of its *motion* that it is able to climb up again, so we have the conversion of gravitational energy into some other form when it reaches the bottom.

We must get a formula for the energy of motion. Now, recalling our arguments about reversible machines, we can easily see that in the motion at the bottom must be a quantity of energy which permits it to rise a certain height, and which has nothing to do with the *machinery* by which it comes up or the *path* by which it comes up. So we have an equivalence formula something like the one we wrote for the child's blocks. We have another form to represent the energy. It is easy to say what it is. The kinetic energy at the bottom equals the weight times the height that it could go, corresponding to its velocity: $K.E. = WH$. What we need is the formula which tells us the height by some rule that has to do with the motion of objects. If we start something out with a certain velocity, say straight up, it will reach a certain height; we do not know what it is yet, but it depends on the velocity—there is a formula for that. Then to find the formula for kinetic energy

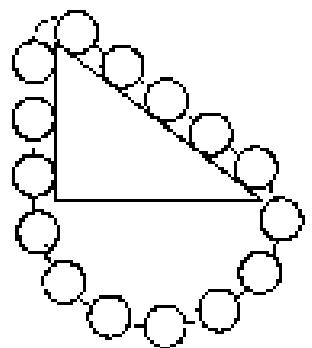

Fig. 4-4. The principle of Stevinus.

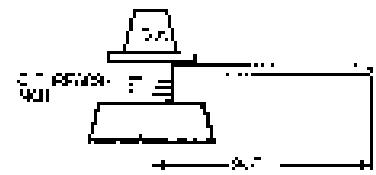

Fig. 4-5. A screw jack.

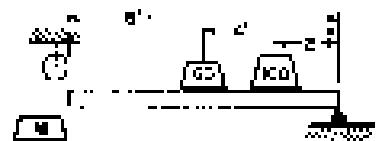

Fig. 4-6. Weighted rod suspended on one end.

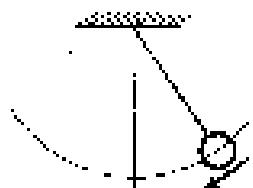

Fig. 4-7. Pendulum.

for an object moving with velocity V , we must calculate the height that it could reach, and multiply by the weight. We shall soon find that we can write it this way:

$$K.E. = \frac{1}{2} m V^2 \quad (4.6)$$

Of course, the fact that motion has energy has nothing to do with the fact that we are in a gravitational field. It makes no difference *where* the motion came from. This is a general formula for various velocities. Both (4.3) and (4.6) are approximate formulas, the first because it is incorrect when the heights are great, i.e., when the heights are so high that gravity is weakening; the second, because of the relativistic correction at high speeds. However, when we do finally get the exact formula for the energy, then the law of conservation of energy is correct.

44 Other forms of energy

We can continue in this way to illustrate the existence of energy in other forms. First, consider elastic energy. If we pull down on a spring, we must do some work, for when we have it down, we can lift weights with it. Therefore in its stretched condition it has a possibility of doing some work. If we were to evaluate the sums of weights times heights, it would not check out—we must add something else to account for the fact that the spring is under tension. Elastic energy is the formula for a spring when it is stretched. How much energy is it? If we let go, the elastic energy, as the spring passes through the equilibrium point, is converted to kinetic energy and it goes back and forth between compressing or stretching the spring and kinetic energy of motion. (There is also some gravitational energy going in and out, but we can do this experiment "sideways" if we like.) It keeps going until the losses—Aha! We have cheated all the way through by putting on little weights to move things or saying that the machines are reversible, or that they go on forever, but we can see that things do stop, eventually. Where is the energy when the spring has finished moving up and down? This brings in *another* form of energy: *heat energy*.

Inside a spring or a lever there are crystals which are made up of lots of atoms, and with great care and delicacy in the arrangement of the parts one can try to adjust things so that as something rolls on something else, none of the atoms do any jiggling at all. But one must be very careful. Ordinarily when things roll, there is bumping and jiggling because of the irregularities of the material, and the atoms start to wiggle inside. So we lose track of that energy; we find the atoms are wiggling inside in a random and confused manner after the motion slows down. There is still kinetic energy, all right, but it is not associated with visible motion. What a dream! How do we *know* there is still kinetic energy? It turns out that with thermometers you can find out that, in fact, the spring or the lever is *warmer*, and that there is really an increase of kinetic energy by a definite amount. We call this form of energy *heat energy*, but we know that it is not really a new form, it is just kinetic energy—internal motion. (One of the difficulties with all these experiments with matter that we do on a large scale is that we cannot really demonstrate the conservation of energy and we cannot really make our reversible machines, because every time we move a large clump of stuff, the atoms do not remain absolutely undisturbed, and so a certain amount of random motion goes into the atomic system. We cannot see it, but we can measure it with thermometers, etc.)

There are many other forms of energy, and of course we cannot describe them in any more detail just now. There is electrical energy, which has to do with pushing and pulling by electric charges. There is radiant energy, the energy of light, which we know is a form of electrical energy because light can be represented as wigglings in the electromagnetic field. There is chemical energy, the energy which is released in chemical reactions. Actually, elastic energy is, to a certain extent, like chemical energy, because chemical energy is the energy of the attraction of the atoms, one for the other, and so is elastic energy. Our modern understanding is the following: chemical energy has two parts, kinetic energy of the electrons inside the atoms, so part of it is kinetic, and electrical energy of interaction of the

electrons and the protons—the rest of it, therefore, is electrical. Next we come to nuclear energy, the energy which is involved with the arrangement of particles inside the nucleus, and we have formulas for that, but we do not have the fundamental laws. We know that it is not electrical, not gravitational, and not purely chemical, but we do not know what it is. It seems to be an additional form of energy. Finally, associated with the relativity theory, there is a modification of the laws of kinetic energy, or whatever you wish to call it, so that kinetic energy is combined with another thing called *mass energy*. An object has energy from its sheer *existence*. If I have a positron and an electron, standing still doing nothing—never mind gravity, never mind anything—and they come together and disappear, radiant energy will be liberated, in a definite amount, and the amount can be calculated. All we need know is the mass of the object. It does not depend on what it is—we make two things disappear, and we get a certain amount of energy. The formula was first found by Einstein; it is $E = mc^2$.

It is obvious from our discussion that the law of conservation of energy is enormously useful in making analyses, as we have illustrated in a few examples without knowing all the formulas. If we had all the formulas for all kinds of energy, we could analyze how many processes should work without having to go into the details. Therefore conservation laws are very interesting. The question naturally arises as to what other conservation laws there are in physics. There are two other conservation laws which are analogous to the conservation of energy. One is called the conservation of linear momentum. The other is called the conservation of angular momentum. We will find out more about these later. In the last analysis, we do not understand the conservation laws deeply. We do not understand the conservation of energy. We do not understand energy as a certain number of little blobs. You may have heard that photons come out in blobs and that the energy of a photon is Planck's constant times the frequency. That is true, but since the frequency of light can be anything, there is no law that says that energy has to be a certain definite amount. Unlike Dennis' blocks, there can be any amount of energy, at least as presently understood. So we do not understand this energy as counting something at the moment, but just as a mathematical quantity, which is an abstract and rather peculiar circumstance. In quantum mechanics it turns out that the conservation of energy is very closely related to another important property of the world, *things do not depend on the absolute time*. We can set up an experiment at a given moment and try it out, and then do the same experiment at a later moment, and it will behave in exactly the same way. Whether this is strictly true or not, we do not know. If we assume that it is true, and add the principles of ~~classical~~ mechanics, then we can deduce the principle of the conservation of energy. It is a rather subtle and interesting thing, and it is not easy to explain. The other conservation laws are also linked together. The conservation of momentum is associated in quantum mechanics with the proposition that it makes no difference ~~when~~ you do the experiment, the results will always be the same. As independence in space has to do with the conservation of momentum, independence of time has to do with the conservation of energy, and finally, if we turn our apparatus, this too makes no difference, and so the invariance of the world to angular orientation is related to the conservation of *angular momentum*. Besides these, there are three other conservation laws, that are exact so far as we can tell today, which are much simpler to understand because they are in the nature of counting blocks.

The first of the three is the ~~conservation~~ of charge, and that merely means that you count how many positive, minus how many negative electrical charges you have, and the number is never changed. You may get rid of a positive with a negative, but you do not create any net excess of positives over negatives. Two other laws are analogous to this one—one is called the *conservation of baryons*. There are a number of strange particles, a neutron and a proton are examples, which are called baryons. In any reaction whatever in nature, if we count how many baryons are coming into a process, the number of baryons* which come out

*Counting antibaryons as —1 baryon.

will be exactly the same. There is another law, the *conservation of leptons*. We can say that the group of particles called leptons are: electron, mu meson, and neutrino. There is an antielectron which is a positron, that is, a -1 lepton. Counting the total number of leptons in a reaction reveals that the number in and out never changes, at least so far as we know at present.

These are the six conservation laws, three of them subtle, involving space and time, and three of them simple, in the sense of counting something.

With regard to the conservation of energy, we should note that *available* energy is another matter—there is a lot of jiggling around in the atoms of the water of the sea, because the sea has a certain temperature, but it is impossible to get them herded into a definite motion without taking energy from somewhere else. That is, although we know for a fact that energy is conserved, the energy available for human utility is not conserved so easily. The laws which govern how much energy is available are called the *laws of thermodynamics* and involve a concept called entropy for irreversible thermodynamic processes.

Finally, we remark on the question of where we can get our supplies of energy today. Our supplies of energy are from the sun, rain, coal, uranium, and hydrogen. The sun makes the rain, and the coal also, so that all these are from the sun. Although energy is conserved, nature does not seem to be interested in it; she liberates a lot of energy from the sun, but only one part in two billion falls on the earth. Nature has conservation of energy, but does not really care; she spends a lot of it in all directions. We have already obtained energy from uranium; we can also get energy from hydrogen, but at present only in an explosive and dangerous condition. If it can be controlled in thermonuclear reactions, it turns out that the energy that can be obtained from 10 quarts of water per second is equal to all of the electrical power generated in the United States. With 150 gallons of running water a minute, you have enough fuel to supply all the energy which is used in the United States today! Therefore it is up to the physicist to figure out how to liberate us from the need for having energy. It can be done.

Time and Distance

5-1 Motion

In this chapter we shall consider some aspects of the concepts of *time* and *distance*. It has been emphasized earlier that physics, as do all the sciences, depends on *observation*. One might also say that the development of the physical sciences to their present form has depended to a large extent on the emphasis which has been placed on the making of *quantitative* observations. Only with quantitative observations can one arrive at quantitative relationships, which are the heart of physics.

Many people would like to place the beginnings of physics with the work done 350 years ago by Galileo, and to call him the first physicist. Until that time, the study of motion had been a philosophical one based on arguments that could be thought up in one's head. Most of the arguments had been presented by Aristotle and other Greek philosophers, and were taken as "proven." Galileo was skeptical, and did an experiment on motion which was essentially this: He allowed a ball to roll down an inclined trough and observed the motion. He did not, however, just look; he measured *how far* the ball went in *how long a time*.

The way to measure a distance was well known long before Galileo, but there were no accurate ways of measuring time, particularly short times. Although he later devised more satisfactory clocks (though not like the ones we know), Galileo's first experiments on motion were done by using his pulse to count off equal intervals of time. Let us do the same.

We may count off beats of a pulse as the ball rolls down the track: "one . . . two . . . three . . . four . . . five . . . six . . . seven . . . eight . . ." We ask a friend to make a small mark at the location of the ball at each count; we can then measure the *distance* the ball travelled from the point of release in one, or two, or three, etc., equal intervals of time. Galileo expressed the result of *his* observations in this way: if the location of the ball is marked at 1, 2, 3, 4, . . . units of time from the instant of its release, those marks are distant from the starting point in proportion to the numbers 1, 4, 9, 16, . . . Today we would say the distance is proportional to the square of the time:

$$D \propto t^2$$

The study of *motion*, which is basic to all of physics, treats with the questions: where? and when?

5-2 Time

Let us consider first what we mean by *time*. What *is* time? It would be nice if we could find a good definition of time. Webster defines "a time" as "a period," and the latter as "a time," which doesn't seem to be very useful. Perhaps we should say: "Time is what happens when nothing else happens." Which also doesn't get us very far. Maybe it is just as well if we face the fact that time is one of the things we probably cannot define (in the dictionary sense), and just say that it is what we already know it to be: it is how long we wait!

What really matters anyway is not how we *define* time, but how we measure it. One way of measuring time is to utilize something which happens over and over again in a regular fashion—something which is *periodic*. For example, a day. A day seems to happen over and over again. But when you begin to think

5-1 Motion

5-2 Time

5-3 Short times

5-4 Long times

5-5 Units and standards of time

5-6 Large distances

5-7 Short distances

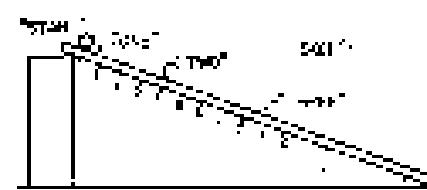

Fig. 5-1. A ball rolls down an inclined track.

about it, you might well ask: "Are days periodic; are they regular? Are all days the same length?" One certainly has the impression that days in summer are longer than days in winter. Of course, some of the days in winter seem to get awfully long if one is very bored. You have certainly heard someone say, "My, but this has been a long day!"

It does seem, however, that days are about the same length *on the average*. Is there any way we can test whether the days are the same length—either from one day to the next, or at least on the average? One way is to make a comparison with some other periodic phenomenon. Let us see how such a comparison might be made with an hour glass. With an hour glass, we can "create" a periodic occurrence if we have someone standing by it day and night to turn it over whenever the last grain of sand runs out.

We could then count the turnings of the glass from each morning to the next. We would find, this time, that the number of "hours" (i.e., turnings of the glass) was not the same each "day." We should distrust the sun, or the glass, or both. After some thought, it might occur to us to count the "hours" from noon to noon. (Noon is here defined *not* as 12:00 o'clock, but that instant when the sun is at its highest point.) We would find, this time, that the number of "hours" each day is the same.

We now have some confidence that both the "hour" and the "day" have a regular periodicity, i.e., mark off successive equal intervals of time, although we have not *proved* that either one is "really" periodic. Someone might question whether there might not be some omnipotent being who would slow down the flow of sand every night and speed it up during the day. Our experiment does not, of course, give us an answer to this sort of question. All we can say is that we find that a regularity of one kind fits together with a regularity of another kind. We can just say that we base our *definition* of time on the repetition of some apparently periodic event.

5-3 Short times

We should now notice that in the process of checking on the reproducibility of the day, we have received an important by-product. We have found a way of measuring, more accurately, *fractions* of a day. We have found a way of counting time in smaller pieces. Can we carry the process further, and learn to measure even smaller intervals of time?

Galileo decided that a given pendulum always swings back and forth in equal intervals of time so long as the size of the swing is kept small. A test comparing the number of swings of a pendulum in one "hour" shows that such is indeed the case. We can in this way mark fractions of an hour. If we use a mechanical device to count the swings—and to keep them going—we have the pendulum clock of our grandfathers.

Let us agree that if our pendulum oscillates 3600 times in one hour (and if there are 24 such hours in a day), we shall call each period of the pendulum one "second." We have then divided our original unit of time into approximately 10s parts. We can apply the same principles to divide the second into smaller and smaller intervals. It is, you will realize, not practical to make mechanical pendulums which go arbitrarily fast, but we can now make *electrical* pendulums, called oscillators, which can provide a periodic ~~succession~~ with a very short period of swing. In these electronic oscillators it is an electrical current which swings to and fro, in a manner analogous to the swinging of the bob of the pendulum.

We can make a series of such electronic oscillators, each with a period 10 times shorter than the previous one. We may "calibrate" each oscillator against the next slower one by counting the number of swings it makes for one swing of the slower oscillator. When the period of oscillation of our clock is shorter than a fraction of a second, we cannot count the oscillations without the help of some device which extends our powers of observation. One such device is the electron-beam oscilloscope, which acts as a sort of microscope for short times. This device plots on a fluorescent screen a graph of electrical current (or voltage) versus time.

By connecting the oscilloscope to two of our oscillators in sequence, so that it plots a graph first of the current in one of our oscillators and then of the current in the other, we get two graphs like those shown in Fig. 5-2. We can readily determine the number of periods of the faster oscillator in one period of the slower oscillator.

With modern electronic techniques, oscillators have been built with periods as short as about 10^{-11} second, and they have been calibrated (by comparison methods such as we have described) in terms of our standard unit of time, the second. With the invention and perfection of the "laser," or light amplifier, in the past few years, it has become possible to make oscillators with even shorter periods than 10^{-11} second, but it has not yet been possible to calibrate them by the methods which have been described, although it will no doubt soon be possible.

Times shorter than 10^{-11} second have been measured, but by a different technique. In effect, a different *definition* of "time" has been used. One way has been to observe the *distance* between two happenings on a moving object. If, for example, the headlights of a moving automobile are turned on and then off, we can figure out *how long* the lights were on if we know *where* they were turned on and off and how fast the car was moving. The time is the distance over which the lights were on divided by the speed.

Within the past few years, just such a technique was used to measure the lifetime of the π^0 -meson. By observing in a microscope the minute tracks left in a photographic emulsion in which π^0 -mesons had been created one saw that a π^0 -meson (known to be travelling at a certain speed nearly that of light) went a distance of about 10^{-7} meter, on the average, before disintegrating. It lived for only about 10^{-16} sec. It should be emphasized that we have here used a somewhat different definition of "time" than before. So long as there are no inconsistencies in our understanding, however, we feel fairly confident that our definitions are sufficiently equivalent.

By extending our techniques—and if necessary our definitions—still further we can infer the time duration of still faster physical events. We can speak of the period of a nuclear vibration. We can speak of the lifetime of the newly discovered strange resonances (particles) mentioned in Chapter 2. Their complete life occupies a time span of only 10^{-24} second, approximately the time it would take light (which moves at the fastest known speed) to cross the nucleus of hydrogen (the smallest known object).

What about still smaller times? Does "time" exist on a still smaller scale? Does it make any sense to speak of smaller times if we cannot measure—or perhaps even think sensibly about—something which happens in a shorter time? Perhaps not. These are some of the open questions which you will be asking and perhaps answering in the next twenty or thirty years.

5-4 Long times

Let us now consider times longer than one day. Measurement of longer times is easy; we just count the days—so long as there is someone around to do the counting. First we find that there is another natural periodicity: the year, about 365 days. We have also discovered that nature has sometimes provided a counter for the years, in the form of tree rings or river-bottom sediments. In some cases we can use these natural time markers to determine the time which has passed since some early event.

When we cannot count the years for the measurement of long times, we must look for other ways to measure. One of the most successful is the use of radioactive material as a "clock." In this case we do not have a periodic occurrence, as for the day or the pendulum, but a new kind of "regularity." We find that the radioactivity of a particular sample of material decreases by the same *fraction* for successive equal increases in its age. If we plot a graph of the radioactivity observed as a function of time (say in days), we obtain a curve like that shown in Fig. 5-3. We observe that if the radioactivity decreases to one-half in T days (called the "half-life"), then it decreases to one-quarter in another T days, and so

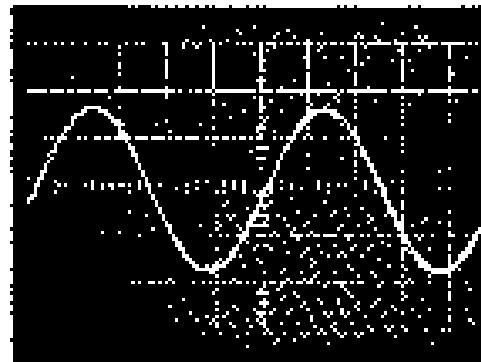

Fig. 5-2. Two views of an oscilloscope screen. In (a) the oscilloscope is connected to one oscillator, in (b) it is connected to an oscillator with a period one-tenth as long.

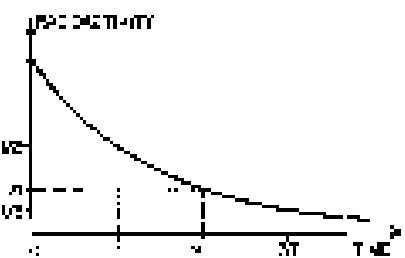

Fig. 5-3. The decrease with time of radioactivity. The activity decreases by one-half in each "half-life," T .

TIME	MEAN LIFE OF	SECONDS	
		SECONDS	SECONDS
10 ⁻¹	Age of universe	3.16 x 10 ¹⁷	
10 ⁻²	Age of earth	4.5 x 10 ⁹	4.5 x 10 ⁹
10 ⁻³	Earthman	10 ⁶	
10 ⁻⁴	Age of pyramid	10 ¹²	
10 ⁻⁵	Age of U.S.	10 ¹⁰	10 ¹⁰
10 ⁻⁶	Life of a man	10 ⁷	10 ⁷
10 ⁻⁷	One day	10 ⁴	
10 ⁻⁸	Light goes from sun to earth	10 ³	10 ³
10 ⁻⁹	One hour sec	10 ²	
10 ⁻¹⁰	1/10 of one minute	10 ¹	
10 ⁻¹¹	Period of red waves	10 ⁻²	10 ⁻²
10 ⁻¹²	Light travels one atom	10 ⁻³	10 ⁻³
10 ⁻¹³	Period of nuclear vibration	10 ⁻⁴	10 ⁻⁴
10 ⁻¹⁴	Light crosses nucleus	10 ⁻⁵	Strong particle
		1 2 3 4 5 6 7	

on. In an arbitrary time interval t there are t/T "half-lives," and the fraction left after this time t is $(\frac{1}{2})^{t/T}$.

If we knew that a piece of material, say a piece of wood, had contained an amount A of radioactive material when it was formed, and we found out by a direct measurement that it now contains the amount B , we could compute the age of the object, t , by solving the equation

$$(1/2)^{t/T} = B/A.$$

There are, fortunately, cases in which we can know the amount of radioactivity that was in an object when it was formed. We know, for example, that the carbon dioxide in the air contains a certain small fraction of the radioactive carbon isotope C¹⁴ (replenished continuously by the action of cosmic rays). If we measure the total carbon content of an object, we know that a certain fraction of that amount was originally the radioactive C¹⁴; we know, therefore, the starting amount A to use in the formula above. Carbon-14 has a half-life of 5000 years. By careful measurements we can measure the amount left after 20 half-lives or so and can therefore "date" organic objects which grew as long as 100,000 years ago.

We would like to know, and we think we do know, the life of still older things. Much of our knowledge is based on the measurements of other radioactive isotopes which have different half-lives. If we make measurements with an isotope with a longer half-life, then we are able to measure longer times. Uranium, for example, has an isotope whose half-life is about 10⁹ years, so that if some material was formed with uranium in it 10⁹ years ago, only half the uranium would remain today. When the uranium disintegrates, it changes into lead. Consider a piece of rock which was formed a long time ago in some chemical process. Lead, being of a chemical nature different from uranium, would appear in one part of the rock and uranium would appear in another part of the rock. The uranium and lead

would be separate. If we look at that piece of rock today, where there should only be uranium we will now find a certain fraction of uranium and a certain fraction of lead. By comparing these fractions, we can tell what percent of the uranium disappeared and changed into lead. By this method, the age of certain rocks has been determined to be several billion years. An extension of this method, not using particular rocks but looking at the uranium and lead in the oceans and using averages over the earth, has been used to determine (within the past few years) that the age of the earth itself is approximately 5.5 billion years.

It is encouraging that the age of the earth is found to be the same as the age of the meteorites which land on the earth, as determined by the uranium method. It appears that the earth was formed out of rocks floating in space, and that the meteorites are, quite likely, some of that material left over. At some time more than five billion years ago, the universe started. It is now believed that at least our part of the universe had its beginning about ten or twelve billion years ago. We do not know what happened before then. In fact, we may well ask again: Does the question make any sense? Does an earlier time have any meaning?

5-5 Units and standards of time

We have implied that it is convenient if we start with some standard unit of time, say a day or a second, and refer all other times to some multiple or fraction of this unit. What shall we take as our basic standard of time? Shall we take the human pulse? If we compare pulses, we find that they seem to vary a lot. On comparing two clocks, one finds they do not vary so much. You might then say, well, let us take a clock. But whose clock? There is a story of a Swiss boy who wanted all of the clocks in his town to ring noon at the same time. So he went around trying to convince everyone of the value of this. Everyone thought it was a marvelous idea so long as all of the other clocks rang noon when his did! It is rather difficult to decide whose clock we should take as a standard. Fortunately, we all share one clock—the earth. For a long time the rotational period of the earth has been taken as the basic standard of time. As measurements have been made more and more precise, however, it has been found that the rotation of the earth is not exactly periodic, when measured in terms of the best clocks. These "best" clocks are those which we have reason to believe are accurate because they agree with each other. We now believe that, for various reasons, some days are longer than others, some days are shorter, and on the average the period of the earth becomes a little longer as the centuries pass.

Until very recently we had found nothing much better than the earth's period, so all clocks have been related to the length of the day, and the second has been defined as $1/86400$ of an average day. Recently we have been gaining experience with some natural oscillators which we now believe would provide a more constant time reference than the earth, and which are also based on a natural phenomenon available to everyone. These are the so-called "atomic clocks." Their basic internal period is that of an atomic vibration which is very insensitive to the temperature or any other external effects. These clocks keep time to an accuracy of one part in 10^9 or better. Within the past two years an improved atomic clock which operates on the vibration of the hydrogen atom has been designed and built by Professor Norman Ramsey at Harvard University. He believes that this clock might be 100 times more accurate still. Measurements now in progress will show whether this is true or not.

We may expect that since it has been possible to build clocks much more accurate than astronomical time, there will soon be an agreement among scientists to define the unit of time in terms of one of the atomic clock standards.

5-6 Large distances

Let us now turn to the question of *distance*. How far, or how big, are things? Everybody knows that the way you measure distance is to start with a stick and count. Or start with a thumb and count. You begin with a unit and count. How

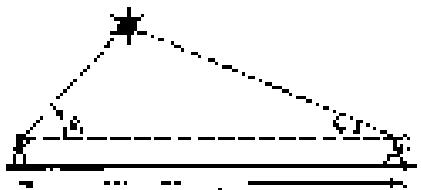

Fig. 5-4. The height of a Sputnik is determined by triangulation

does one measure smaller things? How does one subdivide distance? In the same way that we subdivided time: we take a smaller unit and count the number of such units it takes to make up the longer unit. So we can measure smaller and smaller lengths.

But we do not always mean by distance what one gets by counting off with a meter stick. It would be difficult to measure the horizontal distance between two mountain tops using only a meter stick. We have found by experience that distance can be measured in another fashion: by triangulation. Although this means that we are really using a different definition of distance, when they can both be used they agree with each other. Space is more or less what Euclid thought it was, so the two types of definitions of distance agree. Since they do agree on the earth it gives us some confidence in using triangulation for still larger distances. For example, we were able to use triangulation to measure the height of the first Sputnik. We found that it was roughly 5×10^5 meters high. By more careful measurements the distance to the moon can be measured in the same way. Two telescopes at different places on the earth can give us the two angles we need. It has been found in this way that the moon is 4×10^8 meters away.

We cannot do the same with the sun, or at least no one has been able to yet. The accuracy with which one can focus on a given point on the sun and with which one can measure angles is not good enough to permit us to measure the distance to the sun. Then how can we measure the distance to the sun? We must invent an extension of the idea of triangulation. We measure the relative distances of all the planets by astronomical observations of where the planets appear to be, and we get a picture of the solar system with the proper relative distances of everything, but with no *absolute* distance. One absolute measurement is then required, which has been obtained in a number of ways. One of the ways, which was believed until recently to be the most accurate, was to measure the distance from the earth to Eros, one of the small planetoids which passes near the earth every now and then. By triangulation on this little object, one could get the one required scale measurement. Knowing the relative distances of the rest, we can then tell the distance, for example, from the earth to the sun, or from the earth to Pluto.

Within the past year there has been a big improvement in our knowledge of the scale of the solar system. At the Jet Propulsion Laboratory the distance from the earth to Venus was measured quite accurately by a direct radar observation. This, of course, is a still different type of inferred distance. We say we know the speed at which light travels (and therefore, at which radar waves travel), and we assume that it is the same speed everywhere between the earth and Venus. We send the radio wave out, and count the time until the reflected wave comes back. From the *time* we infer a *distance*, assuming we know the speed. We have really another definition of a measurement of distance.

How do we measure the distance to a star, which is much farther away? Fortunately, we can go back to our triangulation method, because the earth moving around the sun gives us a large baseline for measurements of objects outside the solar system. If we focus a telescope on a star in summer and in winter, we might hope to determine these two angles accurately enough to be able to measure the distance to a star.

What if the stars are too far away for us to use triangulation? Astronomers are always inventing new ways of measuring distance. They find, for example, that they can estimate the size and brightness of a star by its color. The color and brightness of many nearby stars—whose distances are known by triangulation—have been measured, and it is found that there is a smooth relationship between the color and the intrinsic brightness of stars (in most cases). If one now measures the color of a distant star, one may use the color-brightness relationship to determine the intrinsic brightness of the star. By measuring how bright the star *appears* to us at the earth (or perhaps we should say how *dim* it appears), we can compute how far away it is. (For a given intrinsic brightness, the apparent brightness decreases with the square of the distance.) A nice confirmation of the correctness of this method of measuring stellar distances is given by the results obtained for groups of stars known as globular clusters. A photograph of such a group is

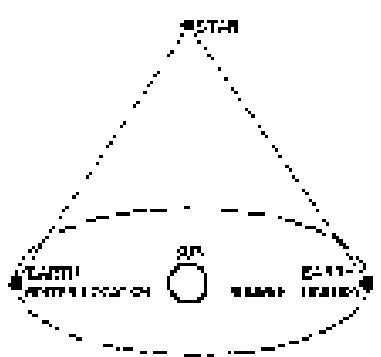

Fig. 5-5. The distance of nearby stars can be measured by triangulation, using the diameter of the earth's orbit as a baseline.

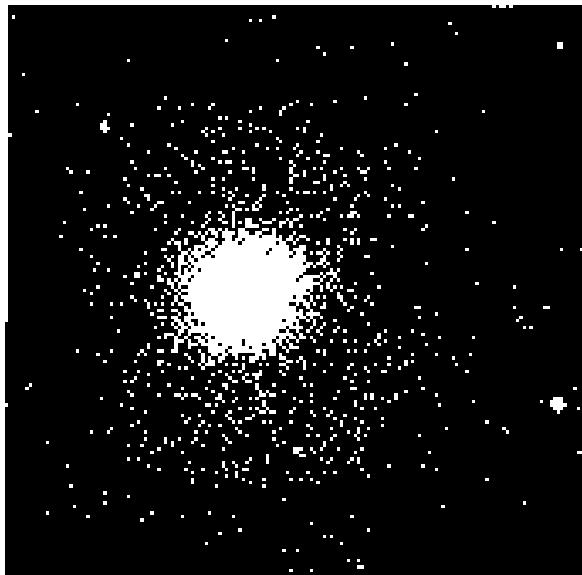

Fig. 5-6. A cluster of stars near the center of our galaxy. Their distance from the earth is 30,000 light-years, or about 3×10^{20} meters.

shown in Fig. 5-6. Just from looking at the photograph one is convinced that these stars are all together. The same result is obtained from distance measurements by the color-brightness method.

A study of many globular clusters gives another important bit of information. It is found that there is a high concentration of such clusters in a certain part of the sky and that most of them are about the same distance from us. Coupling this information with other evidence, we conclude that this concentration of clusters marks the center of our galaxy. We then know the distance to the center of the galaxy—about 10^{20} meters.

Knowing the size of our own galaxy, we have a key to the measurement of still larger distances—the distances to other galaxies. Figure 5-7 is a photograph of a galaxy, which has much the same shape as our own. Probably it is the same size, too. (Other evidence supports the idea that galaxies are all about the same size.) If it is the same size as ours, we can tell its distance. We measure the angle it subtends in the sky; we know its diameter, and we compute its distance—triangulation again!

Fig. 5-7. A spiral galaxy like our own. Presuming that its diameter is similar to that of our own galaxy we may compute its distance from its apparent size. It is 30 million light-years (3×10^{23} meters) from the earth.

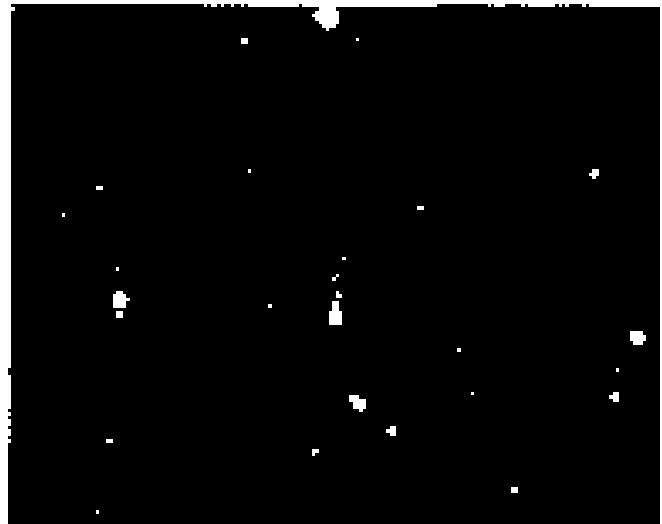

Fig. 5-8. The most distant object, 3C295 in BOOTES (indicated by the cross), measured by the 200-inch telescope to date (1960).

Photographs of exceedingly distant galaxies have recently been obtained with the giant Palomar telescope. One is shown in Fig. 5-8. It is now believed that some of these galaxies are about halfway to the limit of the universe— 10^{26} meters away—the largest distance we can contemplate!

5-7 Short distances

Now let's think about smaller distances. Subdividing the meter is easy. Without much difficulty we can mark off one thousand equal spaces which add up to one meter. With somewhat more difficulty, but in a similar way (using a good microscope), we can mark off a thousand equal subdivisions of the millimeter to make a scale of microns (millionths of a meter). It is difficult to continue to smaller scales, because we cannot "see" objects smaller than the wavelength of visible light (about 5×10^{-7} meter).

We need not stop, however, at what we can see. With an electron microscope, we can continue the process by making photographs on a still smaller scale, say down to 10^{-8} meter (Fig. 5-9). By indirect measurements—by a kind of triangulation on a microscopic scale—we can continue to measure to smaller and smaller scales. First, from an observation of the way light of short wavelength (x-radiation) is reflected from a pattern of marks of known separation, we determine the wave-

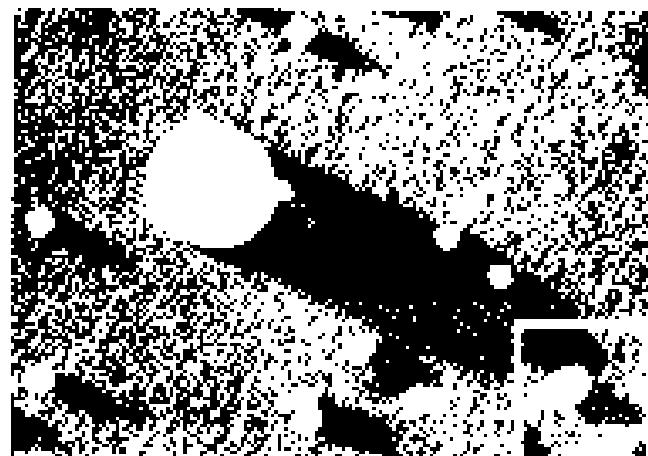

Fig. 5-9. Electron micrograph of some virus molecules. The "large" sphere is for calibration and is known to have a diameter of 2×10^{-7} meter (2000 Å).

DISTANCES	
LIGHT-YEARS	METERS
10^{27}	10^{27} meters
10^1	Edge of universe
10^6	Nearest neighbor galaxy
10^{21}	To center of our galaxy
10^8	To nearest star
10^{15}	Radius of orbit of Pluto
10^{11}	To the sun
10^9	In the moon
10^3	Height of a Spurri
10^2	Height of a TV antenna tower Height of a child
10^{-3}	A grain of salt
10^{-4}	A virus
10^{-5}	Radius of an atom
10^{-10}	Radius of a nucleus
10^{-13}	10^{-13} meters

length of the light vibrations. Then, from the pattern of the scattering of the same light from a crystal, we can determine the relative location of the atoms in the crystal, obtaining results which agree with the atomic spacings also determined by chemical means. We find in this way that atoms have a diameter of about 10^{-10} meter.

There is a large "gap" in physical sizes between the typical atomic dimension of about 10^{-10} meter and the nuclear dimensions 10^{-13} meter, 10^3 times smaller. For nuclear sizes, a different way of measuring size becomes convenient. We measure the *apparent area*, σ , called the effective *cross section*. If we wish the radius, we can obtain it from $\sigma = \pi r^2$ since nuclei are nearly spherical.

Measurement of a nuclear cross section can be made by passing a beam of high-energy particles through a thin slab of material and observing the number of particles which do not get through. These high-energy particles will plow right through the thin cloud of electrons and will be stopped or deflected only if they hit the concentrated weight of a nucleus. Suppose we have a piece of material 1 centimeter thick. There will be about 10^8 atomic layers. But the nuclei are so small that there is little chance that any nucleus will lie behind another. We might *imagine* that a highly magnified view of the situation—looking along the particle beam—would look like Fig. 5-10.

The chance that a very small particle will hit a nucleus on the trip through is just the total area covered by the profiles of the nuclei divided by the total area in the picture. Suppose that we know that in an area A of our slab of material there are N atoms (each with one nucleus, of course). Then the total area "covered" by the nuclei is $N\sigma/A$. Now let the number of particles of our beam which arrive at the slab be n_1 and the number which come out the other side be n_2 . The fraction which do *not* get through is $(n_1 - n_2)/n_1$, which should just equal the

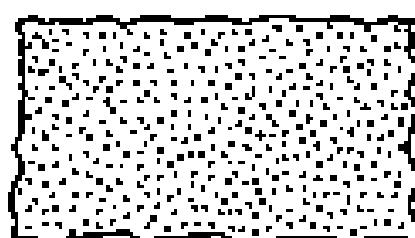

Fig. 5-10. Imagined view through a block of carbon 1 cm thick if only the nuclei were observed.

fraction of the area covered. We can obtain the radius of the nucleus from the equation*

$$\pi^2 = \sigma = \frac{A}{N} \frac{\sigma_0 - \sigma_1}{\sigma_L}$$

From such an experiment we find that the radii of the nuclei are from about 1 to 6 times 10^{-13} meter. The length unit 10^{-13} meter is called *the fermi*, in honor of Enrico Fermi (1901-1958).

What do we find if we go to smaller distances? Can we measure smaller distances? Such questions are not yet answerable. It has been suggested that the still unsolved mystery of nuclear forces may be unravelled only by some modification of our idea of space, or measurement, at such small distances.

It might be thought that it would be a good idea to use some natural length as our unit of length—say the radius of the earth or some fraction of it. The meter was originally intended to be such a unit and was defined to be $(\pi/2) \times 10^{-13}$ times the earth's radius. It is neither convenient nor very accurate to determine the unit of length in this way. For a long time it has been agreed internationally that the meter would be defined as the distance between two scratches on a bar kept in a special laboratory in France. More recently, it has been realized that this definition is neither as precise as would be useful, nor as permanent or universal as one would like. It is currently being considered that a new definition be adopted, an agreed-upon (arbitrary) number of wavelengths of a chosen spectral line.

Measurements of distance and of time give results which depend on the observer. Two observers moving with respect to each other will not measure the same distances and times when measuring what appear to be the same things. Distances and time intervals have different magnitudes, depending on the coordinate system (or "frame of reference") used for making the measurements. We shall study this subject in more detail in a later chapter.

Perfectly precise measurements of distances or times are not permitted by the laws of nature. We have mentioned earlier that the errors in a measurement of the position of an object must be at least as large as

$$\Delta x = h/\Delta p,$$

where h is a small quantity called "Planck's constant" and Δp is the error in our knowledge of the momentum (mass times velocity) of the object whose position we are measuring. It was also mentioned that the uncertainty in position measurements is related to the wave nature of particles.

The relativity of space and time implies that time measurements have also a minimum error, given in fact by

$$\Delta t = h/2E,$$

where $h/2E$ is the error in our knowledge of the energy of the process whose time period we are measuring. If we wish to know *more* precisely *when* something happened we must know less about *what* happened, because our knowledge of the energy involved will be less. The time uncertainty is also related to the wave nature of matter.

* This equation is right only if the area covered by the nuclei is a small fraction of the total, i.e., if $A/N \ll \pi R^2$ is much less than 1. Otherwise we must make a correction for the fact that some nuclei will be partly obscured by the nuclei in front of them.

Probability

"The true logic of this world is in the calculus of probabilities."

—Isaac Todhunter

6-1 Chance and likelihood

"Chance" is a word often used without real everyday living. The radio reports speaking of tomorrow's weather may say, "There is a 50% chance of rain." You might ask, "There is a 50% chance that it won't rain for the next ten years?" Because after all, there were chance. A seismologist may be interested in the question, "What is the chance that there will be an earthquake somewhere in Los Angeles in California next year?" A physicist might ask the question, "What is the chance that a particular geiger counter will register radioactive counts in the next ten seconds?" A politician or a citizen might be interested in the question, "What is the chance that there will be a nuclear war within the next ten years?" You may be interested in the chance that you will learn something here. In chapter 1.

By chance, we mean something like a guess. Why do we make guesses? We make guesses when we wish to make a decision but have incomplete information or uncertain knowledge. We want to make a guess as to what things are, or what things can happen. Often we wish to make a guess because we have to make a decision. For example, shall I take my chances with the incorrect? For what in the moment should I design a new building? Shall I build myself a fallout shelter? Shall I change my goals in entrepreneurial negotiations? Shall I go to class today?

Sometimes we make guesses because we wish, with our limit of knowledge, to say as much as we can about some situation. Really, any generalization is of the nature of a guess. Any theorized theory is a kind of guesswork. There are several types of more or less educated guesses. The theory of probability is a way for formulating better guesses. The language of probability allows us to speak specifically about some situation which may be highly variable, but which does have some consistent, average behavior.

Let us consider the flipping of a coin. If the two sides head and tail are "heads" we base our way of knowing what to expect on the number of experiments done. You would flip a coin a large number of times; there should be about equal numbers of heads and tails. We say, "The probability that a toss will land heads is 0.5."

You speak of probability only for observations carried out because being made in the future. By the "potential" of a particular outcome of an observation we mean our estimate for the most likely frequency of a number of repeated observations that will yield that particular outcome. If we imagine repeating an observation such as tossing a die 1000 times, and if we call N_j the outcome of the most likely number of outcomes that will give some specified result j , say the result "heads," then by $N_j/1000$, the probability of observing j , we mean

$$P(j) = N_j/1000 \quad (6.1)$$

Our definition requires several comments. First of all, we may speak of a probability of something happening only if the outcome is a possible outcome of some reasonable observation. It is not clear exactly what makes any sense at all. "What is the probability that there is a ghost in that house?"

6-1 Chance and likelihood

6-2 Likelihood

6-3 The random walk

6-4 A probability distribution

6-5 The uncertainty principle

You may object that no situation is exactly repeatable. That is right. Every different observation must have at least one different aspect. All we can say is that the "unrepeated" observations coincide for our intended purpose, appear to be equivalent. We should assume, at least, that each observation was made from an approximately parallel situation, and especially with the same day or of approximately the same. (If we could do experiments here in a controlled way, our estimates of the chance of winning are different than if we do not.)

We should emphasize the word "best". In Fig. 16, the curve is entitled to represent numbers based on actual observations. It is our best estimate of what would occur in a large number of trials. Probability depends therefore on our knowledge and our state of mind or estimate. In this, you cannot argue with it! But this only means there is a certain amount of agreement in the estimated sense on many things, so that different people will make the same estimate. Probabilities need not however, be "theoretical" numbers. Since they depend on our ignorance, they may become different if our knowledge changes.

You may have noticed another ratio between we expect of our daily coin of probability. We have referred to it as our estimate of the most likely number... I mean that we expect to obtain exactly N_0 , but that we expect a number near N_0 , and then N_1 numbers. N_1 is more likely than any other number in the scoring. If we toss a coin, say, 10 times, we would expect that the number of heads would not be very likely to be exactly 10. But a close value would be more likely, say, 9, 10, 11, 8, 9, 10, 11. However, if we knew closely, we would decide that 10 heads is about twice that any other number. We would write $P(N_0) = 0.5$.

Why did we choose to be more ready than my sister is? Well, we might have argued that because of the "theoretical" number of heads, the likely number of heads is N_0 , i.e., a total number of tosses N . But the true likely number of heads is $N_0 + \Delta N$. (We are assuming that every toss gives either heads or tails, and no "other" result.) So, it seems "most likely" there is an excess of heads to tails. On the basis some assumes this is the case (or "as good"), we might give a "theoretical" for heads and tails. So we might set $N_0 = N_1 = N_0$. It follows that $N_0 = N_1 = N/2$, or $P(N_0) = P(N_1) = 0.5$.

We can generalize our reasoning to any situation in which there are no restrictions to "hypothetical" (that is, equally likely) possibilities of making a hit. Our particular example is to probability that a "single draw" from a scuttled deck of 52 cards will show the ten of clubs in \mathcal{J}_0 . The probability of finding a card with a picture is $1/52$.

If there are several different colored balls in an opaque box and we pick one out, "at random" (that is, without looking), the probability of getting a ball of a particular color is c . To probability that a "single draw" from a scuttled deck of 52 cards will show the ten of clubs is \mathcal{J}_0 . The probability of finding a card with a picture is $1/52$.

In Chapter 5 we described the idea of a "series" in various ways and one of them went like this: "When we did so we were talking about probabilities." When we drew a single card, probability then was known. There is no chance that it will pass right through and come through that hole with a cushion. Once the needle is in one, that's our control over it, we probably are right at 10 cards. We just don't know if it will be a diamond, a heart, and the rest of the cards have a cross-hatch, or not, then the card will "pass through" by the needle, etc. In a large number of random draws, we expect certain "number" of hits, N_0 , of course, will be in the neighborhood of the total number of the cards in the deck.

$$N_0/N = n_0/d$$

(6.2)

We note n_0/d , that is, that the probability that a single projectile particle will make a collision with a target atom is n_0/d .

$$P_0 = \frac{n}{d} \cdot d$$

(6.3)

where n/d is the number of atoms per unit cross section.

6.3 FLUCTUATIONS

We would like now to remember what probability we consider to consider all same gender detail can be asked: "How many heads do I really expect to get if I flip a coin $N = 10$?" Before answering the question, however, it is good to what does happen in such an "experiment". Figure 6-1 shows the results obtained in the first class "first" of 1000 experiments in which $N = 10$. The sequences of "heads" and "tails" are known just as they were recorded. The first game gave 11 heads; one second also had the same 11. In three trials we did not get 10 heads. Should we begin to suspect the coin? Or even, knowing in thinking that the most likely number of "heads" in such a game is 15? Many tests made 7023 were made to obtain a total of 100 experiments of 100 tosses each. The results of the experiment are given in Table 6-1.

Table 6-1
Number of heads in successive trials of 100 tosses of a coin

	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20

Fig. 6-1. Observed sequence of heads and tails in 100 games of 30 moves each.

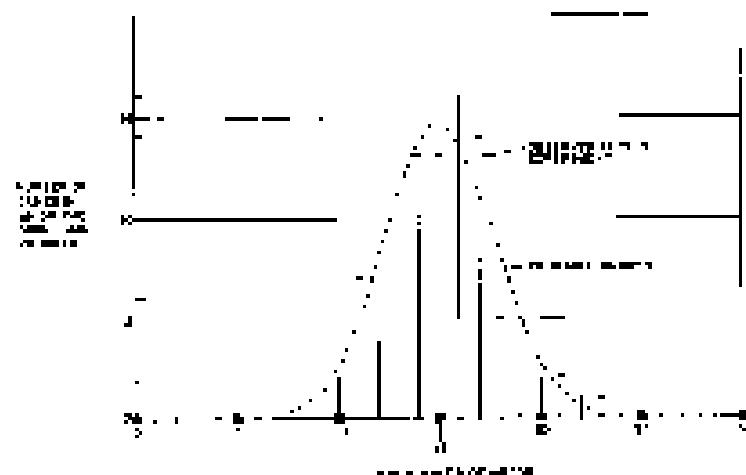

Fig. 6-2. Summary of the results of 1000 games of 100 moves each. The vertical bars show the number of games in which a score of H was obtained. The dashed curve shows the expected number of games with the score H obtained by a probability theory.

Looking at the numbers in Table 6-1, we see that some of the results are "surprised"; indeed they are between 12 and 13. We can gain a better feeling for the details of their results if we plot a graph of the distribution of the results. We start the "number of games" in which a score of H was obtained, and put the numbers for each H . Such a graph is shown in Fig. 6-2. A score of 14 heads was obtained in 11 games. A score of 15 heads was also obtained 11 times. Scores of 16 and 17 were each obtained 12 times. At 12, 13, and 18 we see 10 games. Is there something unusual? Was our "luck" not good enough?"

* After the first three games, the game theory was actually lost by taking 27 photons to exactly 100, but these forming the number of heads that showed.

we conclude now that the "most likely" score for a game of 10 tosses is not 50% heads? Strangely, in all the games in our together, there were 100 tosses. And the mean number of heads obtained was 14.92. The fraction of tosses that gave heads is 0.497, very nearly, but slightly less, than half. We should certainly not assume that the probability of obtaining heads is greater than 0.5. The fact that one particular set of characters just happened most often is no argument. We still expect that the most likely number of heads is 5.

We may ask the question, "What is the probability that a game of 10 tosses will yield 5 heads—or 6 or any other number?" We know well that in a game of one toss, the probability of obtaining one head is 0.5, and the probability of obtaining no head is 0.5. In a game of 10 tosses there are now possible outcomes: HHH, HTT, and so on. Since each of these sequences is equally likely, we conclude that (a) the probability of a score of two heads is $\frac{1}{5}$, (b) the probability of a score of one head is $\frac{2}{5}$, (c) the probability of zero heads is $\frac{1}{5}$. There are two ways of obtaining one head, but only one of obtaining either zero or two heads.

Consider next a game of 5 tosses. The same toss is equally likely to be heads or tails. There is only one way to obtain 3 in 5, we must have obtained 2 heads or 2 tails and two tails, and then, since on the last. Therefore, there are 10 ways of obtaining 2 heads. We know three odds after having thrown 100 heads (see page 20); we could have heads after the 50th only one head in the first 50 tosses (one way), for scores of 1-50, 2-50, 3-50, 4-50, 5-50 we have then the number of equally likely scores 5, 1, 3, 3, 1, with a total of 16 different possible sequences. The probabilities are in Fig. 6.3.

The argument we have been going over by diagrammatical analogy like that in Fig. 6.3. It is clear how the diagram should be extended for games with a larger number of tosses. Figure 6.4 shows such a diagram for a game of 6 tosses. The number of "ways" to any point on the diagram is just the number of different "path" sequences of heads and tails which can be taken from the starting point. The vertical position gives us the total number of heads thrown. The set of numbers which appears in such a diagram is known as Pascal's triangle. The numbers are also called the binomial coefficients because they also appear in the expansion of $(a + b)^n$. If we count the number of tosses and the number of heads thrown, the 16 numbers in the diagram are usually denoted by the symbol $\binom{n}{k}$. We may note that in passing that the binomial coefficients can also be computed from

$$\binom{n}{k} = \frac{n!}{k!(n-k)!}, \quad (6.4)$$

where $n!$, or "factorial," represents the product $(n)(n-1)(n-2)\dots(2)(1)$.

We are now ready to compute the probability $P(k)$, or of throwing k heads in n tosses, using our definition Eq. (6.1). The total number of possible sequences is 2^n (since there are 2 outcomes for each toss) and the number of ways of getting k heads is $\binom{n}{k}$, all equally likely, so we have

$$P(k, n) = \frac{\binom{n}{k}}{2^n}. \quad (6.5)$$

Since $P(k, n)$ is the fraction of games which we expect to yield k heads, then in 100 games we should expect to find 5 heads 100 $\cdot P(5, 100)$ times. The actual curve in Fig. 6.2 passes through the points computed from $100 \cdot P(k, 100)$. We see that we never in about a score of 15 heads in 14 in 15 games, whereas the score was observed in 13 games. We expect a score of 16 in 15 or 16 games, but we obtained that score in 16 \pm 6. Such fluctuations are "part of the game."

This method we have used can be applied to the most general situation in which there are many possible outcomes of a single observation. Let us designate the n -outcomes by M (for "multi;" and L , "less")¹. In the general case, the probability of M or L in a single event need not change. Let p_M be the probability of obtaining the result M . Then, if the probability of L , is necessarily

Fig. 6.3. A diagram for showing the number of ways to score 0, 1, 2, or 3 heads in a game of 5 tosses.

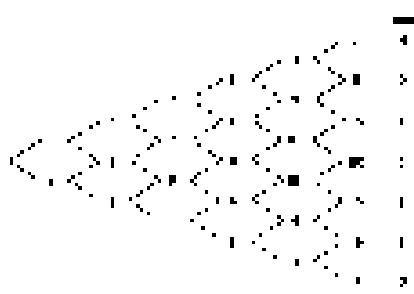

Fig. 6.4. A diagram like that of Fig. 6.3, for a game of 6 tosses.

(1) $\forall i$: In a set of events, the probability $P(E_i)$ that E_i will be observed is given by

$$P(E_i) = \text{exp}(E_i^2 \tau)^{-1} \quad (6.6)$$

This probability function is called the *exponential distribution probability*.

6-3 The random walk

There is another interesting problem in which the idea of probability p is required. Let's consider a "one-dimensional walk." In its simplest version, we imagine a "game" in which a "player" starts at the point $x = 0$ and at each "turn" is required to take a step either forward (forward $+x$) or backward (backward $-x$). The driving force behind such a walk is, for example, the presence of a cloud. You can't see through the foggy weather. In its general form, the random walk is related to the motion of atoms (or other particles) in a gas (cf. Brownian motion), and can be the random walk of some measurements. You will see that the random walk problem is closely related to the coin tossing problem we have already discussed.

First let us look at a few examples of a random walk. We may characterize the walker's progress by the net distance D traveled in N steps. We show in the graphs of Fig. 6-5 three examples of typical D 's a random walker (We have used four colors to distinguish the results of the coin tosses shown in Fig. 6-1)

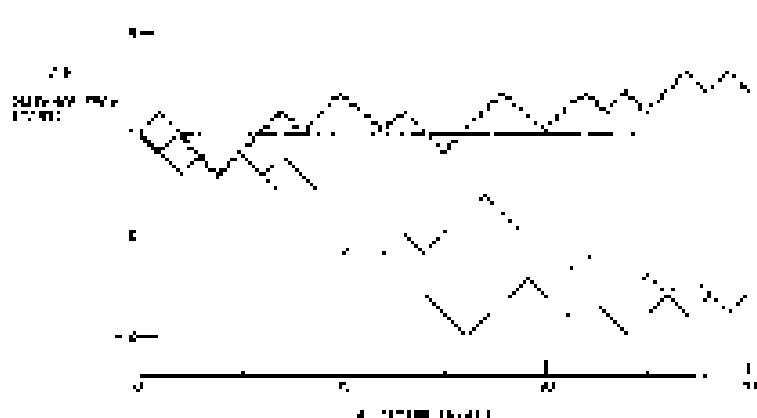

Fig. 6-5. The progress made in a random walk. The horizontal coordinate D is the total number of steps taken in the walk. Eccentric ERINI's last night he moved from his starting position.

What can we say about such a motion? We might first ask: "How far does he get on the average?" We may expect that the average progress will be zero, since he is equally likely to go either forward or backward. But we have the following situation: if, instead, he is more likely to have a good flight from the start up coast, we might, therefore, ask what is his average distance travelled in objective miles. I.e., is $\langle D \rangle$ the average of $|D|$? I.e., because it is convenient to deal with another measure of "progress," namely one of "the distance" D^2 is positive for either positive or negative motion, and is therefore a reasonable measure of such random walking.

We can thus use the expected value of D^2 as just $\langle D^2 \rangle$, the number of steps taken. By "expected value" we mean the probable value (our best guess), which we can think of as the expected average behavior in many repeated experiments. We represent $\langle D^2 \rangle$ as an expected value by $\langle D^2 \rangle$, and may refer to it also as the "mean squared distance." A relationship $\langle D^2 \rangle = \langle D \rangle^2 + \langle D^2 - D^2 \rangle$ is often approximately ($D^2 - D^2 \rangle \ll \langle D^2 \rangle$) true. Distances will be measured in terms of units of distance. We shall not concern here the units of distance.)

The expected value of D_N^2 for $N > 1$ can be obtained from D_{N-1} . If, after $(N-1)$ steps, we have $D_{N-1} = k$, then after N steps we have $D_N = D_{N-1} + 1$ or $D_N = D_{N-1} - 1$, with equal probability.

$$D_N^2 = \begin{cases} D_{N-1}^2 + 1 & \text{if } D_{N-1} = 1, \\ & \dots \\ D_{N-1}^2 - 2D_{N-1} + 1 & \text{if } D_{N-1} = N-1. \end{cases} \quad (6.7)$$

In a random of independent sequences, we expect to obtain each value one half of the time, so our average expectation is just the average of the two possible values. The expected value of D_N^2 is $\langle D_N^2 \rangle = 1$. In general, we should expect for D_{N-1}^2 the "expected value" $\langle D_{N-1}^2 \rangle$ by definition. So

$$\langle D_N^2 \rangle = \langle D_{N-1}^2 \rangle + 1 \quad (6.8)$$

We have already shown that $\langle D_0^2 \rangle = 1$; it follows that

$$D_N^2 = N, \quad (6.9)$$

(*per definitionem* $\langle D_N^2 \rangle = N$)

If we wish a number like a distance, rather than a distance squared, to represent the "progress made toward the origin" in a random walk, we can use the "root-mean-square distance," D_{rms} :

$$D_{\text{rms}} = \sqrt{\langle D^2 \rangle} = \sqrt{N}. \quad (6.10)$$

We have pointed out that the random walk is closely similar in its mechanics to the coin-tossing game we considered at the beginning of the chapter. Let's suppose the direction of each step is in correspondence with the appearance of heads or tails in a coin toss. If $D > 1$ just $N_0 = N_1$, the 2 times in N number of head-tail pairs. Since $N_0 = N_1 = N/2$, the total number of steps (two tosses), we have $D = 2N_0 = N$. We have derived earlier an expression for the expected distance, $\langle N_0 \rangle$, from the origin N_0 and, recall, the result of $\langle D \rangle$ (6.5). Since N is just a constant, we have the corresponding expression for D , namely for every head-tail pair, $N/2$ there is a tail-tail, "return" of 2 between N_0 and D). The graph of $\langle D \rangle$ vs N represents the distribution of distances, or "right get in 10 random steps until $D \approx 15$ is to be read $D \approx 3$; $N = 12$, $D = 2$, etc.)

The variance of D_N from its expected value $N/2$ is

$$M_{DD} = \frac{N}{2} = \frac{D}{2}, \quad (6.11)$$

so the correlation is

$$\left(\frac{D_N - \langle D \rangle}{\sqrt{M_{DD}}} \right)_{\text{rms}} = \frac{1}{2}\sqrt{N} \quad (6.12)$$

According to our result for D_{rms} , we expect that the "typical" distance is 10 steps, roughly $\sqrt{N} = \sqrt{30} = 5.5$, so a typical k should be about $5.5/2 = 2.8$ units from 15. We see that the "tail" of the curve in Fig. 6.2, measured from the center, is just about 3 units, in agreement with this result.

We are now in a position to consider a question we have avoided up to now. "How shall we tell whether a walk is "random" or "biased"?" We can give here at least a partial answer. For an honest walk, we expect the fraction of the times heads appears, $\langle N_0 \rangle/N$, to be,

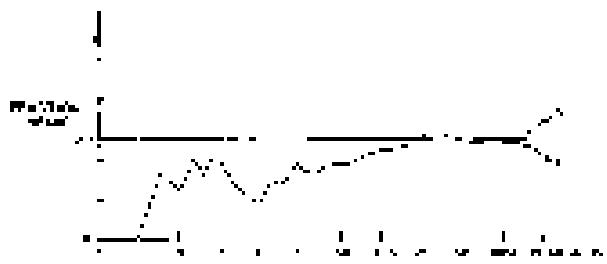

$$\frac{\langle N_0 \rangle}{N} = 0.5. \quad (6.13)$$

We also expect an overall N_0 to deviate from $N/2$ by about $\sqrt{N}/2$, or 2 or more to deviate by

$$\frac{\sqrt{N}}{N/2} = \frac{2}{\sqrt{N}}.$$

The larger N is, the closer we expect the fraction N_0/N to be to 0.5000.
6-3

Fig. 6-6. The fraction of the times that gave heads in a particular sequence of N heads or tails.

In Fig. 6-6 we have plotted the fraction N_H/N for the coin results reported earlier in this chapter. We see the tendency for the fraction of heads to approach 0.5 for large N . Unfortunately, for any given finite combination of runs, there is no guarantee that the observed frequency will be exact, even the expected deviation. There is always the chance that a large fluctuation, a "long run," of heads or tails will give an abnormally large deviation. All we can say is that if the deviation is near the expected value (as was often the case of 2 or 3), we have no reason to suspect the honesty of the coin. If it is much larger, we might begin to suspect, but cannot prove that the coin is loaded for tails (the fraction is lower).

We have also not considered how we should treat the case of a "short" or even single "long" run that always lands in either of two positions than we have just assumed: heads or tails. We have defined $P(H) = N_H/N$. How will we know what to expect for N_H ? In some cases, the best we can do is to measure the number of heads occurring in long numbers of tosses. In a way of anything better, we must set $N_H = P_H(\text{observed})$. (How could we expect anything else?) We must understand, however, that in such a case a different type of error, called the antecedent, might result in statistical significance. One would expect, however, that the various answers should agree within the certainty limit if $P(H)$ is near one half). All regions in which a result actually occurs that an "asymmetrical distribution" probability has an "error," one writes

$$P(H) = \frac{N_H}{N} \pm \frac{1}{\sqrt{N}}. \quad (6.14)$$

There is an implication in such an expression that there is a "true" or "natural" probability which could be compared if we knew enough, and that the observation may be in "error" due to a fluctuation. There is, however, no way to make such thinking logically consistent. It is probably better to realize that the probability concept is to a sense subjective, that it is always based on incomplete knowledge, and that its quantitative evaluation is subject to change as we obtain more information.

6-4 A probability distribution

Let us return now to the random walk and consider a modification of it. Suppose that in addition to a random choice of the direction (+ or -) of each step, the length of each step also varied in some unpredictable way, the only constraint being that on the average the step length was one unit. This case is more representative of something like the thermal motion of a molecule in a gas. If we let the length of a step be, then S may have any value, but nevertheless will be "near" 1. To be specific, we shall let $\langle S^2 \rangle = 1.0$, equivalently, $S_{\text{rms}} = 1$. Our definition for $\langle D^2 \rangle$ would proceed as before except that Eq. (6.8) would be changed now to read

$$\langle D^2 \rangle = \langle D_{\text{ave}}^2 \rangle + \langle S^2 \rangle = \langle D_{\text{ave}}^2 \rangle + 1.0. \quad (6.15)$$

We have, as before, that

$$\langle D_{\text{ave}}^2 \rangle = N. \quad (6.16)$$

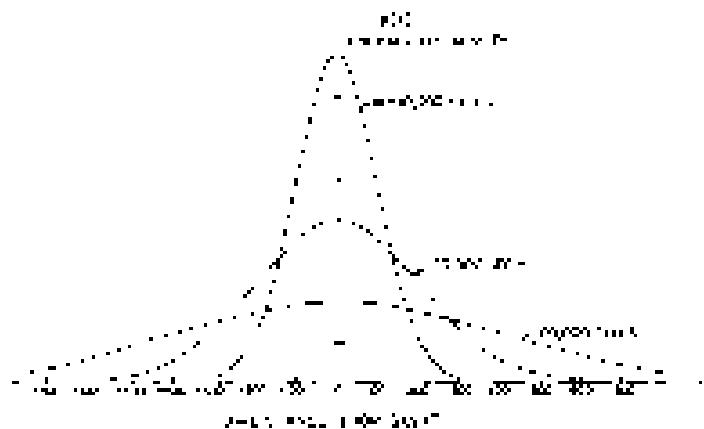

Fig. 6-7. The probability density for walking up or the distance D from the starting place in a random walk of N steps. (It is measured in units of the step length.)

What would we expect now for the distribution of distances D ? What is for example the probability that $D = 0$ after 40 steps? The answer is zero—the probability is zero that D will be an indefinite result, since there is no cause in all this, the sum of the successive steps (of varying lengths) would usually exceed the sum of forward steps. We cannot plot a graph like that of Fig. 6-2.

We can, however, obtain a representation similar to that of Fig. 6-2, if we ask, not what is the probability of obtaining D exactly equal to 0, 1, or 2, but instead what is the probability of obtaining D between 0, 1, or 2. Let us define $p(x, \Delta x)$ as the probability that D will lie in the interval Δx located at x (say from x to $x + \Delta x$). We expect that $p(x, \Delta x)$ is the fraction of D having D proportional to Δx , the width of the interval. So we can write

$$p(x, \Delta x) = p(x) \Delta x. \quad (6.13)$$

The function $p(x)$ is called the probability density.

The form of $p(x)$ will depend on N , the number of steps taken, and also on the distribution of individual step lengths. We cannot determine the $p(x)$ here, but for large N , $p(x)$ is the same for all reasonable distributions of individual step lengths, and depends only on N . We plot $p(x)$ for three values of N in Fig. 6-7. You will notice that the "bell-shaped" regions spread from $x = 0$ as these curves $\propto \sqrt{N}$, as we have shown it should be.

You may wonder that the value of $p(x)$ near zero is "curiously" proportional to \sqrt{N} . This occurs because the curves are all of a similar shape and ratio to one another. The areas must all be equal. Since $p(x) \Delta x$ is the probability of finding D in the interval Δx , we can determine the chance of finding D somewhere inside an arbitrary interval, from x_1 to x_2 , by cutting the interval in a number of small increments Δx and calculating the sum of the terms $p(x) \Delta x$ for each increment. The probability that D lies everywhere between x_1 and x_2 , which we may write $P(x_1 < D < x_2)$, is equal to the shaded area in Fig. 6-8. The smaller we take the increments Δx , the more correct is our result. We can write therefore,

$$P(x_1 < D < x_2) = \sum p(x) \Delta x = \int_{x_1}^{x_2} p(x) dx. \quad (6.14)$$

The area under the whole curve is the probability that D lies somewhere (that is, has some value between $x = -\infty$ and $x = +\infty$). That probability is surely 1. We must have that

$$\int_{-\infty}^{+\infty} p(x) dx = 1. \quad (6.15)$$

Stochastic curves in Fig. 5-7 go, while in proportion to \sqrt{R} , their heights must be proportional to $1/\sqrt{M}$ to maintain the total area equal to 1.

The probability density function we have been describing is one that is uncorrected mass moments. It is known as the normal or gaussian probability density. It has the mathematical form

$$p(v) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(v-\bar{v})^2}{2\sigma^2}}, \quad (6.20)$$

where σ is called the standard deviation and is given, in our case, by $\sigma = \sqrt{N}$ if the mass per gram is sufficient. Our $\bar{v} = \sqrt{RT}/M$.

We remember neither can the motion of a molecule, or of any particle, in a gas is like a random walk. Suppose we drop a small bit of organic compound and its mass of it vapor escape into the air. If there is no air currents, so that the air is circulating, the excess will also carry the vapor with them. But even in perfectly still air the vapor will gradually spread out until it has permeated throughout the room. We might detect it by its color or odor. The individual molecules of the organic vapor spread out in ∞ as because of the molecular collisions caused by all sorts of other molecules. If we know the average "step" size, say the number of steps is b in 10^{-10} sec., we can find the probability that one, or several molecules will be found at some distance from their starting point after any given time, t sec. As time passes, more steps are taken and the gas spreads out as in the successive curves of Fig. 5-7. In a later chapter, we shall find out how the step sizes and step frequencies are related to the temperature and pressure in a gas.

Earlier, we said that the pressure of a gas is due to the molecules bumping against the walls of the container. When we come later to make a more quantitative description, we will wish to know how fast the molecules are going. Why? because, since the impact they make will depend on that speed. We cannot, however, speak of the speed of the molecules. It is necessary to use a probability description. A molecule may have any speed, but some speeds are more likely than others. We describe what is going on by saying that the probability that any particular molecule will have a speed between v and $v + \Delta v$ is $p(v) \Delta v$, where $p(v)$ is probability density, a given function of the speed v . We shall see later how Maxwell, using common sense and the idea of probability, was able to find a mathematical expression for $p(v)$. The result of the form $p(v) \Delta v$ is shown in Fig. 6-9. Velocities may have any value, but are most likely to be near the true particle in expected value (\bar{v}).

We consider first of the curves of Fig. 6-9 in a somewhat different way. If we consider the molecules in a typical container (with a volume of, say, one liter), then there are a vast large number, N , of molecules present ($N \approx 10^{23}$). Since $p(v) \Delta v$ is the probability that one molecule will have its velocity in Δv by our definition of probability we mean that the expected number (ΔN) to be found with a velocity in the interval Δv is given by

$$\langle \Delta N \rangle = N p(v) \Delta v. \quad (6.21)$$

We call $\langle \Delta N \rangle$ the "fully situated in velocity." The area under the curve for two velocities v_1 and v_2 (for example the shaded area in Fig. 6-9, representing for the curve $p(v)$) the expected number of molecules with velocities between v_1 and v_2 . Since with a gas we are usually dealing with large numbers of molecules, we expect the deviations from the expected numbers to be small (like $1/\sqrt{N}$), so we often neglect to say the "expected" number, and say instead: "The number of molecules with velocities between v_1 and v_2 is the area under the curve." We should remember, however, that such statements are always about probable numbers.

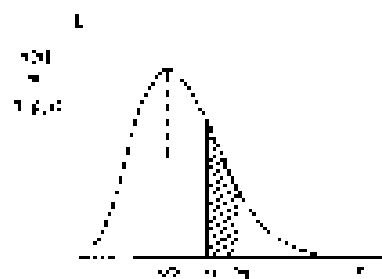

Fig. 6-9. The distribution of velocities of the molecules in a gas.

* Maxwell's expression is $\langle \Delta N \rangle = C v^2 / \sqrt{\pi R T}$, where C is a constant related to the mass density and C is chosen so that the total probability is one.

6-5 The uncertainty principle

The theory of probability was originally used in describing the behavior of the 10^{23} or so molecules in a sample of a gas, for it is clearly unphysical even to attempt to write down the position or velocity of each molecule. When probability was first applied to such problems, it was considered to be a convenience, a way of dealing with very complex situations. We now believe that the ideas of probability are essential in a description of atomic properties. According to quantum mechanics, the mathematical theory of particles, there is always some uncertainty in the specification of positions and velocities. We can, in fact, say that there is a certain probability that any particle will have a position near some coordinate x .

We can give a probability density $p_1(x)$ such that $p_1(x)dx$ is the probability that the particle will be found between x and $x + dx$. If the particle is reasonably well localized, say near x_0 , the function $p_1(x)$ might be given by the graph of Fig. 6-1(a). Similarly, we can specify the velocity of the particle by means of a probability density $p_2(v)$, with $p_2(v)dv$ the probability that the velocity will lie between v and $v + dv$.

It is one of the fundamental tenets of quantum mechanics that the two functions $p_1(x)$ and $p_2(v)$ cannot be chosen independently since, in particular, x and v must inherently interact. If we call the "width" of the $p_1(x)$ curve Δx , and that of the $p_2(v)$ curve Δv , the factor in the figure, $\Delta x \Delta v$, denotes that the product of the two will be at least as big as the number $\hbar/2\pi$, where \hbar is the mass of the particle and Δ is a Greek letter δ which means "and" or that "there is". We may write this basic relationship as

$$(\Delta x)(\Delta v) \geq \hbar/2\pi. \quad (6-22)$$

This equation is a statement of the Heisenberg uncertainty principle that we mentioned earlier.

Since the right-hand side of Eq. (6-22) is a constant, the equation says that if we try to "pin down" a particle by trying to fix its position or place it goes up by having a high speed. Or if we try to force it to go very slowly, or at a precise velocity, it "spreads out" so that we do not know very well just where it is. Particles behave in a funny way!

The uncertainty principle describes an inherent fuzziness that just can't, in any attempt, be described away. Our most precise description of nature must be in terms of probabilities. There are some people who do not like this way of describing nature. The best example that I have could only tell $\hbar/2\pi$ to myself, you will never live; they would know its speed and position him however. In the early days of the development of quantum mechanics, Heisenberg was quite worried about his publisher. He went to Ehrenfest and said, "He, I simply find that I don't know how to determine how electrons should go!" He worried about this problem for a long time and he really never really committed himself to the fact that this is the best description of nature that we can give. There are still one or two physicists who are working on the subject who have an intuitive conviction that it is possible somehow to describe the world in a definite way and that all of this uncertainty about the way things are set to removed. He has not been successful.

The necessary uncertainty in our specification of the position of a particle becomes most important when we wish to describe the structure of atoms. In the hydrogen atom, which has a nucleus of one proton with one electron outside of the nucleus, the uncertainty in the position of the electron is so large, as the atom itself is. We cannot, therefore, properly speak of electron buzzing in some "orbit" around the proton. The result we can say is that there is a certain chance per unit volume of finding the electron in an element of volume ΔV at the distance r from the proton. This probability density $\rho(r)$ is given by quantum mechanics. For an undisturbed hydrogen atom $\rho(r) = 4\pi r^2 n$, which is a bell-shaped function like that in Fig. 6-5. This is known as the "hydrogen" atom, where the function is decreasing rapidly. Since there is a solid probability of finding the electron at the mass of a proton.

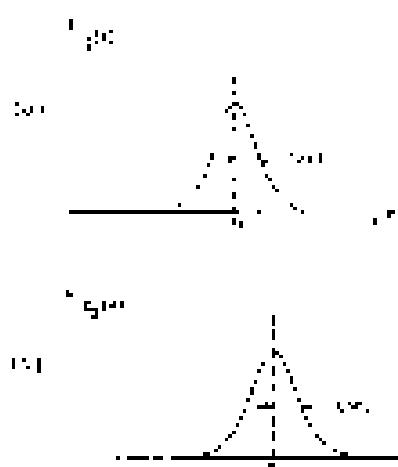

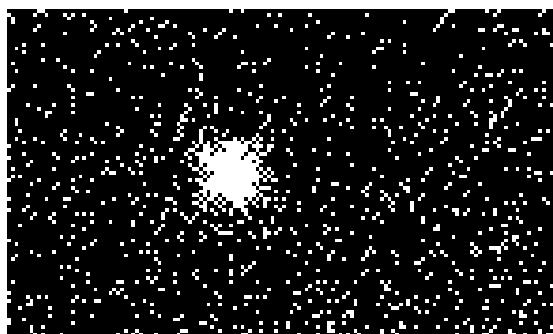

Fig. 6-1. Probability densities for observation of the position and velocity of a particle.

Fig. 6.11. A way of visualizing a hydrogen atom. The density (whiteness) of the cloud represents the probability density for observing the electron.

from the nucleus which greater than a , we may think of a as "the radius of the atom," about 10^{-10} meters.

We can form an image of the hydrogen atom by calculating a "cloud" whose density is proportional to the probability density for observing the electron. A sample of such a cloud is given in Fig. 6.11. This our best "picture" of a hydrogen atom is a nucleus surrounded by an "electron cloud" (although we really mean a "probabilistic cloud"). The electron is there somewhere, but "where" permits us to know only the chance of finding it at any particular place.

In its efforts to learn as much as possible about the atom, nuclear physics has found that certain things can never be "known" with certainty. Much of our knowledge must always remain uncertain. The word we can know is in terms of probabilities.

The Theory of Gravitation

7-1 Planetary motion

In this chapter we shall extend one of the most far-reaching generalizations of the human mind. While we are extending the human mind, we should take some time now to recall in case of anyone that could follow with sufficient interest and generality even an elementary science principle as the law of gravitation. What is the law of gravitation? It is that every object in the universe attracts every other object with a force which the two bodies in question¹ to the mass of each other varies inversely as the square of the distance between them. This statement can be expressed mathematically by the equation

$$F = G \frac{Mm}{r^2}$$

Now the we add the fact that an object responds to a force by accelerating in the direction of the force by an amount that is inversely proportional to the mass of the object, we shall have seen everything you need, for a sufficiently brilliant mathematician could then deduce all the consequences of these two principles. However, since you are not expected to be sufficiently brilliant as yet, we shall discuss the consequences in more detail, and not just leave you with only these two bare principles. We shall briefly relate the story of the discovery of the law of gravitation and discuss some of its consequences, its effects on history, the masses can prove a law easily, see some references of the law—say my favorite: we shall also discuss the relationships of the law to the other laws of physics. All this cannot be done in one chapter, but these subjects will be treated in due time in subsequent chapters.

The story begins with the ancients inserting the motions of planets among the stars, and finally showing that they were around the sun, a fact that was rediscovered later by Copernicus. Exactly how the planets were around the sun, with exactly what motion, took a little more work to discover. In the beginning of the 17th century there were great debates over whether they really went around the sun or not. Tycho Brahe had an idea that was different from anything proposed by the ancients. His idea was that these debates about the nature of the motions of the planets would be unnecessary if predicted positions of the planets in the sky were measured sufficiently accurately. If measurement showed exactly how the planets moved, then perhaps it would be possible to establish one or another viewpoint. This was a tremendous idea—that to find something out, is better to make some accurate experiments than to carry on deep philosophical arguments. Pursuing this idea, Tycho Brahe studied the position of the planets for many years in his observatory in the island of Hven, near Copenhagen. He made voluminous tables, which were then studied by the mathematician, Kepler, after Tycho's death. Kepler discovered from the data some very beautiful and remarkable relationships regarding planetary motion.

7-2 Kepler's laws

First of all, Kepler found that each planet goes around the sun in a curve called an ellipse, with the sun at a focus of the ellipse. An ellipse is not just one thing; there is a very specific and precise curve that can be obtained by using two forces, one at each focus, a force of引力 and a force of repulsion; mathematically, it

7-7 What is gravity?

7-8 Gravity and relativity

is defined as equal to the sum of whose distances from two fixed points (the foci) is a constant. Or if you will, it is a function of distance (Fig. 7-1).

Kepler's second observation was that the planets do not go around the sun in uniform speeds, but move faster when they are nearer the sun, and move slowly when they are farther from the sun, in precisely this way. Suppose a planet is observed at any two successive times, let us say a week apart, and that the radius vector is shown in the figure. In each time its position. The white arc is covered by the planet during the week, and the two radii require, since a certain plane now, the shaded area shows it (Fig. 7-2). If two similar observations are made a week apart at a pair of the orbit, farther from the sun, then the planet moves more slowly, the primary bounded area is greater than that in the first case. So, in accordance with the second law, the orbital speed of each planet is such that the same "average" equal areas in equal times.

Finally, a third law was discovered by Kepler much later; this law is of a different character. From the other two, however, it does not with only a single short jump relate all the planets to one another. This law says that when the orbital periods and orbit sizes of any two planets are compared, the periods are proportional to the $3/2$ power of the orbit size. In this statement the period is the time interval it takes a planet to go completely around its orbit, and the size is measured by the length of the greatest diameter of the elliptical orbit, technically known as the major axis. More simply, if the planets went in circles, as they nearly do, the time required to go around the circle would be proportional to the $3/2$ power of the diameter (or radius). Thus Kepler's three laws are:

- I. Each planet moves around the sun in an ellipse, with the sun at one focus.
- II. The areas swept from the sun to the planet, whether real or imaginary, are equal intervals of time.
- III. The squares of the periods of any two bodies are proportional to the cubes of the semimajor axes of their respective orbits: $T^2 \propto a^{3/2}$.

7-2 Development of dynamics

While Kepler was discovering these laws, Galileo was studying the laws of motion. The problem was, what makes the planets go around? (In those days one of the theories proposed was that the planets went around because holding them were invisible angels, keeping them and driving the planets forward. You will see that this theory is now modified. It is assumed that in order to keep the planets going around, the invisible angels take them in a different direction and they have no wings. Otherwise, it is a conceivable celestial theory!) Galileo was interested in very remarkable forces when he lived, which was unusual for understanding these laws. That is, the principle of inertia—of something moving with uniform speed, resists changing its uniformity, once started, it will go on forever, existing at a uniform speed in a straight line. (Why does it keep on curving? We do not know, but that is the way it is.)

Newton modified this idea, saying that the only way to change the motion of a body is to use force. If no body speeds up, a force has been applied to the vector of motion. On the other hand, if its motion is changed to a new direction, a force has been applied, also. Newton thus asked the question: If there is a force, it must change the speed or the direction of motion of a body. For example, if a stone is released to falling and is pulled around in a circle, it takes a force to keep it in the circle. We have to pull on the string. In fact, it is less so that the acceleration produced by the force is inversely proportional to the mass, or the force is proportional to the mass times the acceleration. The more massive a thing is, the stronger the force required to produce a given acceleration. (The mass can be measured by pulling other stones on the end of the same string and making them go around the same circle at the same speed. In this way it is found that more or less force is required, the more massive object requiring more force.)

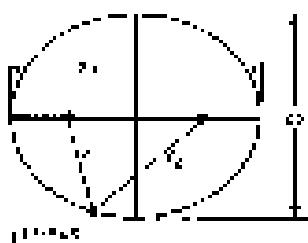

Fig. 7-1. An ellipse.

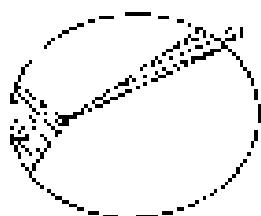

Fig. 7-2. Kepler's law of areas.

* A radius vector is a line drawn from the sun to the point in a planet's orbit.

The brilliant idea resulting from these considerations is that no mechanical force is needed to keep a planet in orbit (the *Leviathan* and *Principia* by sympatheticity) because the planet would move in that direction anyway—if there were nothing at all to distract the planet would go off in a straight line. But the actual motion deviates from the line on which the body would have gone if there were no force; this gives the body necessarily an angle relative to the moving line in the direction of its motion. In other words, because of the principle of inertia, the force needed to cause the motion of a planet around the sun is not a force around the sun but around the sun. (If there is a force toward the sun, the star might be the angel, *“because”*.)

2.4 Newton's law of gravitation

From his better understanding of the theory of motion, Newton appreciated that it was could be the attractive nature of forces that govern the motion of the planets. Newton wrote to himself (and perhaps we may be able to prove it soon) that “the very fact that celestial motions are swept out in equal times is a pretty argument of the composition of forces” (his italics) and “certainly motion—then. Below of course is a direct consequence of this fact, that all of the forces are directed exactly toward the sun.”

Next, by analyzing Kepler's third law it is possible to show that the further away the planet, the weaker the forces. If two planets of different distances from the sun are compared, the analysis shows that the forces are inversely proportional to the square of the respective distances. With the compilation of the laws, Newton concluded that there must be a force, inversely as the square of the distance, directed in a line between the two objects.

Bring in more of evidence in favoring for gravity. The Newton suggestion, of course, was this relationship applied more generally than just to the sun holding the planets. It was already known, for example, that the planet Jupiter had moons going around it as the moon of the earth goes around the earth, and Newton felt certain that each planet held its moons with a force. He already knew of the force holding a man to the earth, so he imagined that this was a universal force that everything held everything else.

The next problem was whether the pull of the earth on its people was the same as a pull on the moon, also inversely as the square of the distance. If an object on the surface of the earth falls 16 feet in the first second, then it is agreed from Galileo¹ that does the moon fall in the same time? We might say that the moon does not fall at all. But if the moon fell as the earth, it would go off in a straight line, rather than goes in a circle instead, so it really falls off from where it would have been if there were no force at all. We can calculate from the radius of the moon's orbit (which is about 240,000 miles and how long it takes to go around the earth (approximately 29 days), how far the moon moves in its orbit in 1 second, and can then calculate how far it falls in one second.^{*} This distance turns out to be, roughly 1/30 of a mile in a second. That fits very well with the inverse square law, because the earth's radius is 3000 miles, and if something which is 240,000 miles from the center of the earth lets 16 feet in a second, something 3000 miles, or 1/80 as far away, should fall only 1/80th of 16 feet, which also is roughly 1/30 of a foot. Trying to put this theory of gravitation to a test by a mile calculation, Newton made his calculations very carefully, and found a discrepancy so large that he hardly was satisfied by facts, and did not publish his results. Six years later a new measurement of the size of the earth showed that the astronomical had been using an incorrect distance to the moon, when they measured it, thus he made the calculations again, and the corrected figures, also obtained beautiful agreement.

This idea that the term “force” is somewhat misleading, because, as you see, it does not cause any change. This idea is sufficiently interesting to merit further

* That is how far the end of the object will fall below the straight line tangent at the point where the object was suspended before.

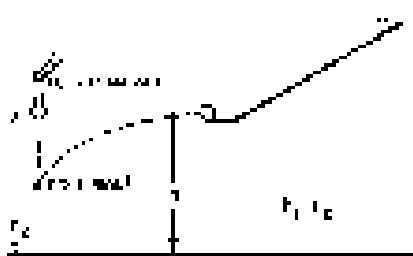

Fig. 7-3. Apparatus for showing the independence of distance and time interval.

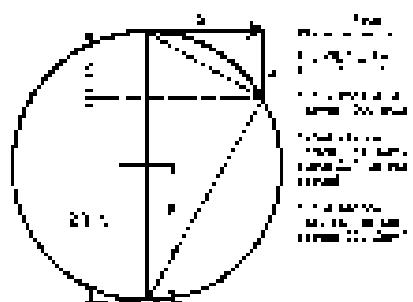

Fig. 7-4. Acceleration toward the center of a spherical earth. From Newton's geometry, $a/r = (G M_{\text{earth}})^{1/2}/r^3$, where M is the mass of the earth, 4000 miles, r is the distance "travelled horizontally" in one second, and G is the constant of gravitation, 6.67 times 10⁻¹¹.

explanation: the motion balls in the same path ought always fall straight down over the world, instead of falling out sideways. Let us take an example in the surface of the earth. An object, released near the earth's surface, will also fall 16 feet; even though it is moving horizontally, it still falls the same 16 feet, in the same time. Figure 7-3 shows an apparatus which demonstrates this. On the horizontal, t_0 is the time it takes for an object to be driven forward a little distance away. At the same instant is a ball which is going to fall vertically, and there is a curve, just switch enough so that it has the same time of fall as the first ball, comes to track. The second ball is released. Then they come to the same depth at the same time as measured by the fact that they fall in the same time. An object like a bullet shot horizontally, in a long enough way in one second—perhaps 1000 feet—he will still fall as far if it is aimed horizontally. What happens if we shoot a bullet lower and lower? Of course, longer than the earth's surface is curved. If we shoot it the same height, then when it falls 16 feet, it may be at just the same height above the ground as it was before. How can that be? It still falls, but the earth curves away, so it falls "backward" the earth. The question is, how far does it fall in one second? And the answer is 16 feet below the horizon! (See Fig. 7-4) we see the earth with us 1000 miles radius, and the angular, straight-line path that the bullet would take if there were no forces. Now, if we use some of Kepler's results in geometry, which says that the tangential to the mean proportionals between the two parts of the diameter cut by an angle of 1 radian, are exactly the horizontal distance travelled is the mean proportional between the 16 feet it has and the 1000-mile diameter of the earth. The square root of $(16/32800) \times 1000$ comes out very close to 5 miles. Thus we see that if the bullet runs out 5 miles a second, it then will continue to fall toward the earth at the rate of 16 feet each second, but will never get any closer, because the earth keeps curving away from it. This is what Galileo Galilei maintained in his "Dialogue Concerning the Two Chief World Systems," namely that the earth moves per second. (He mighta little longer because he was a little lighter.)

Another consequence of a new law is useful only if we can take more than we put in. Now, Newton used the second and third of Kepler's laws to derive his law of gravitation. What did he prefer? First, the analysis of the moon's motion was a predictive scheme. It connected the falling of objects on the earth's surface with that of the moon. Second, the question is, is the orbit an ellipse? We shall see in a later chapter how it is possible to rule this out theoretically, and in this one will prove that it should be an ellipse. So the first is needed by Kepler's first law. That Newton made his first guess full prediction.

Let us go to gravitation again. Many phenomena had previously undergone. For example, the pull of the moon on the earth causes the ocean tides. In mysterious the moon pulls the water up under it and makes the tides—people had thought of this before, but they were not as clear as Newton, and so they thought there ought to be only one tide during the day. The reasoning was that the moon pulls the water up uniformly making a high tide and a low tide, and since the earth spins under such a tide, the tide goes up and down in 12 hours. Astronomers thought that the high tide should be on the side out of the earth because as they argued, the moon pulls the earth away from the center. Most of these theories are wrong. It actually works like this—the pull of the moon for the earth and for the water is "backward" at the center. So, now, in which a place in the moon is pulled there *less* the average and the water which is farther away from it is pulled *more* than the average. Furthermore, the water can flow while the moon rotates, causing the tide picture to be something of this form:

What do we need to "balance"? What balances? Is the moon plus the whole earth toward it, why don't the earth fall right "up" to the moon? Because the earth does the same trick as the moon, it gives the earth around a point which is inside the earth but not at its center. The moon does the just as much the

* The sand is not present in this diagram.

earth, the earth and the moon both go around a central point, each following toward this common center, as shown in Fig. 7-5. This action around the common center is what balances the "pull" of each. So the earth is not going in a straight line toward the center, since it is moving. The word on the outside is "unbalanced" because the moon's attraction there is weaker than it is at the center of the earth, where it just balances the "centerugal force." The result of this unbalance is that the earth goes away from the center of the earth. On the near side, the attraction from the moon is stronger, and the unbalance is in the opposite direction, in space, the earth moves from the center of the earth. The net result is that we get an tidal bulges.

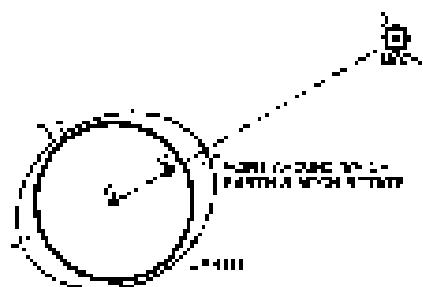

Fig. 7-5. The earth moves away with tides.

7-6 Erroneous gravitation

Who, then, can understand when we discuss gravity? Everyone knows the earth is round. Why is "heavier" toward? That is easy; it is due to gravitation. The earth can be understood to be round merely because everything about everything else and so it has attracted itself together so far as it can. If we go farther, the earth is no longer a sphere, when you are running, and this brings in additional effects which tend to oppose gravity near the equator. It is noted that the earth doesn't lie elliptical, and we can get the right shape for the ellipse. The error comes because now the sun, the moon, and the earth should be (nearly) spheres, just from the law of gravitation.

What does one do with the law of gravitation? If we look at the moons of Jupiter we can understand everything about the way they move around that planet. Incidentally, there was once a rather difficult problem with the moons of Jupiter that is worth remarking on. These four moons were studied very carefully by Galileo, who noted that the moons sometimes seemed to be ahead of schedule, and some times behind. (He calculated their orbits by waiting a very long time and finding out how long it took for the moons to go around.) Now they were ahead when Jupiter was particularly close to the earth and they were behind when Jupiter was further from the earth. This would have been a very difficult thing to explain according to the law of gravitation—it would have been, in fact, the death of the standard theory if there were no other explanation. If a law does not work even in one place where it ought to, it is just wrong. But the reason for the discrepancy was very simple and beautiful: it took a little while to see the moons of Jupiter because of the time it takes light to travel from Jupiter to the earth. When Jupiter is closer to the earth the time is 4½ hours, and when it is far from the earth, the time is more. This is why moons appear to us, on the average, a little earlier or a little behind, depending on whether they are closer to or farther from the earth. This phenomenon shows that light does not travel instantaneously, and destroyed the first estimate of the speed of light. This was done in 1656.

If all of the planets had had pull on each other, the force which controls, let us say, Jupiter in going around the sun is not just the force from the sun, there is also a pull from, say, Saturn. This force is not really strong, since the pull is much more massive than Sun—uh, but there is some pull, so the orbit of Jupiter should not be a perfect ellipse, and it is not, it is slightly off and "wobbly," around the exact elliptical orbit. Such a motion is a little more complicated. Attempts were made to analyze the motion of Jupiter, Saturn, and Uranus on the basis of the law of gravitation. The effects of each of these bodies on each other were calculated to see whether or not the right directions and integrations in these motions could be completely in accordance. It is one law. Go and behold, for Jupiter and Saturn, it was well, but Uranus was "wobbly." It behaved in a very peculiar manner. It was not traveling in an exact ellipse, but that was understandable because of the actions of Jupiter and Saturn. But, even if Uranus were made for these corrections, Uranus still was not going right on the laws of gravitation were it change, of being overruled, a possibility that could not be ruled out. Two men, Adama and Levenson, in England, at Paris, independently,

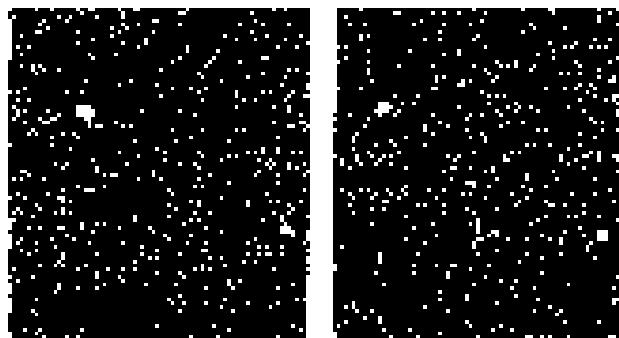

Fig. 7-6. A double star system.

entered at another possibility: perhaps there is another planet dark and invisible, which we have not seen. This planet, N , could put on charms. They calculate where such a planet would have to be in order to cause the observed perturbations. They send messages to the respective observatories, saying, "Gentlemen, point your telescopes in such and such a place, and you will see a new planet." It does depend on which whom you are working with, whether they say "they are sure it is not there" or not. They did pay attention to Newton; they looked, and there is no planet N now! The other observatory then also looked very quickly in the next few days and saw it not.

This discovery shows that Newton's laws are absolutely right in the solar system; not do they hold beyond the relatively small distances of the nearest stars! Two test best in the question, do stars affect each other as well as planets? We have definite evidence that they do in the double stars. Figure 7-6 shows a double star—two stars very close together (there is also a third star in the picture so that we will know that the photograph was not tampered). The stars are shown as they appeared several years later. We see that, relative to the "fixed" star, the two of the pair have rotated, i.e., the two stars are going around each other. Do they rotate according to Newton's law? Circular measurements of the true positions of one such double star system are shown in Fig. 7-7. There we see a beautiful ellipse, the minimum being in 1862 and going all the way around to 1904 (or now it must have gone around once more). Everything coincides with Newton's law, except that the star B has A near on the focus. Why should that be? Because the plane of the ellipse is not to be "perpendicular," say. We are not looking at right angles to the orbit plane, and when an ellipse is viewed at a tilt, it appears an ellipse but no longer a circle at the same place. Thus we can detect double stars, moving about each other, according to the requirements of the gravitational law.

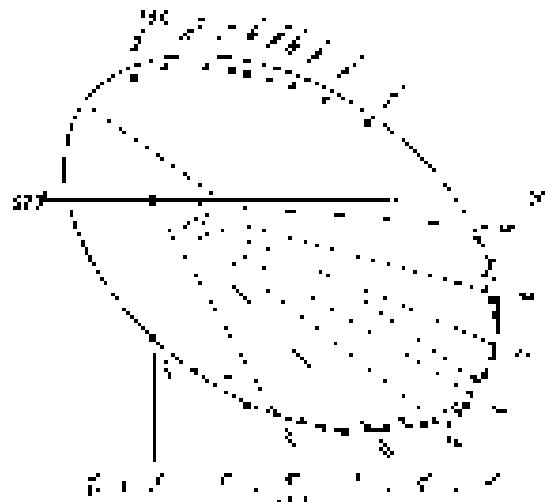

Fig. 7-7. Orbit of Star B with respect to Star A.

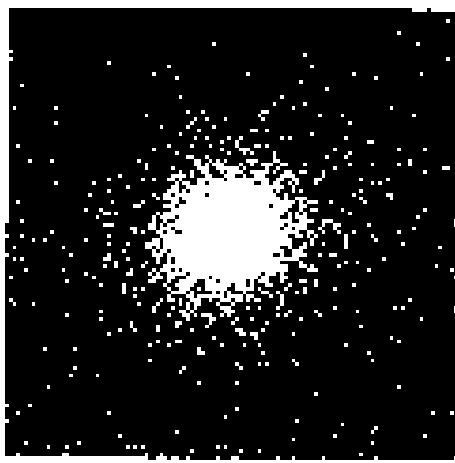

Fig. 7-8. A cluster of galaxies.

that the law of gravitation is true at even larger distances is indicated by Fig. 7-8. If one farther see gravitation acting here, he has no need. This figure shows one of the most beautiful things in the sky—a galactic star cluster. All of the galaxies cluster together, though they are packed so close toward the center. It is due to the pull of gravity of all the units. As a rule, the distances between even the nearest stars are very great and they very rarely collide. There are about 10^{11} stars in the cluster, and as we move outward there are fewer and fewer. It is obvious that due to the attraction among these stars it is clear that gravitation exists at these enormous dimensions, perhaps 100,000 times the size of the solar system. Let us now go further, and look at the galaxy photographs in Fig. 7-9. The shape of this galaxy indicates an obvious tendency for its matter to gather in a center. Of course we cannot prove that the law here is just as it is at square, only that there is at least some law in the enormous dimension, that holds the whole thing together. One may say, "Well, this is all very clever but who is it not just a bull?" Because it is obvious that the gravitation which a smaller gives up is transmitted, it must interact mostly in a plane. Accidentally, if you are looking for a good problem, the exact details of how the matter and forces here that determines the shape of these galaxies has not been worked out. It is, however, clear that the shape of the galaxy is due to gravitation; even though the complexities of the structure have not yet allowed

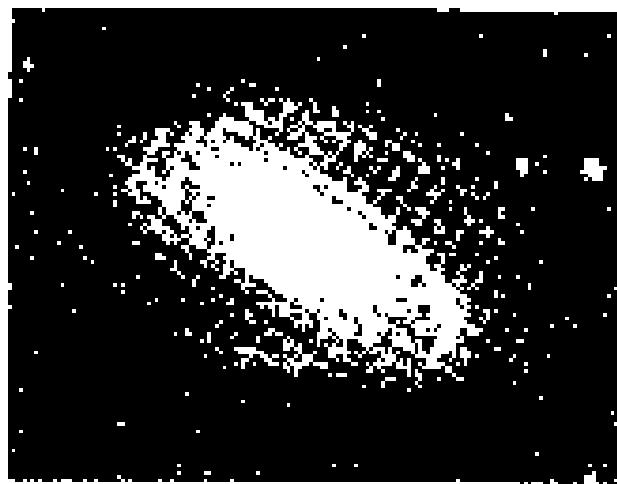

Fig. 7-9. A galaxy.

us to analyze it completely. In a galaxy we have a scale of perhaps 50,000 to 100,000 light years. The earth's distance from the sun is 8½ light minutes, so you can see how huge these dimensions are.

Gravity appears to act at these huge dimensions, as indicated by Fig. 7-10, which shows many "little" things clustered together. This is a cluster of galaxies, just like a star cluster. The galaxies attract each other so much that they form an agglomeration into clusters. Perhaps gravitation exists even over distances of over a million of light years, so far as we now know, gravity seems to go on forever regardless of the size of the system.

Not only can we understand the mechanics, but from the law of gravitation we can now get some idea about the origin of the stars. We have a big cloud of dust and gas, as indicated in Fig. 7-11, the gravitational attractions of the pieces of dust pull one another together until little lumps begin to form in the Figure (Fig. 7-12). These "lump" blocks which may be the beginning of the accumulation of dust and gases when due to their gravitation, begin, in turn, stars. Whether we have ever seen a star born or not is still open while Fig. 7-13 shows us the place of origin which suggests that we have. At the left is a picture of a region of gas with some stars in it taken in 1947, and at the right is another picture, taken only 7 years later, which shows two new bright spots. Has gravitation drawn the gravity center of each of them and reflected it into a lump enough that the stellar nucleus separation occurs in the manner and turns it into a star? Perhaps, and perhaps not. It is conceivable that in only seven years we should be so lucky as to see a star change its "face" visible to us; it is much less probable that we should see just

7-6 Cavendish's experiment

Gravitation, therefore, extends over enormous distances. But if there is a force between tiny particles, we might be led to believe it must be a force between our own objects. Instead of trying to watch the stars go around each other, why don't we make a pair of lead balls and make them orbit around the center of the ball of lead? The difficulty of this experiment when done in such a simple manner is the very weakness or deficiency of the force. It must be some sort of attractive force, which means something has to happen to keep the air molecules from flying off the Earth. And another: how the force can be measured. It was first measured by Cavendish, who, an apparatus which is schematically indicated in Fig. 7-13. The idea demonstrated the effect between two large, lead spheres of low density and another pair of lead spheres which were supported by a very fine fiber, called a torsion fiber. By measuring how much the fiber gets twisted, one can measure the strength of the force, so if the force is inversely proportional to the square of the distance, one can determine how strong it is. Thus, one may accurately determine the constant G in the formula

$$\delta \propto G \frac{m_1 m_2}{r^2}$$

All the masses and distances are known. You say, "We know G already for the earth." Yes, but we didn't know the mass of the earth. By knowing G , from this measurement and by knowing how strongly the earth attracts, we can indirectly know how great is the mass of the earth! This experiment has been called "weighing the earth." Cavendish claimed he was weighing the earth, but when he was measuring G , the coefficient of the gravity law, that is the only way in which the mass of the earth can be determined. G turns out to be

$$6.673 \times 10^{-11} \text{ newton} \cdot \text{m}^2/\text{kg}^2.$$

It is hard to exaggerate the importance of the effect on the history of science produced by this exactness of the theory of gravitation. Compare the situation, the scientific fulcrum, the incomplete knowledge, and the power in the earlier days when there were endless debates and disputes, with the courage and simplicity of this law. The fact that all the known and unknown and unknown parts of the sky were able to prevent them, and to make this man work undeterred if ever disaster hit the planets it could prove. This is the reason for the success of the sciences in following years, for it gave hope that the hidden phenomena of the world might also have such beautifully simple laws.

7-7 What is gravity?

But is this such a simple law? What about the machinery of it? All we have done is to deduce from the earth moves around the sun, but we have not said what makes it go. Newton made my hypothesis about this; he was so afraid to do that, that he did without getting into the controversy at all. No one has since given any machinery. There is no characteristic of the physical laws that they have this abstract character. The law of conservation of energy is, however, concerning gravitation, can have to be calculated and added together, two no mention of the machinery, and likewise the law of mechanics can not, that the mathematical laws for which no machinery is available. Why can we not manufacture to describe nature without a mechanism behind it? No one knows. We have to keep going because we find out more that way.

Many mechanisms for gravitation have been suggested. I am interested to consider one at least, which many people have thought of from time to time. A tree, for example, is quite subject to changes when he "falls over" it, but he does this "in his dream". It was first suggested about 1750. Suppose there were tiny vehicles moving in space at very high speed in a circular path and being only slightly attracted to gravity through mass. When they are disturbed, they give an impulse to the earth. However, given there are so many gravity and very no center, the

-----*

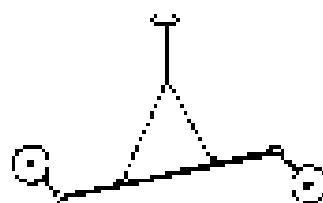

Fig. 7-13. A schematic diagram of the apparatus used by Cavendish to verify the law of universal gravitation by actually measuring the gravitational constant G .

imposes no balance. But when the sun is nearby, the particles coming toward the earth through the sun's rays are partially absorbed, so fewer of them are coming from the sun than are coming from the other side. Therefore, the earth feels a net impulse toward the sun, and it does not take much longer for the sun to impinge at 1% of the distance—because of the reduction of the resistance of the solid angle that the sun subtends as we vary the distance. What is wrong with that machinery? It involves some new consequences which you can prove. This particular view has the following merit over the earth, in circling around the sun, would impinge on more particles which are coming from the front side than from the hind side when you are in the sun. So even in your face is stronger than that on the back of your head. Therefore there would be more impulse given to the earth from the front, and the earth would feel a resistance to move and would be slowing up in its orbit. You can calculate how long it would take for the earth to slow as a result of this resistance, and it would not take long enough for the earth to still be in a orbit, so this mechanism does not work. You can very easily have an inverted "U" explaining gravity without also predicting some other phenomenon that does not exist.

But we still cannot yet make a relation of gravitation to other forces. This is an angle of view that in terms of other forces at the present time, it is not an angle of electricity or anything like that, so we have no explanation. However, gravitation and other forces are very similar and it is interesting to note analogies. For example, the force of attraction between two charged objects is exactly like the law of gravitation; the force of electricity is also similar with a minus sign. Times the product of the charges, and inversely to the square of the distance. It is in the opposite direction of a repel. But it is still not very remarkable that the two laws involve the same function of distance! Perhaps gravitation and electricity are just some closely related law, we think. Many attempts have been made to unify them: the so-called unified field theory is only a very elegant attempt to combine gravitation and magnetism. But in unifying gravitation and electricity, the most curious thing is to combine strength of the forces. Any theory that combines even both measurable deduces how strong the gravity is.

If we take, in some natural or in the caption of two electrons (i.e., it's a "natural" charge due to electricity), and the attraction of two electrons due to their masses, we can measure the rate of electrical repulsion to the gravitational attraction. The ratio is independent of distance and is a fundamental constant of nature. The ratio is shown in Fig. 7-11. The gravitational attraction relative to the electrical repulsion between two electrons is 1 divided by 4.17×10^{39} . The question is, who chose such a large number in some form? It is not accidental. Like this, is it the volume of the entire observable universe? We have considered two equal charges of the same mass, one electron. This "united number" is a natural constant, as it involves something deep in nature. When you say "united number" you mean something like "the ratio of the universe." When you say "united constant," you mean it is of the ratio of the ratio of the universe. It is very difficult to find an equation for which such a farcical number is a natural root. Other possibilities have been thought of: one is to relate it to the age of the universe. Certainly we have to find another "united number": But the age is 10¹⁰ years. The ratio is 10¹⁰ years? No, because years are not "natural"; they were devised by man. As an example of something natural, let us consider the time it takes light to go across a proton, 10^{-22} second. Two components have to do with the age of the universe? 2×10^{10} years, the sequence 2×10^{10} ? It is about the same number of zeros going off it, so it has been suggested that the gravitational constant is related to the age of the universe. If this is true, the gravitational constant would change over time, because as the universe got older the ratio of the age of the universe to the time which it takes for light to go across a proton would be gradually increasing. In this case, the gravitational constant is changing with time! Of course the changes would be so small that it is quite difficult to be sure.

One test which we can think of is to determine when we shall have the $\sqrt{2}$ of the change: during the past 10¹⁰ years, which is approximately the age from the earliest life on the earth to now, a thousandth of the age of the universe. In this case, the gravity constant would have increased by about 10 percent. D 7-3

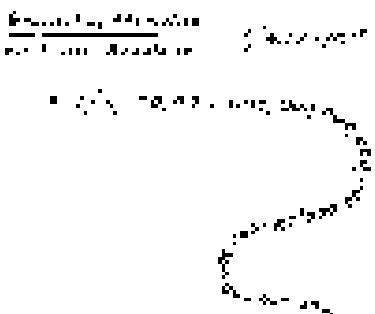

Fig. 7-4. The relative strength of electrical and gravitational interactions between two electrons.

but if we do, if we consider the structure of the sun—the balance between the weight of its material and the tension which holds it together—is maintained inside it—we can deduce that if the gravity were 10 percent stronger, the sun would be much more massive, 10 percent brighter, by the fifth power of the gravity constant! If we calculate what happens to the orbit of the earth when the gravity is changing, we find that the earth was then closer in. Anywhere the sun would be stronger, the gravitational acceleration, and all of the states, would not have been in the sun, but separate the air or life would not have to live in the sun. So we know now believe that the gravity constant is changing with the age of the universe. But such arguments as the one we have just given are not very convincing, and the subject is not completely closed.

It is a fact that the force of gravitation is proportional to the mass. PROPORTIONAL means it holds exactly a measure of inertia. If one hand it is to hold something which is going around in a circle. Therefore two objects, one heavy and one light, spin around the same axis at the same speed because of gravity, will stay together because they form a circle requires a force which is enough for a bigger mass. And as the gravity is stronger for a given mass in just the right proportion so that the two objects will go around together. If one object were made the other would always move; it is a perfect balance. Therefore Galileo in Time would find things "weightless" inside a space ship, as they happened to let go of a piece of it. For example, it would go around the earth, instead the earth goes to the whole space ship, and you would appear to move "weightless" because the ship spaces. It is very interesting that this force is exactly proportional to the mass with great precision, because if it were not exactly proportional there would be some effect by which inertia and weight would differ. This absence of such an effect has been checked with great accuracy by an experimental done first by Eötvös in 1909 and more recently by Dicke. For a kilometer-sized, the masses and weights are exactly proportional within 1 part in 100,000,000 or less. This is a famous cubic experiment.

7.3 Gravity and relativity

Another topic regarding gravitation is Einstein's modification of Newton's law of gravitation. I skip all the excitement it created, Newton's law of gravitation is very good! It was modified by Einstein to take into account the theory of relativity. According to Einstein, the gravitational effect is instantaneous. That is, if we were to move a mass, we would feel a new force because of the new presence of the mass by such means we could send signals at infinite speed. Einstein advanced arguments which suggest that we cannot send signals faster than the speed of light so the law of gravitation must be wrong. By correcting it to make the change is a constant, we have the so-called Einstein's law of gravitation. One feature of this new law which is quite easy to understand is this. In the Einstein's relativity theory, anything which has energy has mass. Mass in the sense that it is affected gravitationally. Two lights which has an energy, has a "mass." When a light has a mass it comes out the sun must be attracted to it by the sun. Thus the light there is going straight but is deflected. Or along the surface of the sun, for example, the comet which approaches the sun could appear deflected. But where they would be if the sun were not there, and this has been observed.

Finally, let us compare gravitation with other theories. In recent years we have discovered that there are more than particles and that there are several kinds of interactions, one is nuclear forces and none of the sources in classical theory has yet been found to exhibit gravitation. The quantum-mechanical argument is still not yet been able to be used to gravitational. While the scale is so small that we can see the quantum effects, the gravitational effects are so weak that the usual form of general theory of gravitation has not yet developed. On the other hand for consistency in our physics, there is it would be important to see whether Newton's law modified to Einstein's law can be further modified to be consistent with the uncertainty principle. This has not been done yet but not yet completed.

Motion

B-1 Description of motion

In order to feel the laws governing the various changes that take place in bodies as time goes by, we must be able to measure the changes and have some way to record them. The simplest change to measure is a change in the position with time, which we call motion. Let us consider some solid object with a permanent mark, which we shall call a point, that we can observe. We shall consider motion of the kind marked, which is just the motion along an immobile or the motion of a falling ball, and shall try to describe the fact that it moves and how it moves.

The velocity is very simple indeed, but many subtleties enter into the description of change. Some changes are more difficult to describe than the motion of a point in a straight line, for example the speed of drift of a cloud that is drifting very slowly, the rapidly changing temperature, or the change of a woman's mind. We do not know a simple way to analyze a change of mind, but since the cloud can be represented or described by many molecules, perhaps we can do the motion of the cloud in principle by describing the motion of individual molecules. Likewise, perhaps even the changes in the sun may have a parallel in changes of the atoms inside the sun, but we have no such knowledge yet.

At any rate, that's why we begin with the motion of "points"; perhaps we should think of them as atoms, but it is probably better to be more rough in the beginning and simply to think of some kind of small objects—small, that is, compared with the distance moved. For instance, in describing the motion of a car that is going a hundred miles, we do not have to distinguish between the front and the rear of the car. To be sure, there are slight differences, but for rough purposes we say "the car," and likewise it does not matter that our points are not absolute points; for our present purposes it is not necessary to be absolutely precise. At any rate, we take a first look at this subject we are going to begin with the three dimensions of the world. We shall not concentrate on moving in one direction, as in a straight line. We shall return to three dimensions later. We are now to describe motion in one dimension. Now, you may say "There is a kind of trick," and indeed it is. How can we describe such a one-dimensional motion—intensity, of course? Nothing could be simpler. Among many possible ways, one would be the following: To determine the position of the car at different times, we measure its distance from the starting point and record all the observations. In Table B-1, I represent the distance of the car, in feet, from the starting point, and I suppose the road is smooth. The first 200 ft can also represent two dimensions and zero time—the car has not started yet. After one minute it has started and has gone 1200 ft. Then in two minutes, 1200 ft far from the starting point, it picked up more distance in the second minute—it has accelerated; cut something happened between 3 & 4, & 4 and even more so at 5—it stopped at a light perhaps? Then it speeds up again and goes 11,000 ft; it travel'd of 6 minutes 15,000 ft; in the end of 7 minutes, and 20,000 feet in 6 minutes; at 9 minutes it was advanced to only 24,000 feet because in the last minute it was stopped by a stop.

That is one way to describe the motion. And the way is by means of a graph. If we plot the time horizontally and the distance vertically, we obtain a curve something like that shown in Fig. B-1. As the time increases, the distance increases, at first very slowly and then more rapidly, and very slowly again for a little while at 4 minutes; then it increases again for a few minutes and finally, at 9 minutes, appears to have stopped increasing. These observations can be made from the

graph, without a graph. Obviously, for a complete description one would have to know where the car is at any particular instant, but we suppose that the graph means something, that it is a function of all the intermediate times.

The motion of a car is complicated, but another example may help illustrating that s does not in general increase uniformly. Let us consider a falling body. At zero seconds the car starts out at zero feet, and at the end of 1 second it has fallen 16 feet. At the end of 2 seconds it has fallen 64 feet, at the end of 3 seconds 144 feet, and so on. If the individual numbers are plotted, every point lies on a parabola, as we showed in Fig. 4-2. The corresponding curve can be written as

$$s = 16t^2. \quad (8.1)$$

This formula enables us to calculate the distance at any time. You might say that ought to be a formula for the first graph too. Actually, one may write such a formula also, namely,

$$s = f(t). \quad (8.2)$$

meaning that s is some quantity depending on t , or, in mathematical language, a function of t . But we do not know what the function f is, there is no way we can write it in full, inside basic form.

We have now seen two examples of motion, and quite satisfied with very simple ideas, in substance. However, there are subtleties, several of them. In the first place who does mean he can call yourself? It turns out that these deep philosophical questions have to be analyzed very carefully in physics, and this is not so easy to do. The theory of relativity shows that our ideas of space and time are not as simple as one might think at first sight. However, for our present purposes, the accuracy that we need at best, we need not be very careful about defining things precisely. Perhaps you are: "That's a terrible thing. I learned that in school we have to define everything logically." We cannot define everything logically! If we attempt to do just that, analysis of thought will come to a standstill, when we express each concept again in the whole. "You don't know what you're talking about!" The person you say, "What do you mean by time?" What do you mean by nothing? What do you mean by your?" and so on. In order to handle all these subtle questions, we just have to agree that we are talking about roughly the same thing. That's how it is in the real world we live in for the present... but remember that there are some subtleties that have to be discussed, we'll discuss them later.

Again, quite logically involved, and strongly mentioned, is that it should be possible to integrate that the interval which we are observing is always between somewhere. (Of course, when we are looking up at the stars, but maybe when we look away, it isn't there.) It turns out that in the motion of objects, that idea also is to be—well, not just a matter of our own and suitable choices. That subtlety we shall have to get into in quantum mechanics. But we are first going to do it with the problems we select later during the considerations, and then we shall be in a better position to judge our estimate in the light of the more exact knowledge of the subject. You see, therefore, like a simple pair of shoes that, time and space we know what these concepts are in a rough way, and those were just driven in by kind of a general means.

8-3 Speed

Even though we know roughly what speed means, there are still some rather deep subtleties involved that the ancient Greeks were not able to adequately describe the sometimes varying velocity. This will be discussed when we try to compute exactly what is meant by "speed." The Greeks got very confused about this, and a new branch of mathematics had to be developed between the geometry and algebra of the Greeks, 400+ years. Babyish! As an illustration of the difficulty, try to solve this problem by sheer algebra! A solution is being indicated on p. 12.

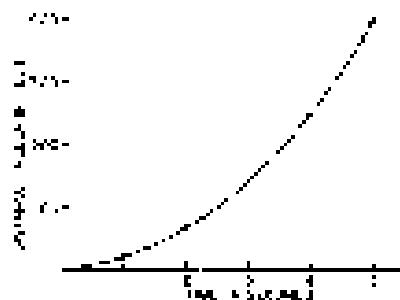

Fig. 8-2. Graph of distance versus time for free fall.

that the volume of the balloon is increasing at the rate of 100 cm³ per second; at what speed is the radius increasing when the volume is 1000 cm³? The Greeks were somewhat confused by such a dilemma, being helped, of course, by some very confusing Greeks. To show just how wrong was their concept of motion, let us consider speed in the time, Zeno proposed a large number of paradoxes, of which we shall mention one. This is to his credit, this is the earliest evidence of difficulty in thinking about motion. "Listen," he says, "to the following argument. Achilles runs 10 times as fast as a tortoise, nevertheless, he can never catch the tortoise. For suppose that they run in a race where the tortoise is 100 m ahead of Achilles; then when Achilles has run the 100 meters to the place where the tortoise was, the tortoise has proceeded 10 meters. During that same time Achilles has run another 10 meters to catch up with the tortoise, but by arriving at the end of each run, Achilles finds the tortoise is still 10 m ahead of him, so again Achilles runs. In this fashion Achilles' continuous motion, and motion, is self-defeating. Therefore, at any moment the tortoise is always ahead of Achilles and Achilles can never catch up with the tortoise." What is wrong with this? It is that all the amount of time can be divided into an infinite number of pieces, just as a long line can be divided into an infinite number of pieces by dividing repeatedly by two. And so, although there are an infinite number of steps (in the argument) in the path... at which Achilles reaches the tortoise, it doesn't mean that this is a finite segment of time. We can see from this example that there are hidden some subtleties in the way about speed.

In order to get to the subtleties in a clearer fashion, we remind you of a joke which will surely stir up some humor. At the point where the lady in the car is caught by a cop, she goes up to him and says, "Sorry, sir, I was going 60 miles an hour!" She says, "It's impossible, sir, I was traveling for only seven minutes. It's ridiculous! How can I go 60 miles an hour? What I wasn't going, sir?" Now, would you believe her? You say, "Oh, right? Of course, you were really the cop, then no stories are intended; it's very simple, go on, say, "I'll stick to the wages!" But let us suppose that we do not have that escape and we take a more honest approach and attack on the problem, and try to explain... Not only what we know by the time that she was going 60 miles an hour. Just what do we know? We say, "What we know, however, is this: if you kept on going the same way as you were going now in the next hour you would go 60 miles." You could say, "Well, my foot was off the accelerator and the car was slowing down, so if I kept on going like this, why it wouldn't go 60 miles." Or, instead, the ball is bounces up and we want to know, especially, at what height it bounces? The ball goes on going the way it is going. What does that mean? Stop or accelerate, just keep it. No, just carrying with it's own velocity. But that is what we are trying to define. For if the ball keeps on going the way it is going, it will just stop on going the way it is going. Thus we need to define the velocity better. What do we do? Just the same. That's all we do. Now, "If I keep on going like this I'm going in one more hour, I would run faster than I did at the end of the street." It is not so easy to see what we mean.

Many physicians think that measurement is the only definition of any thing. Obviously, then, we should use one instrument that measures the speed—the speedometer—and say, "Look, lady, your speedometer reads 60." So she says, "My speedometer is broken and didn't read at all." Does this mean the car is standing still? We believe that there is something to measure before we talk of a speedometer. Only, does our, for example, "The speedometer isn't working right," or "The speedometer is broken?" That would be a meaningful sentence if the velocity and so resulting independence of the speedometer. As we know it, we can make claim that is independent of the speedometer, since the speedometer is not the only to measure this idea. So, in case if we can get a better definition of the idea, we say, "Yes, of course, before you went an hour, you would do that well, but, if you are not measured, you would go 60 feet; but, you were going 60 for per second, and if you kept on going, the next second, you would be 60 feet, and the will down. There is far less than that." She says, "This is... I don't know how fast I am going 60 feet per second." There is only a few

against going 80 miles an hour." "But," we reply, "it's the same thing." If it is the same thing, it should not be necessary to go into the circumlocution about 96 feet per second. In fact, the falling ball would not keep going the same way even one second because it would be changing speed, and we shall have to define speed somehow.

Now we seem to be getting on the right track: it goes something like this: If the lady kept on going for another 1/1000 of an hour, she would go 1/1000 of 80 miles. To other words, if she did not have to keep on going for the whole hour, the speed is then for a moment she is going at that speed. Now what that means is that if she went just a little bit more in time, the extra distance she goes would be the same as the distance that you, at a constant speed of 80 miles an hour. Perhaps the idea of the 80 foot per second is right; we say how far she went in the last second, divide by 80 feet, and if it comes out 1/1000 of an hour was 80 miles an hour. In other words, we can find the speed in this way. We don't know how far we go in a very short time. We divide this distance by the time, and that gives the speed. But the time should be made as short as possible, the better the better, because some change would take place during that time. If we take the time of ϵ for my body as an hour, the idea is ridiculous. If we take ϵ as a second, the result is pretty good for a car, because the car's constant change is great. But not for a falling body; so in order to get the speed more and more correctly, we should take a smaller and smaller time interval. What we should do is take a millionth of a second, and divide the distance by a millionth of a second. The result gives the velocity per second, which is what we mean by the velocity, or we can define it that way. That is a suggested answer for the lady, or rather, that is the definition that we are going to use.

The foregoing definition involves a new idea, an idea that was not available to the Greeks in a general form. That idea was to take a. infinitesimal distance and the corresponding infinitesimal time from the ratio, and when it comes to that ratio as the time and the distance become smaller and smaller and smaller. In other words, take a "unit" of the distance traveled divided by the time required, as the times taken give smaller and smaller and infinitesimal distances. This idea was invented by Newton and by Leibnitz, independently, and is the beginning of a new branch of mathematics, called the differential calculus. Calculus was invented in order to describe motion, and its first application was to the problem of "finding what is meant by going 80 miles an hour."

Let us try to define velocity a little better. Suppose that in a short time, ϵ , the car or other body goes a short distance Δx ; then the velocity, v , is defined as

$$v = \Delta x/\epsilon$$

an approximation that however nearer and nearer to the v is taken smaller and smaller. If a mathematical expression is desired, we can say that the velocity equals the limit as ϵ is made larger and larger in the expression above:

$$v = \lim_{\epsilon \rightarrow 0} \frac{\Delta x}{\epsilon}. \quad (8.1)$$

We cannot do the same thing with the lady in the car, because the table is incomplete. We know only where she was at intervals of one minute; we can get a rough idea that she was going 8000 ft/min during the 7th minute, but we do not know, exactly the moment 7 min, or whether she had been speeding up and the speed was 9000 ft/min at the beginning of the 6th minute, and is now at 8 ft/min, or decelerating etc., because we do not have the exact details in between. So only if the table were completed with an infinite number of rows could we really calculate the velocity from such a table. On the other hand, when we have a complete mathematical formula as is the case of a falling body (Eq. 8.7), then it is possible to calculate the velocity, because we can calculate the position in any time whatsoever.

Let us take as an example the problem of determining the velocity of the falling ball at the particular instant t seconds. One way to do this is to see from

Table 4-2 was stated in the problem; it was $400 = 256 = 174$ ft, so it is going 144 ft/year; however, that is wrong, because the speed is changing. In the average it is 144 ft/year, using this is great, but the ball is speeding up and is really going faster than 144 ft/year. We want to find our velocity after four. The technique involved in this process is the following: We know where the ball was at 5 sec. At 5 sec we saw the distance that it has gone all together is $16(5)^2 = 400$ ft (see Eq. 4.3). At 5 sec it had already fallen 400 ft; in the last tenth of a second it fell $400 - 360 = 16.0$ ft. Since 16.0 ft in 0.1 sec is the same as 160 ft/sec, that is the speed more or less, but it is not exactly correct. Is that the speed at 5, or at 5.1, or the change between at 5.05 sec, or what is that the speed? Never mind — the problem was to find the speed at 5 seconds, and we do not know exactly what we have to do a better job. So, we take one-thousandth of a second more than 5 sec, or 5.001 sec, and calculate the total fall as

$$s = 16(5.001)^2 = 16(25.000001) = 400.00015 \text{ ft}$$

In the Sec. 6.2C we saw the ball fell 0.160006 ft, and if we divide this number by 0.001 sec we obtain the speed as 1600.6 ft/sec. That is closer, very close, but it is still not exact. It should now be evident what we must do to find the speed exactly. To perform the mathematics we state the problem: "Take more time to find the velocity at a specific time, in which in the original problem was 5 sec. Now the total distance, which we call s_2 , is 16 t^2 , or 400 ft, in $t > 5$ sec. In order to find the velocity, we ask 'At what time $t_0 + \Delta t$ falls s_2 , or $s_2 = s_1 + \Delta s$, where is the body?' The new position is $16(t_0 + \Delta t)^2 = 16t_0^2 + 32t_0\Delta t + \Delta s$. So it is falling along when it was before, but also before it was only 16 t_0 . This distance we shall call $s_3 = (\Delta t)$ little bit more, or $s_3 = x$ if you like extra x . Now if we subtract the distance at t_0 from the distance at $t_0 + \Delta t$ we get the extra distance $s_3 = 32t_0\Delta t + \Delta s = 16\Delta t^2$. Our first approximation to the velocity is

$$v = \frac{s}{t} = 32t_0 + \Delta s. \quad (4.4)$$

The true velocity is the value of the ratio, v/t , when Δt becomes infinitesimally small. In other words, after forming the ratio, we take the limit as Δt gets smaller and smaller, that is, approaches 0. The equation reduces to

$$\lim_{\Delta t \rightarrow 0} \frac{s}{\Delta t} = 32t_0.$$

In our problem, $t_0 = 5$ sec, so the solution is $s = 16(5)^2 = 400$ ft/sec. A few times later when we took $\Delta t = 0.1$ and 0.01 sec successively, the value we got for v was a little more than 160, but now we see that the actual velocity is probably 1600 ft/sec.

4-4 Speed as a Derivative

The procedure we have just carried out is performed whenever we calculate that for nonuniform (or special) motion have been assigned to our quantities s and v in this section, the cases above because s and v becomes s_1 . This is because "you can't hit of it" and don't be implying that s can be made smaller. The prefix Δ is not a multiplier, any more than can s means $s \cdot 1$; in Δs is simply added a time increment, and remains as of its special character. Δs has no analogous meaning for the distance s . Thus, Δs is not a factor. It cannot be cancelled in the ratio $\Delta s/\Delta t$ to give s/t , any more than the ratio s/t can be reduced to 1/2 by cancellation. In this situation, velocity is added to the unit of s/t as when Δt gets smaller or

$$v = \lim_{\Delta t \rightarrow 0} \frac{\Delta s}{\Delta t}. \quad (4.5)$$

This is really the same as the previous expression (Eq. 4.4), but it has the advantage of showing that something is changing, and a *slope* — that of what is changing.

Inertial "y," or a *local approximation*. We know another law, which says that the change of distance of a moving point is the velocity times the time interval $\Delta t = t - \tau$. This statement is true only if the value v is not changing during that time interval; and the condition is not very far from the truth as Δt goes to 0. Physicists like to state it as $\Delta s \approx v \Delta t$, because by Δs they mean an *infinitesimal* in which Δt is very small; while Δt is *meaningful*. In such case it is valid to a close approximation. If Δt is too long, the velocity might change during the interval, and the approximation would become less accurate. For a time Δt approximating $v \Delta t$ is *infinitesimally*. To this end here we can write $\Delta s \approx v \Delta t$.

$$v = \lim_{\Delta t \rightarrow 0} \frac{\Delta s}{\Delta t} = \frac{ds}{dt}.$$

The quantity ds/dt which we found here is called "the derivative of s with respect to t " (this language begins to keep track of what was computed), and the computational process of finding it is called finding a derivative. In the ordinary $f(x)$'s and $g(x)$'s which appear separately are called *arguments*. To familiarize you with the words, we say we found the derivative of the "function $f(x)$ ", or the derivative (with respect to x) of $f(x)$ is $f'(x)$. When we get used to the words, the f 's are more easily understood. The process, for us and the derivative of a more complicated function. We shall consider the function $s = At^2 + Bt + C$, which might describe the motion of a point. The letters A , B , and C represent constant numbers, as in the common general form of a quadratic equation. Starting from the formula for the motion, we wish to find the value v at any time. To find the velocity in the more elegant manner, we change s to $t + \Delta t$ and note that s has changed to $s + \Delta s$; then we find v at $t + \Delta t$. That is to say,

$$\begin{aligned} s + \Delta s &= A(t + \Delta t)^2 + B(t + \Delta t) + C \\ &= At^2 + Bt + C + 2At\Delta t + A(\Delta t)^2 + B\Delta t. \end{aligned}$$

But since

$$s = At^2 + Bt + C,$$

we find also

$$\Delta s = 2At\Delta t + B\Delta t + A(\Delta t)^2 \approx A(\Delta t)^2.$$

But we do not want Δs — we want s divided by Δt . We divide the preceding expression by Δt , getting

$$\frac{\Delta s}{\Delta t} = 2At^2 + B + B(\Delta t) + A(\Delta t)^2.$$

Table B-3. A Short Table of Derivatives

For the differentiable functions of t , s , v , and a arbitrary constants

Function	Derivative
$s = t^n$	$\frac{ds}{dt} = nt^{n-1}$
$s = ct$	$\frac{ds}{dt} = c$
$s = s_0 + v_0 t + \frac{1}{2}at^2 + \dots$	$\frac{ds}{dt} = \frac{dv}{dt} = v_0 + \frac{da}{dt}t = \dots$
$s = c$	$\frac{ds}{dt} = 0$
$s = e^{kt} + c$	$\frac{ds}{dt} = k \left(\frac{d}{dt}e^{kt} + \frac{d}{dt}c + \frac{d}{dt} \frac{dc}{dt} + \dots \right)$

As A goes toward 0 the limit of $\Delta x/\Delta t$ is dx/dt and is equal to

$$\frac{dy}{dt} = 3x^2 + 5.$$

This is the fundamental process of calculus, differentiating functions. The process is even more simple than it appears, however, because there are various ways to find dy/dx from which we can subtract terms or cube or any higher power of dx , since terms may be dropped when we take the limit as A goes to 0. When the limit is taken, A has a value greater than zero, so we know what x is going to. There are many rules for differentiating various types of functions. These will be summarized, or can be found in tables. A short list is found in Table 8-1.

8-1 Distances for Discrete

Now we have a discrete time-varying problem. Suppose the initial distance of distances we have a table of speeds at 5 discrete times, starting from zero. Just the falling ball, such speeds and times are shown in Table 8-4. A similar table could be made for the velocity of the car by measuring the speed each second every minute or half minute. If we know how fast the car is going at any time, can we determine how far the car is going? This problem is just the inverse of the one solved above; we are given the velocity and asked to find the displacement. How can we find the distance if we know the speed? If the speed of the car is constant, and the only goes very quickly but for a moment, then slows down, speeds up, and so on, how can we determine how far one has gone? That is easy. We use the same idea, and replace the Δt by Δx and v by a . Let us say, "In the first second her speed was v_1 and x_1 , and from the formula $x = v_1 t$ we can calculate x_2 for the car went the first second at that speed." Now at the next second he speed is v_2 , by the same but slightly different, we can calculate x_3 for the second the Δx is the Δx_2 by taking the new speed times the Δt . We generate Δx 's for each second, to the end of the car. We now have a number of little distances, and the total distance will be the sum of all these little pieces. That is, the distance will be the sum of the velocities times the times, or $\sum v_i \Delta t$, where the Greek letter Σ (Sigma) is used to denote addition. To be more precise, it is the sum of the velocity at a certain t . Let us say the car is interrupted at t_0 ,

$$x = \sum v_i \Delta t. \quad (8.6)$$

The rule for the times is that $t_{i+1} = t_i + \Delta t$. However, the distance we obtain by the method will not be exactly, because the velocity changes during the time interval Δt . If we take the times short enough, the sum is precise, or we take them smaller and smaller until we obtain the desired continuum. That is, it is

$$x = \lim_{\Delta t \rightarrow 0} \sum v_i \Delta t. \quad (8.7)$$

These terms allow have invented a symbol for this limit, analogous to the symbol for the derivative. The symbol \int is also required so that the time is as small as we can be, the velocity is then called v at the time t , and the addition is written as a sum with a Greek Σ (from sigma), which has become distance and is now unfortunately just called an integral sign. Thus we write

$$x = \int v(t) dt. \quad (8.8)$$

The process of adding all these terms together is called integration, and \int is the opposite process to differentiation. The derivative of the integral is v , or the operator d/dt makes the other (\int). One can get experience for integrals by taking the formulas for derivatives and turning them backwards, because they are integrating each other inversely. Thus you can work out the own value of integrals by differentiating all sorts of functions. For every function that is differentiable, we get an integral: "Guru's if we turn it around."

Table 8-1

Velocities of a Falling Ball

t (sec)	v (ft/sec)
0	0
1	32
2	64
3	96
4	128

Every function can be differentiable analytically, i.e., the process can be carried out algebraically, and leads to a definite function that it is not possible in a simple manner to write an analytical value for any integral of $\vec{F}(t)$. You can calculate it, for instance, by taking a derivative, and then multiplying again with a function $\vec{v}(t)$ and again with a other function until you have it nearly right. In general, given some particular function, it is not possible to find, analytically, what the integral is. One may always try to find a function which, when differentiated, gives some desired function, but one may not find it, and it may not exist, at the sense of being expressible in terms of known, but not already been given names.

8-5 Acceleration

The next step in developing the equations of motion is to introduce another term which goes beyond the concept of velocity in the of change of velocity, and we now ask: "How does the velocity change?" In previous chapters we have discussed cases in which force produce changes in velocity. You may have worked with your environment where you can think about from a car to fall miles an hour, or even seconds. From such a performance we can say how fast the speed changes, but only on the average. What we do, *i.e.*, discuss is the next level of complexity, which is how fast the velocity is changing. In other words, by how many feet per second does the velocity change in a second, maybe, how many feet per second does *s* change? We have already derived the formula for the velocity of a falling body as $v = \sqrt{2gt}$, which is charted in Table 8-4, and now we want to find out how much the velocity changes per second; this quantity is called the acceleration.

Acceleration is defined as the ratio $\frac{\Delta v}{\Delta t}$ of change of velocity. From the preceding discussion we *already* enough already to state the acceleration as the derivative $\frac{dv}{dt}$; in the same way that the velocity is the derivative of the position if we *now* differentiate the formula $v = \sqrt{2gt}$ we obtain, for a falling body,

$$a = \frac{dv}{dt} = \frac{d}{dt}(\sqrt{2gt}) \quad (8-9)$$

[In differentiating the term $\sqrt{2gt}$ we can utilize the result obtained in a previous problem, where we found that the derivative of \sqrt{x} is simply $\frac{1}{2\sqrt{x}}$ times unity. So by letting $B = 32$, we have at once that the derivative of $\sqrt{2gt}$ is $\frac{B}{2}\sqrt{2g}$.] This means that the velocity of a falling body is changing by 16 ft/s per second, per second changes. You may ask, from logic, that the velocity increases by 16 ft/s in each second. This is a very simple case, for most objects are usually not constant. The reason the mass is not *so* constant is, is that the force on the falling body is constant, and Newton's law says that the acceleration is proportional to the force.

As a further example, *i.e.*, to find the acceleration in the problem we have already solved for the velocity, bringing up:

$$s = 2t^2, \quad \vec{s} = \vec{v}, \quad \vec{v}$$

and differentiating $s = 2t^2$ with respect to time,

$$v = 2t^2 = \vec{v}$$

After acceleration is the derivative of the velocity with respect to the time, we need to differentiate the last expression above. Recall the rule that the derivative of the sum of terms on the right equals the sum of the derivatives of the individual terms. To differentiate the first of the terms, instead of going through the fundamental process again we note that we have already differentiated a quadratic term when we *f* learned "*to f*", and the effect was to double the initial coefficient and change t^2 to t^3 in order to get the corresponding derivative of the linear, and you can check this result yourself. The derivative of $3t^2$ will then be $6t$. Next we differentiate \vec{v} , a sine wave, which has been treated previously. The derivative of \vec{v} is zero, because this term contributes nothing to the acceleration. So final result, therefore, $a = \frac{dv}{dt} = 6t$.

For reference, we state two very useful formulas which can be obtained by integration. If a body starts from rest and moves with a constant acceleration a , its velocity v at time t is given by

$$v = at.$$

The distance it covers in this same time is

$$x = \frac{1}{2}at^2.$$

Various modifications of these are used in solving derivatives. Since velocity is *displacement* and acceleration is the time derivative of the velocity, we can also write

$$a = \frac{d(v)}{dt} = \frac{dv}{dt}, \quad (8.10)$$

which are common ways of writing a second derivative.

We have noted how total velocity is equal to the integral of the acceleration. This is just the opposite of $v = at$ — if you integrate the acceleration, the result is the integral of the velocity, so distance can be found by twice integrating the acceleration.

In the foregoing discussion of motion was in only one dimension, and experiments only in one dimension were done in three dimensions. Consider a particle P which moves in three dimensions in a very narrow window. As we began our discussion of the three-dimensional case of a moving car by observing the distance of the car from its starting point in $1/1000$ th miles. We then discussed velocity in terms of three distances, x , y , z , and acceleration in terms of changes in velocity. You can see the three-dimensional motion analogously. It will be simpler to illustrate the motion on a two-dimensional diagram, and then extend the ideas to three dimensions. We establish a pair of axes at right angles to each other, and determine the position of the particle along each axis by measuring how far it is from each of the two axes. Thus each position is given in terms of x -distance and y -distance, and the motion can be seen as that by constructing a table in which both these distances are given as functions of time. Extension of this process to three dimensions requires only one additional right angle to the first two, and measuring a third distance, the z -distance. (The distances are *not* measured from coordinate planes instead of lines.) Having established a table with x - and y -distances, we can determine the velocity. We then find the components of velocity in each direction. The horizontal part of the velocity, or *horizontal component*, is the derivative of the x -distance with respect to the time, or

$$v_x = \frac{dx}{dt}. \quad (8.11)$$

Similarly, the vertical part of the velocity, or *vertical component*, is

$$v_y = \frac{dy}{dt}. \quad (8.12)$$

As for circumference,

$$v_z = \frac{dz}{dt}. \quad (8.13)$$

Now given the components of velocity, how can we find the velocity along the actual path of motion? In the two-dimensional case, consider two successive positions of the particle separated by a short distance ds and a short time interval $dt = t_2 - t_1$. The horizontal distance traveled horizontally is distance $\Delta x = v_x dt$, and vertically a distance $\Delta y = v_y dt$. (The symbol " \sim " is read "is approximately.") The total distance traveled is approximately

$$ds \sim \sqrt{(\Delta x)^2 + (\Delta y)^2}, \quad (8.14)$$

as shown in Fig. 8-1. The approximate velocity during this interval can be obtained by dividing by dt and by letting $ds \rightarrow 0$, or at the beginning of the interval.

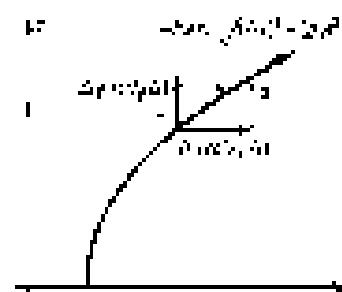

Fig. 8-1 Description of the motion of a body in two dimensions and the computation of its velocity.

We then get the relation 35

$$\tau = \frac{dr}{dt} = \sqrt{\left(\frac{dx}{dt}\right)^2 + \left(\frac{dy}{dt}\right)^2} = \sqrt{1 - r^2} \quad (3.5)$$

In three dimensions the result is

$$\tau = \sqrt{V^2 + \frac{d\theta}{dt} + \frac{d\phi}{dt}}. \quad (3.6)$$

To this same 3D as we defined velocities, we can define accelerations; we have an x -component of acceleration \ddot{x}_x , which is the derivative of \dot{x}_x , the x -component of the velocity (that is, $\ddot{x}_x = d\dot{x}_x/dt$), the second derivative of x with respect to t , and so on.

Let us consider one simple example of projectile motion in a plane. We shall take a z -axis to where a body moves horizontally with a constant velocity v_0 , and at the same time under gravity it falls vertically with a constant acceleration $-g$; what is its motion? We can say $\dot{x}_x = v_0$ and $\ddot{x}_x = 0$. Since the velocity s is constant,

$$s = \omega, \quad (3.7)$$

and since the downward acceleration $-g$ is constant, the distance r the object falls can be written as

$$r = -\frac{1}{2}gt^2. \quad (3.8)$$

What is the curve of its path, i.e., relation between y and x ? We can eliminate t from (3.7) and (3.8), since $t = \omega/\dot{x}_x$. When we make this substitution we find that

$$y = -\frac{g}{2\omega^2}x^2. \quad (3.9)$$

This relation between y and x may be considered as the equation of the path of the falling body. When this equation is plotted we obtain a curve now called a parabola, any freely falling body that is shot out in any direction will travel in a parabola, as shown in Fig. 3-4.

Fig. 3-4. The parabola described by a falling body with initial horizontal velocity.

Newton's Laws of Dynamics

9-1 Momentum and force

The discovery of the laws of dynamics, or the laws of motion, was a cornerstone moment in the history of science. Before Newton's time, the motions of things like the planets were, say, roughly, but far from clear and complete understanding. Even the slight deviations from Kepler's laws, due to the perturbations of the planets, were unpredictable. The kinetics of pendulums, oscillators with springs and so on, in their smallness, could all be analyzed completely by Newton's laws were it not for one. So it is with this chapter. Before this chapter we could not calculate how a mass on a spring would move, much less predict the orbit of a planet on the year. This is not true now. After this chapter we will be able to calculate not only the motion of the sun, "planetary motion," but also the motion of the planet Venus, just as in Chapter 4. In Chapter 9 we will learn about the planet Venus, just as in Chapters 4 and 8, and so on.

Galileo made a great advance in the understanding of motion when he discovered the principle of inertia. An object in a straight line, if not disturbed, continues to move with a constant velocity in a straight line. "It was originally moving, and it continues to move still; it has just been moving still." Of course this was quite unlike the common sense (or "folklore") that people back then believed, but "that's how it is and it's in itself" - "nothing against the law." A logical argument therefore had the right rule, and that argument was supplied by Galileo.

Of course, the law thing which is needed to rule for finding how an object changes its speed if something is affecting it. That is the formulation of Newton's law, or we call it three laws. The First Law was a mere restatement of the Galilean principle of inertia just mentioned. The Second Law gives a specific way of doing this, how the weight, change in direction influences called force, can change velocity and hence the motion of, and we shall discuss that in another time. Here we shall discuss only the Second Law, which asserts that the motion of an object is changed by forces in this way: the greater influence of a gravity related movement is proportional to the force. We shall do this more qualitatively, but let us first explain the law.

Momentum is not the same as weight. A lot of words are used in physics, and they all have precise meaning in physics, although they may not have such precise meanings in everyday language. Momentum is an example, and we must define it precisely. There is a certain part of the motion of an object that is larger, if you're pushing it, pushing it than another object. But it's not because in the usual sense, the one object has more mass. Actually, we must do it the same, "from 'light'" and "heavy" for two masses and two velocities. There is a difference to be understood between the weight of an object and its weight. "How hard it is to get it going again, how much force is needed to accelerate it, weight and inertia are proportional" and so on. Gravity's influence is often taken to be numerically equal, which causes a certain confusion to the students. On Mars, weights would be different but the amount of force needed to accelerate would be the same.

We use the term mass as a quantitative measure of inertia, and we rely primarily on, for example, how much an object is accelerated at a certain speed and measuring how much force we need to keep it in the circle. In this way we find a certain quantity of mass for every object. Now the mass of an object is a product of its mass in increasing its velocity. That Newton's Second Law says

9-1 Momentum and force

9-2 Speed and velocity

9-3 Components of velocity, acceleration and force

9-4 What is the force?

9-5 Meaning of the dynamical equations

9-6 Numerical solution of the equations

9-7 Planetary motion

be written in this form, namely this way:

$$F = -\frac{d}{dt}(mv), \quad (9-1)$$

Now there are several points we have to consider: In writing down very low orbits so far, we have made intuitive sense, simplifications, and assumptions which are at best combined approximations into our "form." Like we may have to come back and study in greater detail exactly who such assumptions, but if we try to do this too soon we shall get confused. Thus at the beginning, we have several things to consider. First, that the mass of an object, is however, it isn't really, but we don't care so much with the Newtonian approximation to many systems, we ignore all the mass, and that, further, when we put two objects together, their masses add. These ideas were of course applied by Newton when he wrote his equations, for otherwise it's meaningless. For example, suppose the most general formula for the velocity; then the momentum would never change. In any case, consider on the low orbits nothing unless you know how the mass changes with velocity. At first we say, it does not change.

Then there are some implications concerning forces. As a useful approximation we think of force as a kind of push or pull that we make work on a body, but we can define it more accurately now that we have the law of motion. The most important thing to realize is that this relationship involves not only changes in the magnitude of the momentum or the velocity but also in their direction. If the mass is constant, then Eq. (9-1) can also be written as

$$\vec{F} = m \frac{d\vec{v}}{dt} = m\vec{a}, \quad (9-2)$$

The acceleration \vec{a} is the rate of change of the velocity, and Newton's Second Law says more than can the effect of a given force varies inversely as the mass; it says also that the derivative of the change in the velocity is of the direction of the force not the same. Thus we must understand that a change in a velocity, or an acceleration, has a wider meaning than its common language. Let velocity of a moving object change by its speeding up, slowing down either a slowdown, we say it accelerates with a negative acceleration, or changing its direction of motion. An acceleration at right angles to the velocity was discussed in Chapter 7. There we saw that an object moving in a circle of radius r with a certain speed v along the circle falls away from a straightline path by a distance equal to $(1/2)(v^2/r)$, or v^2/r . Thus the formula for acceleration at right angles to the motion is

$$a = v^2/r, \quad (9-3)$$

and a force at right angles to the velocity will cause an object to move in a curved path whose radius of curvature can be found by dividing the force by the mass to get the acceleration, and then using (9-3).

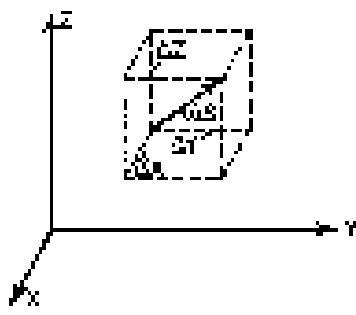

Fig. 9-1. A small displacement of an object.

9-2. Speed and Velocity

In order to make our language more precise, we shall make one further distinction at one use of the words speed and velocity. Ordinarily we think of speed and velocity as being the same, and in ordinary language they are the same. But in physics we have taken coverage of the term v ; there are two words and we've chosen to use them to distinguish each other. We carefully distinguish velocity, which has both magnitude and direction, from speed, which we choose to mean the magnitude of the velocity, but which does not include the direction. We can further elaborate this more precisely by defining three, the x , y , and z -components of an object's velocity with time. Suppose, for example, that at a certain instant an object is moving as shown in Fig. 9-1. In a given small interval of time it will cover certain distances due to the translation, dx in the x -direction, and dy in the y -direction. The resultant net of these three coordinate changes is a displacement as along the diagonal of a parallelepiped whose sides are dx , dy , and dz . In terms

of the velocity. The displacement Δx is the x -component of the velocity times Δt , and similarly for Δy and Δz :

$$\Delta x = v_x \Delta t, \quad \Delta y = v_y \Delta t, \quad \Delta z = v_z \Delta t. \quad (9.5)$$

9.3 Components of velocity, acceleration, and force

In Eq. (9.4) we have recorded the velocity in components by taking first that the object is moving in the x -direction, the y -direction, and the z -direction. The velocity is completely specified, but in an unimpressive direction. It is good to summarize velocity in its three-dimensional components:

$$v = \sqrt{v_x^2 + v_y^2 + v_z^2} \quad v_x = v \cos \theta_x \quad v_y = v \cos \theta_y \quad (9.6)$$

On the other hand, the speed of the object is

$$|v| = \sqrt{v_x^2 + v_y^2 + v_z^2}. \quad (9.7)$$

Now suppose that, because of the action of a force, the velocity changes in some particular direction at a different time. Take, as shown in Fig. 9.2, the change in the x , y , and z components of velocity. The change in the x -component of the velocity in the x -direction is $\Delta v_x = v_x - v_0$; it is v_0 in what we call a component of the acceleration. Similarly, we see that $\Delta v_y = v_y - v_0$, and $\Delta v_z = v_z - v_0$. In these terms, we can put Newton's Second Law, $F = m a$, in two dimensions as the second law in the y -direction, or in the z -direction, so the component of the force in the y -, or z -direction is equal to the mass times the rate of change of the corresponding component of velocity:

$$\begin{aligned} F_y &= m a_{y,y} = m (\Delta v_y / \Delta t) = m v_0, \\ F_z &= m a_{z,z} = m (\Delta v_z / \Delta t) = m v_0, \\ F_x &= m a_{x,x} = m (\Delta v_x / \Delta t) = m v_0. \end{aligned} \quad (9.8)$$

Just as the velocity and acceleration have been resolved into components by projecting onto axes, representing one quantity along each of three coordinate axes, so, in the same way, a force is resolved. F itself is represented by just a magnitude F . That is, F is a scalar:

$$\begin{aligned} F &= F \cos (\theta_x, F_x) \\ F_y &= F \cos (\theta_y, F), \\ F_z &= F \cos (\theta_z, F) \end{aligned} \quad (9.9)$$

where F is the magnitude of F ($F = \sqrt{F_x^2 + F_y^2 + F_z^2}$) and θ is the angle between the vector and the direction of F .

Newton's second law is given in complete form as Eq. (9.8). If we know the forces on an object and resolve the forces in the x , y , and z components, then we can find the motion of the object from one moment in time to the next. Let us consider a simple example. Suppose there are no forces in the x and y directions; the only force acting is the gravitational, say, vertically. Equation (9.8) tells us that there would be changes in the velocity in the vertical direction, but no changes in the horizontal direction. This was demonstrated in a special apparatus in Chapter 7 (see Fig. 7.1). A falling body moves horizontally without any change in the horizontal motion, while it moves vertically the same way as it would move in the horizontal motion were zero. In other words, motions in the x , y , and z -directions are independent if they are in the horizontal.

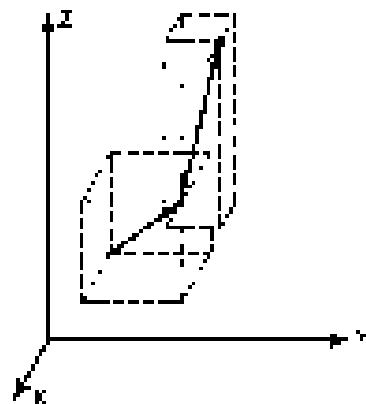

Fig. 9.2. A change in velocity is also both the magnitude and direction of a_{\perp} .

9.4 What is the Force?

In order to use Newton's laws, we now need some formulae for the forces. These laws are independent of the forces. If an object is undergoing some motion, it is always, find it. Our program for the future of dynamics, as set by Isaac Newton,

law for the force. Newton himself was not to give such examples. In the case of gravity he gave a specific formula for the force, i.e. the law of other forces he gave even less of the information. In his Second Law, which we will study in the next chapter, having to do with the causality of motion and reaction.

Extending our previous example, what are the forces on objects near the earth's surface? Near the earth's surface, the force of the vertical direction due to gravity is proportional to the mass of the object and is nearly independent of height, for heights small compared with the earth's radius R : $F = GmM/R^2 = mg$, where $g = GM/R^2$ is called the acceleration of gravity. Thus the law of gravity tells us that weight is proportional to mass; the force is in the vertical direction and is the mass times g . Again we find that the motion in the horizontal direction is at constant velocity. The interesting motion is in the vertical direction, and Newton's Second Law tells us

$$mg = m(gx'/dt^2) \quad (9.9)$$

Dividing both sides we find that the acceleration in the vertical motion is constant and equal to g . This is of course the well-known law of free fall under gravity, which leads to the equation

$$\begin{aligned} x' &= v_0 t + \frac{1}{2} g t^2 \\ x &= x_0 + v_0 t + \frac{1}{2} g t^2. \end{aligned} \quad (9.10)$$

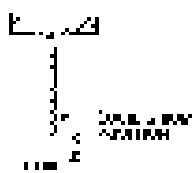

Fig. 9.3. A mass on a spring.

As another example, let us suppose that we have here able to pull a weight (Fig. 9.3) which applies a force proportional to the distance and directed oppositely to x' . If we start about x_0 , which is at one we balanced out by the mutual stretch of the spring, and apply a uniform force, we see that if we pull the mass down, the spring pulls up, while if we push it up the spring pulls down. This machine has been designed exactly so that the mass is periodic, the more we pull it up, in exact proportion to the displacement from the balanced condition, and the force applied is similarly proportional to how far we pull down. Is the whole the dynamics of this machine, we see a rather beautiful motion—up, down, up, down, ... The question is, will Newton's equations correctly describe this motion? Let us see how we can exactly calculate how it moves with this periodic oscillation, by applying Newton's law (9.7). In the present instance, the equation is

$$-kx = m(gx'/dt^2) \quad (9.11)$$

From which we see that when the velocity in the x -direction changes at a rate proportional to x . Having this to go on by repeating numerous oscillations, we shall imagine either that the scale of time has changed or that there is an accident in the name, to this we compare to have $v_0 = 1$. But we shall try to solve the equation

$$gx'/dt^2 = -x \quad (9.12)$$

provided, we must know what x is, but of course we know that the velocity is the rate of change of the position.

9.5 Meaning of the dynamical equations

Now let us try to analyze just what Eq. (9.12) means. Suppose that at a given time t the object has a certain velocity v_0 and position x_0 . What is the velocity and what is the position at a slightly later time $t + \Delta t$? If we can answer this question a problem arises, for then we can start with the given condition and compute how it changes for the first instant, the next instant, the next instant, and so on, and in this way fully analyze the motion. To be specific, let us assume that at the time $t = 0$ we are given that $v_0 = 1$ and $x_0 = 0$. Why does the object move at all? Because there is a force in. Unless it is at rest initially except $x = 0$, if $v_0 = 0$ no force is applied. Therefore the velocity which is zero is not to change, because of the law of motion. Once it starts to build up some velocity it cannot start to move less, and so on. Now at any time t , if Δt is very small,

as may happen. In position, we think in terms of the position x . $x(0) = 100$ and the velocity at time t is a very good approximation as

$$x(t) \approx x(0) + v_0 t \quad (9.10)$$

The problem is, the more accurate this expression is, the less useful it becomes because v_0 is not constantly zero. Now when when "the velocity" is zero, in order to get the velocity later, say exactly at the time $t + \Delta t$, we need to know how the velocity changes, the acceleration. And how are we going to find the acceleration? That is where the law of dynamics comes in. The law of dynamics tells us what the acceleration is. If, like the acceleration, $a = 0$,

$$v(t + \Delta t) = v(t) + a \Delta t \quad (9.11)$$

$$= v(0) + a t \Delta t. \quad (9.12)$$

Equation (9.12) is merely *definitional*; it says that a velocity changes because of the presence of acceleration. But Eq. (9.11) is *dynamical*; that is, it relates the acceleration to the velocity. So that at the particular time for the particular problem, you can replace the acceleration by $-a(t)$. Therefore, if we knew both the $v(0)$ and $a(t)$ at given time, we know the acceleration, which tells us the new velocity, and we know the new position—this is how the mechanics works. The velocity changes a little bit because of the force, and the position changes a little bit because of the velocity.

9.6 Numerical solution of the equations

Now let us really solve the problem. Suppose that we take $\Delta t = 0.100$ sec. At the end of the first Δt we find that this is not small enough we may have to go round and round you with $v = 0.010$ sec. Starting with our initial value $v(0) = 1.00$ m/sec $v(0.100) = 1.00$. It is the x position $x(0)$; and the velocity which is zero at $t = 0.100$ sec. Thus $v(0.1)$ is still 1.00, because it has not yet started to move. But the new velocity at 0.100 sec will be the old velocity $v(0)$ + 0 plus the current acceleration. The acceleration is $a(0) = -1.00$. Thus

$$v(0.1) = 0.00 + -0.10 \times 1.00 = -0.10$$

Now at 0.200 sec:

$$\begin{aligned} v(0.2) &= v(0.1) + a(0.1) \\ &= -0.10 + 0.10 \times 0.10 = 0.00 \end{aligned}$$

and

$$\begin{aligned} v(0.2) &= v(0.1) - a(0.1) \\ &= 0.00 - 0.10 \times 0.10 = -0.10. \end{aligned}$$

And so, so and so and on, we can calculate the rest of the motion, and that is just what we shall do. However, for practical purposes, there are some little tricks by which we can increase the accuracy. For example, in this case, after we have started it, we would find the motion only moves slightly because $a = -0.100$ sec $k = 1.0$ is only, and we would have to go through a very long Δt to move, say, $x = 0.01$. Then to go through a reasonable total time interval would take a lot of cycles of computation. So we shall examine the trick in a way that will increase the precision of our calculations using the same time interval $\Delta t = 0.100$ sec. This can be done if we make a small improvement in the technique of the analysis.

Notice that the new position x is defined just implies the time it, *exactly*, bands the velocity v . But the velocity $v(0)$? The velocity at the beginning of the time interval is one velocity and the velocity at the end of the time interval is another velocity. Our improvement is to use the velocity *midway* between. If we know the speed now, but the speed is changing, then we are not going to get the right answer by going at the same speed all time. We would use some speed between the "true" speed and the "fast" speed at the end of the interval. The same considerations also apply to the velocity to compute the velocity changes. So

Table 9.1

solution of $v' = v - at$ Interval, $\Delta t = 0.10 \text{ sec}$

the planet times the rate of change of its velocity in the x-direction. Thus we find the following steps:

$$\begin{aligned} m(\dot{x}_x, \ddot{x}_x) &= -GMm_x/r^2, \\ m(\dot{x}_y, \ddot{x}_y) &= -GMm_y/r^2, \\ r &= \sqrt{x^2 + y^2}. \end{aligned} \quad (3.17)$$

This, then, is the set of equations we must solve. Again, in order to simplify the numerical work, we shall suppose that the unit of time, or the mass of the sun, are both so adjusted (or fixed in units) that $GM = 1$. For our specific example we shall suppose that the initial position of the planet is $x = \pi = 0.500$ and $y = 0.000$, and that the velocity is $\dot{x} = 1$ in the x -direction at the start, and is of magnitude 1.600. Now how do we make the calculation? We again make a table with columns for the time, the x -position, the x -velocity x_x , and the x -acceleration \ddot{x}_x , each separated by a double line, three columns for y -position, y -velocity x_y , and acceleration \ddot{x}_y in the y -direction. In order to get the accelerations we begin by need Eq. (3.17); it tells us that the acceleration in the x -direction is $-\dot{x}_x/r$, and the acceleration in the y -direction is $-\dot{x}_y/r$, and therefore the square root of $x^2 + y^2$. Thus, given x and y we just do a little calculating on the side. Taking the square root of the sum of the squares to find r and then, to get ready to calculate the two accelerations, it is useful also to evaluate $1/r^2$. This work can be done rather easily by using a slide rule of logarithmic values and reciprocals; then we need only multiply x by $1/r^2$, which we do on a slide rule.

Our calculation thus proceeds by the following steps, taking time intervals $\epsilon = 0.001$: Initial velocities $\dot{x} = 1$

$$\begin{aligned} x(0) &= 0.500 & y(0) &= 0.000 \\ \dot{x}(0) &= 0.000 & \dot{y}(0) &= 1.600 \end{aligned}$$

From these we find

$$\begin{aligned} r(0) &= 0.500 & 1/r^2(0) &= 8.000 \\ \dot{x}_x &= -4.000 & \dot{r}_x &= 0.070 \end{aligned}$$

Thus we may calculate the velocities $-\dot{x}_x/r$ and $-\dot{x}_y/r$:

$$\begin{aligned} \dot{x}_x(0.1) &= 0.000 - 4.000 \times 0.070 = -0.280; \\ \dot{x}_y(0.1) &= 1.600 + 0.000 \times 0.070 = 1.600. \end{aligned}$$

Now our main calculation begins:

$$\begin{aligned} x(0.1) &= 0.500 - 0.00 \times 0.1 = 0.500 \\ \dot{x}(0.1) &= 0.0 - 1.60 \times 0.1 = 0.160 \\ r &= \sqrt{0.500^2 + 0.160^2} = 0.507 \\ \dot{x}_x(0.1) &= 0.480 \times 0.507 = 0.24 \\ \dot{x}_y(0.1) &= -0.160 \times 0.507 = -0.126 \\ \dot{x}_x(0.2) &= 0.000 - 0.04 \times 0.1 = -0.008 \\ \dot{x}_y(0.2) &= 1.600 - 0.08 \times 0.1 = 1.508 \\ \dot{x}(0.2) &= 0.440 - 0.508 \times 0.1 = 0.422 \\ \dot{x}_x(0.3) &= 0.160 - 0.00 \times 0.1 = 0.160 \end{aligned}$$

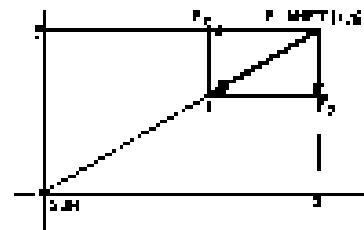

Fig. 9-5. The force of gravity on a planet.

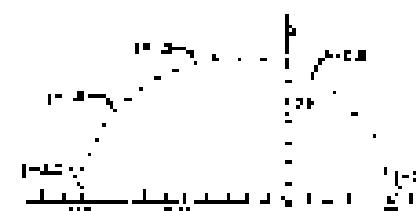

Fig. 9-6. The calculated motion of a planet around the sun.

In this way we obtain the values given in Table 9-2, and in 20 steps or so we have closed the planet initially around the sun. In Fig. 9-6 are plotted the x - and y -coordinates given in Table 9-2. The dots represent the positions of the planet at times t (unit: 0.001). We see that at $t = 0$ start the planet moves rapidly

Table 9-2
Solutions of $d^2\theta/dt^2 + \omega_0^2/r^2 \sin^2\theta d\phi/dt = -\omega_0^2/r^2$, $r = \sqrt{\mu^2 - \epsilon}$

and at the end it increases slowly, and so the shape of the curve is determined. Thus we see that we really do know how to calculate the motion of planets.

Now let us see how we can calculate the position of Neptune, Jupiter, Mars, etc., in any year, given the planet. If we have a great number of planets, and let the sun move slow, can we do the same thing? Of course we can. We can take as reference a particular planet, let us say planet number i , when last at position (x_1, y_1, z_1) ; $i = 1$ may represent the sun, $i = 2$ Mercury, $i = 3$ Venus, and so on. We must know the positions of all the bodies. The force acting on i is due to all the other bodies which are located, let us say at positions (x_j, y_j, z_j) . Therefore the equations are

$$\begin{aligned} M_1 \cdot \frac{\partial \phi_1}{\partial t} + \sum_{j=1}^n &= G(m, m_1)(x_j - x_1), \\ M_2 \cdot \frac{\partial \phi_2}{\partial t} + \sum_{j=1}^n &= G(m, m_2)(x_j - x_2), \\ M_3 \cdot \frac{\partial \phi_3}{\partial t} + \sum_{j=1}^n &= G(m, m_3)(x_j - x_3). \end{aligned} \quad (9.13)$$

For the next few days, we will be dedicating time to the planning and design phase.

$$s_1 = \sqrt{(\bar{s}_1 - s_1) + (\bar{(s_{1-1})}(\bar{Y}_{1-1} - \bar{s}_1))} \quad (217)$$

Also, $\sum_{i=1}^n \omega_i > 0$ since over all masses of i , ω_i other bodies' orbital velocities, for $i = 1$. Thus all we have to do is to make many iterations, few more estimates, we never run out time, for the motions of Jupiter, time for the motions of Saturn, and so on. Each time we have all initial positions and velocities we can calculate all the accelerations from Eq. (9.18) by first calculating all the distances using Eq. (9.19). How long will it take to do this? If you do it at home, it will take a very long time! But in modern times we have machines which do astronomical calculations at very good computing machine speed. I mentioned earlier that it is a millionth of a second, to do an addition. To do a multiplication takes longer, say 10 microseconds. It may be that in one cycle of iteration, according to our problem, we may have 300 multiplications, or something like this, so one cycle will take 300 microseconds. This means that we can do 3000 cycles of computation per second. In other words, if we were up, of say, one part in a billion, we would need 3×10^9 cycles to correspond to one revolution of a satellite around the sun, that corresponds to 1.6 minutes. One of 100 seconds or about two minutes. Thus it takes only two minutes to follow Jupiter around the sun with all the pre-estimates of all the planets correct to one part in a billion, by this method! It turns out that the error comes down as the square of the time scale. If we make the interval a thousand times smaller, it is a million times more accurate. So, let us trace the motion of Mars again starting

So, as we see, the basic idea of the method is to calculate even the motion of a massless spring. Now, armed with the machinery of Newton's laws, we can not only calculate such simple motions but also, given sufficient time, the motion of every tiny particle in one of the planets, to as many a degree of precision as we wish.

Conservation of Momentum

10-1 Newton's Third Law

On the basis of Newton's second law of motion, which gives the relation between the acceleration of a body and the force acting on it, any problem in mechanics can be solved in principle – or requires, to summarize the motion of a few particles, one can use the numerical methods developed in the preceding chapter. But there are just reasons to make further study of Newton's laws. First, there are quite simple cases of motion which can be analyzed not only by numerical methods, but also by direct mathematical analysis. For example, although we know that the acceleration of a falling body is $g = 9.8 \text{ m/s}^2$, and from this fact could calculate the motion by numerical methods, it is much easier and more satisfactory to analyze the motion and find the general solution, $x = x_0 + v_0 t - \frac{1}{2} g t^2$. In fact, however, although we can work out the problem of a harmonic oscillator by numerical methods, it is also possible to show analytically that the potential is given by a trigonometric function. This solution is necessary to prove all that nothing is difficult when there is a simple and more accurate way to get the result. In the same manner, although the motion of one body around the sun, determined by gravitation at a fixed point by solving the equations of motion of Lagrange, which show the general shape of the orbit, it is necessary to get the exact shape when analysis reduces to a perfect ellipse.

Thus far, however, very few problems which can be solved exactly by any means. In the case of the harmonic oscillator, for example, if the spring force is not proportional to the displacement, but is something more complicated, one must fall back on the numerical method. Or, if there is, say, a varying mass of the sun, so that the total number of bodies is three, such analysis cannot produce a simple formula for the motion, and in practice the problem is still done numerically. This is the famous three-body problem, which is long and longer than powers of analysis; it is very interesting how long it took people to appreciate the fact that perhaps the power of mathematical analysis was limited and it might be necessary to use the numerical methods. Today an enormous number of problems that cannot be done analytically are solved by numerical methods, and the old three-body problem, which was supposed to have solved, is solved in a manner of solving in exactly the same manner and was described in the preceding chapter, namely, as being a tough nut to crack. However, there are also situations where both methods fail: the single problem can be solved by analytic and the inexpressibly difficult problem by numerical, approximate methods, but the very same disease will always be met by either method. An complicated problem is, for example, the collision of two antinuclei, or a formation of microcosmics of a gas. There are countless particles in a cubic centimeter of gas, and it would be ridiculous to try to make calculations with so many variables (about 10^{23} – a hundred million trillion). Anyways like the majority of problems the mass of a gas or a bunch of atoms, or the motion of the stars in a galaxy cluster, instead of just two or three stars, using standard classical mechanics we cannot do directly, so we have to give up for me.

In the solutions of these we cannot follow details, we need to know some general properties, that is, general theorems or insights which are independent of Newton's laws. One of these is the principle of conservation of energy, which was discussed in Chapter 4. Another is the principle of conservation of momentum, the subject of this chapter. And he can see everything mechanics is when we find there are certain patterns of motion that are repeated in many different circum-

10-2 Newton's Third Law

10-3 Conservation of momentum

10-4 Momentum & conserved!

10-5 Momentum and energy

10-6 Relativistic mechanics

shocks, so it is good to study these problems in some particular circumstances. For example, we shall study oscillations, different kinds of oscillations such as harmonic. In the theory of fluids it does not make much difference what "fluid" is, the laws of the flow are similar. Other problems that we shall study are vibrations in classifications and, in particular, the peculiar phenomena of mechanical waves—sound, vibrations of solids, and so on.

In our discussion of Newton's laws it was explained that these laws are a kind of saying on fact, and "Pay attention to the forces," and that Newton could hardly give things other than the nature of forces. In the case of gravitation, he gives us the complete law of the force. In the case of the very complicated forces between atoms, he was not able to give the right laws for the forces; however, he did give us one rule, one general property of forces, which is expressed in his third law, and that is the total knowledge that Newton had about the nature of forces. The law of gravitation and this principle, but no other.

This principle is the *conservation of momentum*.

What is meant by something of this kind? Suppose we have two small bodies, say particles, and suppose that the first one exerts a force on the second one, pushing it with a certain force. Then, simultaneously, according to Newton's third law, the second particle will push on the first with an equal force, in the opposite direction; otherwise, these forces effectively act at the same time. This is the hypothesis, in fact, that Newton assumed, and it seems to be quite accurate, though not exact (see also [this article](#) for the errors). For the moment we shall take it to be true that action equals reaction. Of course, if there is a third particle on the same line, another law, the law of the third, says that the total force on the first one is equal to the total force on the second, since the third particle, for this law, exerts its own pull on each of the other two. The result is that the total effect on the first two is in some intermediate form, and the forces on the first two particles are, in general, neither equal nor opposite. However, the forces on each particle can be resolved into parts, there being one parallel to the particle to each other interacting particle. Then each pair of particles has corresponding components of mutual interaction that are equal in magnitude and opposite in direction.

10-2 Conservation of momentum

Now what are the interesting consequences of the above relationships? Suppose, for simplicity, that we have just two interacting particles, possibly of different masses, and a mutual force due to the forces between them, the equal and opposite what we call antiparticles? According to Newton's Second Law, since in the case of a change of the momentum, we have nothing but the rate of change of momentum v , if particle 1 is equal to minus the rate of change of momentum p_2 , or exactly

$$\frac{dp_1}{dt} = -\frac{dp_2}{dt} \quad (10-1)$$

Now if the rate of change is always equal and opposite, it follows that the total change is the summation of particle 1 to zero, and opposite to the total change in the momentum of particle 2. This means that if we add the momentum of particle 1 to the momentum of particle 2, the rate of change of the sum of these, due to the mutual forces (called internal forces) between particles, is zero; that is

$$(p_1 + p_2)/dt = 0 \quad (10-2)$$

This is sometimes called the law of the system. If the rate of change of this sum is always zero, there is just another way of saying that the quantity $p_1 + p_2$ does not change. This quantity is also written p , \mathbf{p} , \mathbf{p}_{tot} , and is called the *total momentum* of the two particles. We have now obtained the result that the total momentum of the two particles does not change because of any mutual interactions between them. This statement expresses the law of conservation of momentum.

momentum in that 2-particle example. We conclude that if there is any kind of force, no matter how complicated, between two particles, and we measure or calculate $p_{1,2} = p_{2,1}$, that is, the sum of the two momenta both before and after the forces act, the results should be equal, i.e., the total momentum is a constant.

If we extend the argument to three or more interacting particles in some complicated situation, it is evident that as long as no net force is experienced, the total momentum of all the particles stays constant, since each particle's momentum is constant, due to another, it exactly compensated by the decrease of the second, due to the first. That is, all the internal forces will balance out, and therefore cannot change the total momentum of the particles. (That is, there are no forces from the outside (other than grav.) that are too large to change the total momentum, since the total momentum is a constant.)

It is worth describing what happens if there are forces that do not add up to the total momentum of the particles. In quantum physics, we realize that this is typical. If there are only mutual forces, then, as before, the total momentum of the particles does not change, so maybe less complicated than forces. On the other hand, suppose there are other forces coming from the particles outside the looks of a group. Any force exerted by one particle on another particle, we call an external force. We can then deduce that the sum of all external forces equals the rate of change of the total momentum of all the particles inside, a very useful theorem.

The conservation of the total momentum of a number of interacting particles can be expressed as

$$m_{1,1} + m_{1,2} + \dots + m_{1,n} = \text{a constant}. \quad (10.2)$$

There are no two external forces. There are masses and corresponding velocities of the particles who are not listed 1, 2, 3, 4, The general statement of Newton's Second Law for each particle,

$$F = \frac{d}{dt}(mv), \quad (10.4)$$

is also specified by the components of the second column, in any given dimension; thus, the component of the force on a particle is equal to the component of the rate of change of momentum of that particle, Δ .

$$F_x = \frac{d}{dt}(mv_x), \quad (10.5)$$

and similarly for the y - and z -directions. The other F_y , (10.3) is nearly the same form, and F_z is also similar.

In addition to the law of conservation of momentum, there is another interesting consequence of Newton's Second Law, to be proved later, but merely stated now. This principle is that no laws of physics will be different whether we are moving x - or moving with a uniform speed in a straight line. For example, a child bounces a ball in one direction; this is the "law." But this is the same as though the child has nothing to do but ground. Even though the airplane is moving with a very high velocity, but at a constant v velocity, the laws look the same to the child as they do when the airplane is standing still. This is however not always principle. As we see it here we shall call it "Galilean relativity" to distinguish it from the more general analysis, called by Einstein, which we shall study later.

We have just studied the law of conservation of momentum from Newton's laws, and we could prove from here to that the speed laws that describe impacts are equivalent. But for the sake of variety, and also as an illustration of a kind of reasoning that can be used in physics in other circumstances, we say, for example, one might not know Newton's laws etc. might take a different approach. We shall consider the laws of physics and collisions from a completely different point of view. We can have a discussion on the principle of Galilean relativity, stated above, and shall end up with the law of an unbroken constant.

We shall start by assuming that we would look at us: "we are along in a certain state and move it as it would if we were standing still." Before our

pushing collision in which two bodies move and stick together, or come together and bounce apart. We shall first consider two bodies that are held together by a spring or something else and are then suddenly released and pushed by the spring or perhaps by a little explosion. In either case, the initial motion is only one direction. First, let us suppose that the two bodies are exactly the same and not symmetrical objects, and then we have a simple explosion to start them. After the explosion, one of the bodies will be moving, let us say toward the right, with a velocity v . Then it appears reasonably that the other body is moving now at the left with a velocity v , because if the objects are different in mass or in center of gravity to be preferred one so the bodies would do something that is somewhat like this. This is an illustration of a kind of thinking that is very useful in many problems you will often be brought up to the just started with the following.

The first result from our experiment is that equal objects will have equal speed. But now suppose that we have two objects made of different materials, say copper and aluminum, and we make the two masses equal. We shall now suppose that if we do the experiment, with two masses that are equal, even though the objects are not alike, the velocities will be equal. Suppose, weight object "But you know, you could do it backwards, you do not have to suppose that. You could define equal masses to mean that they have equal velocities in the experiment." We follow his suggestion and make a simple extension between the copper and a very large piece of aluminum, so heavy that the copper flies out and the aluminum in all angles. That is too much of a strain on our nerves and mind to do. Let us just take a very tiny piece, such that when we make the extension the aluminum goes flying away and the copper hardly budges. That is interesting aluminum. Evidently there is some effect there in returning to the beginning again the time in which the velocities come out equal. Very well then, let us take it around, and say that when the velocities are equal, the masses are equal. This appears to be just as difficult, and it seems reasonable that we can transform physical laws into laws of numbers. Nevertheless, there are some physical laws involved, and this necessary this definition of equal means we immediately find out of the laws of physics.

Suppose we know from the foregoing experiment that two mass velocities, v_1 and v_2 for example, of aluminum, may be equal masses, and we compare a third body, say a piece of gold, with the copper in the same manner as above, making sure that its mass is equal to the mass of the copper. If we now make the experiment between the aluminum and the gold, there is no change in experiment except the mass of the copper however, the aluminum shows that they actually are. So again, by experiment, we have found a new law, a statement of it is now probably that two masses are equal if their mass velocities measured by equal velocities in the experiment are the same as each other. (The statement does not follow to all from a similar statement of a principle regarding measurement of quantity.) From this example we learn to take more seriously what things if we are careless. It is very easy a distinction to say the masses are equal when the velocities are equal, because we may be inclined to say it is implying the same kind of equality which in turn may be a misleading about an experiment.

As a second example, suppose that A and B are found to be equal by using the experiment of the other path of registration, which gives a certain velocity, if we then use another experiment will it be true or not true that the velocities now obtained are equal? Again, at least there is nothing that can decide this question, but experiment of course that it is true. So here is another law which might be stated: If two bodies have equal masses, as measured by equal velocities at one velocity, they also have equal masses when measured at another velocity. From these examples we see that appears to be only a preliminary result involved some laws of physics.

In the development of this follows we find that as is true for equal masses have equal and opposite velocities when an explosion occurs between them. We can make another assumption in the inverse case. If two unequal objects, moving in opposite directions with equal velocities, collide and stick together by some kind of glue, then which body will carry the moving after the collision? This is again a law.

symmetrical situation, with no preference between right and left, so we assume that they stand still. We shall also suppose that any two objects of equal mass, even if the objects are made of different materials, will collide and stick together when moving with the same velocity. As opposite direction's will come to rest at the collision.

10-3 Momentum & momentum

We can readily the above assumptions experimentally: first, if two identical objects of equal mass, separated by an explosion may well move apart with the same speed, and second, if two objects of equal mass, moving toward each other with the same speed, collide and stick together they will stop. This we can do by means of a explosive, invented as follows (Fig. 10-1). When you fire at another, the bullet will commonly penetrate. So does (Fig. 10-1). We could not do experiments by firing this gun because there is not only "fatty, but, by adding a large force, we can easily get rid of friction. Any object will slide without difficulty, even on at a constant velocity, as advocated by Galileo. This is done by suspending the objects on strings. Because air has very low friction, an object glides along with practically constant velocity when there is no applied force. Thus, we use two glide blocks which have been made carefully to have the same weight, or mass (their weight was measured results), but we know the frictional drag is proportional to the mass, and we place a small explosive cap to a close cylinder between the two blocks (Fig. 10-2). When all start, the blocks fly apart at the center point of the track and stay them apart by exploding the cap with an electric spark. Why should happen? If the speeds are equal, when they fly apart, they should arrive at the ends of the trough at the same time. On reaching the ends they will both bounce back with practically equal elasticity, and re-occur together and stop at the center. When they started it is a good test; when it is actually done the result is just as we have described (Fig. 10-3).

Now, the next thing we might like to agree on is what happens in a less simple situation. Suppose we have two equal masses one moving with velocity v_1 and the other standing still, and they collide and stick - what's going to happen? There is a nice allegory when we are discussed, driving with an unknown velocity. What velocity? That is the problem. To find the answer, we make the assumption that if we ride along in a car, passing over, look the same as if we are standing still. You start with the knowledge that two equal masses moving in opposite directions with equal speeds, will stop dead when they collide. Now suppose you're with the humans, you are riding in an automobile at a velocity v_1 . What total does it look like? Since we are riding along a lane of the two masses which are coming together, don't you appear to me to have zero velocity. The other mass, however, going past us with velocity v_2 , will appear to be coming toward us at a velocity $-v_2$ (Fig. 10-4). Evidently, the combined velocities the collision will seem to be going by with velocity v_1 . We therefore conclude that an object with velocity v_1 , hitting an object, one at rest, will end up with velocity v_1 , or what is mathematically speaking the same. An object with velocity v_1 hitting and sticking to another, now at v_2 , produces an object moving with velocity $v_1 + v_2$. Note that if we multiply the mass and the velocity separately and add them together, we [1/2] we get the same answer as when we multiply the mass and the velocity of everything it contains. The times we do this, allows when happens when a mass of velocity v_1 and v_2 is head-on.

Exactly the same manner we can deduce what happens when equal objects having any two velocities, fire each other.

Suppose we have two equal bodies with velocities v_1 and v_2 , respectively. Each collide and stick together. What is their velocity after the collision? Again we ride by in a car which is going at velocity v_1 , so that one body appears to be at rest. The other runs appears to have a velocity $-v_2$, v_2 , and we have the same result as we had before. When it is all finished they will be moving at $(v_1 - v_2)$ with respect to the car. What then is the actual speed on the ground?

Fig. 10-1. Top view of linear air bag test.

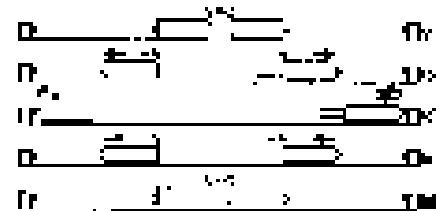

Fig. 10-3. Schematic view of collision-reaction experiments with equal masses.

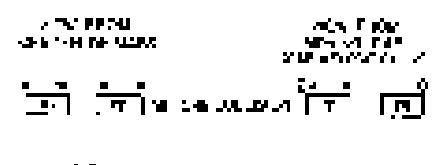

Fig. 10-4. Two views of an inelastic collision between equal masses.

$$E_{\text{kin}} + E_{\text{pot}} = m_1 v_1^2 + m_2 v_2^2 + \frac{1}{2} m_1 v_1^2 + \frac{1}{2} m_2 v_2^2 \quad (\text{Again we neglect})$$

the potential energy due to the motion of the center of mass.

Fig. 10-6. Two views of another reaction between equal masses.

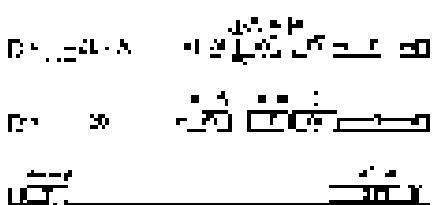

Fig. 10-6. An experiment to verify that a reaction with relatively small kinetic energy gives the same velocity $v/2$.

Fig. 10-7. Two views of another collision between m_1 and m_2 .

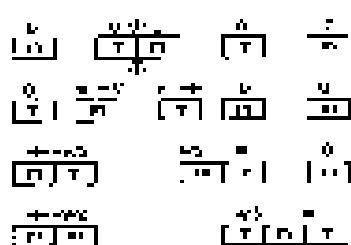

Fig. 10-8. Another one reaction between m_1 and m_2 .

$$m_1 v_1 + m_2 v_2 = m_1 v_1' + m_2 v_2' \quad (10-9)$$

Thus, using this principle, we can analyze any kind of collision to which two types of objects meet, hit each other, and stick. To see it through we have worked many of the collisions, we conducted quite a few experiments, made some simplified calculations by assuming that the collision happened in one dimension. The principle is the same, but the details get somewhat complicated.

In order to test experimentally whether an object moving with velocity v collides with 2 unequal masses m_1 and m_2 , let us consider a reaction between two objects of mass m_1 and m_2 moving with equal initial velocities $v/2$. We place in the trough two equally massive objects, two of which are initially joined together with their respective initial velocities, the third being very near to but still slightly separated from these and positioned such as nicely to approach but not yet stick to either object when hit. Now, a moment after the collision, we have two objects of mass m_1 moving with equal and opposite velocities v . A moment after that, one of these collides with the third object and makes an angle of θ with the incoming, so we calculate with velocity $v/2$. How do we test whether it is really $v/2$? By comparing the initial positions of the masses on the trough so that the distances to the ends are not equal, but are in the ratio 2:1. Using our tape, which continues to move with velocity v , we can now travel a much distance to a given position on the trough and stop by pulling the string to the smallest slot available by the second object before it collides with the third. The mass m_1 and the mass $2m_1$ should reach the end at the same time, and when we try it we find that they do (Fig. 10-9).

The next problem that we want to work out is what happens if we have two different masses. Let us take a mass m_1 and a mass $2m_1$ and apply our exclusive interaction. What will happen then? In a situation of the collision, we know m_1 releases m_2 to the left; what velocity does m_2 attain? The experiment we have just done may be repeated with an experiment between the second and third masses and when m_2 moves, we get the same result, namely, the resulting masses m_1 and $2m_1$ attain velocities $-v$ and $v/2$. Thus the direct reaction between m_1 and $2m_1$ gives the same result as the symmetric collision between m_1 and m_2 because the sum between m_1 and $2m_1$ is a third mass m_3 which they stick together. Furthermore, we find that m_2 moves toward $2m_1$ starting from the end of the trough, but when velocities (simply) inversely reversed stop and if they stick together.

Now the new question we may ask is this: What will happen if a mass m_1 with velocity v , say, hits an object that is at rest, $2m_1$, at rest? This is very easy to answer using our principle of collision reciprocity, for we simply note that when m_1 and m_2 have just separated from each other with velocity $-v/2$ (Fig. 10-9). From the law of velocities we:

$$v' = v - \text{velocity of } m_2 = v - v/2 = v/2$$

and

$$v_2' = -v/2 - \text{velocity of } m_1 = -v/2 + v/2 = 0.$$

After the collision, the mass m_1 appears to us to be moving with velocity $v/2$, thus we have the law (i.e., the law of velocities before and after collision is $v_1' + v_2' = 0$) of conservation of momentum, with a rather simple proof since m_1 is the only thing moving on, stuck together, with a velocity $v/2$ as much. The general consequence is that the sum of the velocities of the masses and the velocities stays the same, and this is because $v/2$, or m_1 , is simply holding up the "center of the conservation of momentum," piece by piece.

Now we have one last item. Using the same arguments, we can repeat the result of the previous three, we ignore them, i.e., the case of m_1 against three unequal mass rect as shown in Fig. 10-9.

In every case we find that the mass of the first object times its velocity, plus the mass of the second object times its velocity, is equal to the total mass of the final object times its velocity. These are all examples that, of course, the conservation of

momentum. Starting from simple astronomical cases, we have demonstrated that for most simple cases, we can in fact do it for any rational mass ratio, and since every case is exceedingly close to a rational ratio, we can banish errors due to irrationality as well.

III-4 Momentum and energy

All the foregoing examples are simple cases where two bodies collide and stick together, or were initially stuck together and later separated by an explosion. However, there are collisions in which the bodies do not stick, as, for example, two bodies of equal mass often collide with equal speeds and then rebound. For a brief moment, they are in contact and then are separated. At the instant of maximum compression they both have zero velocity and energy is stored in the elastic bodies, as in a compressed spring. This storage is derived from the kinetic energy that had been lost before the collision, which however comes at the instant their velocity is zero. The loss of kinetic energy is only temporary, however. The unbalanced condition is analogous to the cap that releases energy in an explosion. The body is now "unstable" decomposes in a kind of explosion, and fly apart again; but we already know that this—the bodies may appear with equal speeds. However, this speed C , should be less, if possible, i.e., the initial speed, because until "kinetic energy" is available for the explosion, depending on $m_1 = m_2$. If the material is purely no kinetic energy is recovered. But if it is something more rigid, some kinetic energy is usually regained. In the collision the rest of the kinetic energy is transformed into heat and vibration, energy—the bodies are hot and stirring. The vibrational energy also is sent transferred to us. It is possible to make the colliding bodies from highly elastic materials, such as steel, with carefully designed spring numbers, so that the collision passes the very little heat and vibration. In these circumstances the velocities of rebound are practically equal to the initial velocities and a collision is called elastic.

That the velocities before and after an elastic collision are equal is not a matter of conservation of momentum, but a matter of conservation of kinetic energy. That the speeds of the bodies remaining after a non-elastic collision are equal to each other, however, is a matter of conservation of momentum.

We might similarly consider collisions between bodies of different masses, different initial velocities, and compare degrees of elasticity, and determine final velocities and the loss of kinetic energy, but we shall not go into the details of these processes.

There collisions are especially interesting for systems that have no natural "years, months, or years." Even when there is a collision there is no rules for the change to be implemented, because the objects that move apart can in the same conditions as when they collided. Therefore, between very elementary objects, the collisions are always elastic or very nearly elastic. For instance, the collisions between atoms molecules or protons would be perfectly elastic. Although this is an excellent approximation, even such collisions are not perfectly elastic otherwise one could not break hand bone energy to the form of light or heat emission could come out of a pair. This is while, in a collision, a large energy is lost if it is emitted, but this occurrence is very rare and the energy emitted is very small. So for most purposes collisions of molecules or atoms can be considered as perfectly elastic.

As an interesting example, let us consider an elastic collision between two objects of equal mass. If they move together with the same speed, they would come apart with same speed, by symmetry. Let now look at this in another circumstance, in which one of them is moving with velocity v and the other one is at rest. What happens? We have been through this before. We watch the system and collision from a car moving along with one of the objects, and we find that if a stationary body is struck elastically by another body of exactly the same mass, the moving body stops and the one that was standing still now moves away with the same speed that the other one had, the bodies simply exchange velocities. This is what is usually demonstrated with a billiard ball apparatus. More

generally, if both bodies are moving with different velocities, they simply exchange velocity or impact.

Another example of an almost elastic interaction is magnetism. If we arrange a pair of U-shaped magnets in our glide blocks, so that they repel each other, when one glide goes up against the other, it pushes it up too, and the glide falls, and now the other goes along. Remarkably,

The principle of conservation of momentum is very useful, because it enables us to solve many problems without knowing the details. We can not know the details of the gas reactions in the cup explosion, yet we could predict the velocities with which the bodies came apart, for example. Another interesting example is rocket propulsion. A rocket of mass M , carries a small amount of mass m with constant velocity V relative to the rocket. After this is thrown, it moves originally steadily still, with the same velocity V . Using the principle of conservation of momentum, we can calculate this velocity to be:

$$v = \frac{m}{M} \cdot V$$

So long as m/M is less than one, the rocket continues to pick up speed. Rocket propulsion is essentially the same as the result of a gun: there is no need for any air to push against.

10.5 Relativistic momentum

In mechanics the law of conservation of momentum has undergone certain modifications. However, this is not Γ , the today's mechanics, but only mainly in the definition of things. In the theory of relativity it turns out that we do have conservation of momentum. The particle has mass and the momentum is still given by $m v$, the mass times the velocity, but the mass changes with the velocity, hence the momentum also changes. The mass varies with velocity according to the law

$$m = \frac{m_0}{\sqrt{1 - v^2/c^2}}. \quad (10.7)$$

where m_0 is the mass of the body at rest and c is the speed of light. It is easy to see from the formula that there is negligible difference between m and m_0 , unless v is very large, so that in ordinary velocities the correction for momentum reduces to the old formula.

The components of momentum for a single particle are written as

$$p_x = \frac{m v_x}{\sqrt{1 - v^2/c^2}}, \quad p_y = \frac{m v_y}{\sqrt{1 - v^2/c^2}}, \quad p_z = \frac{m v_z}{\sqrt{1 - v^2/c^2}}, \quad (10.8)$$

where $v^2 = v_x^2 + v_y^2 + v_z^2$. If the components are summed over all the interacting particles, both before and after a collision, the sums are equal; that is, momentum is conserved in the collisions. The same holds true in any directions.

In Chapter 1 we saw that the law of conservation of energy is an axiomatic, we recognize that energy appears in different forms, kinetic energy, mechanical energy, radiant energy, heat energy, and so on. In some of these cases, like a soap for example, the energy might be said to be "hidden." This example might suggest the question, "Are there also hidden forms of momentum — perhaps heat momentum?" The answer is that it is very hard to hide momentum for the "visible" reasons.

The sufficient condition of the nature of a body (variable measure of heat energy, if the square of the velocities are summed). This sum will be a positive result having no direction, etc. later. The fact is there, whether or not the body moves as a whole, and conservation of energy is the form of this conservation. On the other hand, if one sums the velocities, which carry direction, and finds a result that is not zero, that means that there is a drift of the entire body in some particular direction, and such a gross momentum is readily observed. Thus there is no reason to hide momentum, because the body has "no memory" not only in F

when it moves to a where. This form momentum, as a "mechanical" quantity, is without a body. Nevertheless, momentum can be added—in the Electromagnetic Field, for example. This is another effect of relativity.

One of the propositions of Newton was that if a charge in a chargeless environment—let us say our car is not the case; in situations involving electrical fields, for instance if an electrical charge in one location is suddenly moved, interactions on another charge, at another place, do not appear instantaneously. There is a time delay. In short, characteristics, such as the forces are equal the momentum will not react until there will be a short time during which the car will be trouble, because first while the first charge will feel a certain reaction force, and will pick up some momentum, but the second charge has not yet come and has not yet changed its momentum. It takes time for the influence to cross the intervening distance, where it goes at 300,000 miles a second. In that case the change from a charge to another is not experienced. Of course if the second charge has felt the effect of the first charge's motion then the momentum is then still check out—right, but during that short interval, momentum is not conserved. We say, well, it is by saying that during this interval there is another kind of momentum besides that of the particle, m_1 , m_2 . That is momentum in the electromagnetic field. If we add the field momentum to the momentum of the particles, then momentum is conserved at any moment of time. The fact that the electromagnetic field can possess momentum and energy makes that field very real, and so the law of relativity, described here that there are just the forces between particles has to be modified so that the two particles make a field, and a field makes another particle, and the field itself has such a similar properties of energy and momentum just as particles can have. To take another example: an electromagnetic field has waves, which we call light; it turns out that light also has the momentum well, so when light interacts on an object it carries in a definite amount of momentum per second. This is equivalent to a force, because if the immovable object is picking up a certain amount of momentum per second, is momentum, by definition and the situation is exactly the same as if there were a force on it. Light can exert pressure by bombarding an object. This pressure is very small, but with sufficiently intense appurtenance it is measurable.

Now in quantum mechanics it turns out that momentum is a different thing—it is no longer true. It is hard to define exactly what is meant by the velocity of a particle, but momentum still exists. In quantum mechanics the difference is that when the particles are represented as waves, the momentum is measured by the number of wave-packets per meter. The greater the number of waves, the greater the momentum, in spite of the differences. The use of construction of waves can help us to understand momentum. Even though the car—thing is false, and all the implications of Newton were wrong, the conservation of momentum, a quantum mechanics nevertheless, is true and the particle has momentum itself.

Werner

11.1 Symmetry in physics

In this chapter we introduce a subject that is technically known in physics as *symmetry in physical laws*. The word "symmetry" is used here with a special meaning, and therefore needs to be defined. What is a *symmetrical law*? In a definition like this we have to picture the law as symmetrical, and this is somehow to go on the other side. Professor Hermann Weyl has given this definition of symmetry: a thing is symmetrical if one can submit it to a certain operation, and it appears exactly the same after the operation. For instance, if we look at a view that is left-right-symmetrical, then turn it 180° around the vertical axis, it looks the same. We do not expect the definition to be similar in Weyl's more general form, and in that form we shall discuss symmetry of physical laws.

Suppose we built a complex machine in a certain place, with a lot of complicated internal parts, and with forces to move them, and so on. Now suppose we built exactly the same kind of equipment at some other place, matching part by part, with the same conditions and the same acceleration, everything else being only displaced laterally by some distance. Then, if we put the two machines in the same initial circumstances, in exact correspondence, we ask: Will one machine behave exactly the same as the other? Will it follow all the motions in exact parallelism? Of course, the answer may well be no, because if we choose the wrong place for our machine it might be inside a wall and influences from the wall would make the machine not work.

All of our laws in physics assume a certain amount of symmetry even in their application; they are not purely mathematical or abstract ideas. We have to understand what we mean when we say that the phenomenon is the same as in the case the apparatus is in a new position. We mean that we move everything that we believe to be relevant, if the phenomenon is not the same, we suggest that something important has not been moved, and we proceed to look for it. Now, however, if there are claim that the laws of physics do not have this symmetry. On the other hand, we have said it: we expect to find it, if the laws of physics do have this symmetry: looking around, we may discover, for instance, that the wall is pushing on the apparatus. The basic question is, if we define things well enough, if >1 the bounded forces are included inside the apparatus, will the forces not be moved from one place to another, will they keep the same? Will the machinery work the same way?

It is clear that what we want to do is to move all the equipment and external influences, but for simplicity let us consider, first, and all—let us if we do this, we have the same phenomena again for the trivial reason that we are right back where we started. Now, we cannot move everything. That is true, and in practice that with a certain amount of intelligence about where to move, the machinery will work. In other words, if we do not go mad about it, if we know the origin of the outside forces, and arrange that these are, moreover, then the machine will work the same in one location as in another.

11.2 Translations

We shall limit ourselves to just one law, for which we now have sufficient knowledge. In previous chapters we have seen the translation of variables and the sum related by a set of three equations for each particle:

$$\pi_0(\theta^0_{\mu}/\theta^{00}) = p_\mu \quad \pi_0(\theta^0_{\nu}/\theta^{00}) = p_\nu \quad \pi_0(\theta^0_{\lambda}/\theta^{00}) = p_\lambda \quad (11.1)$$

11.1 Symmetries in physics

11.2 Translations

11.3 Rotations

11.4 Forces

11.5 Factor algebras

11.6 Newton's laws in vector notation

11.7 Scalar product of vectors

Now this means that there exists a way to measure x_1 , y_1 , and z on three perpendicular axes, and the force along these directions will be the same and one doesn't need to measure from some origin, but where should we origin? Well, Joe would tell us at least it's OIC; there is some place that we can measure from, perhaps because of the universe, such that these forces are constant. But we can also immediately that we can never find the center, because if we use some other origin, it would make an difference. To take notes, anyone that there are two people, say, who has an origin \vec{r} in one place, and Max, who has a parallel system where origin is somewhere else (the \vec{r}'). Now when Joe measures the distance of \vec{r} from \vec{r}' he finds it to be a and it's well-knownly known that, because it is the defining of a (area of a parallelogram). After one a for \vec{r} , when measuring the same point \vec{r}' he finds a different a (in order to distinguish it). We will call it a' , and in principle it's different a . Though in our example they are numerically equal, so we can

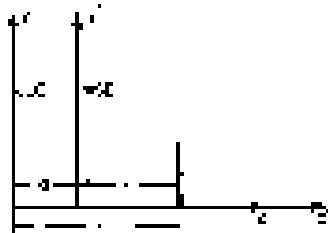

Fig. 11-1. Two parallel coordinate systems.

Now in order to complete our analysis we must know what Max would obtain for the forces. The force is supposed to be along parallel to and by the form in the introduction or mean the part of the total which is in the x -direction, which is the magnitude of the force times the cosine of its angle with the x -axis. Now we see that Max would get exactly the same projection as Joe did just, as we have a set of equations:

$$F_x = F_{x_1} - F_{x_2}, \quad F_y = F_{y_1} - F_{y_2}, \quad (11.1)$$

Let's look at the relationships between these like as given by the first line.

The question is, if Joe knows Newton's laws, and it has to be with when Newton's laws, and they didn't know Farhi's? Then it makes no difference from where origin we measure the points? In other words, assuming that equations (11.1) are true and the Eqs. (11.2) and (11.3) give the relationship of the components, is it or is it not true that

$$\begin{aligned} (11.2) \quad m_1(x_1^2 + y_1^2)^{1/2} &= F_{x_1}, \\ (11.3) \quad m_2(x_2^2 + y_2^2)^{1/2} &= F_{x_2}, \\ (11.4) \quad m_1(x_1^2 + y_1^2)^{1/2} &= F_{x_1}, \end{aligned}$$

In order to use these equations we shall calculate the formula for x_1 twice. First of all

$$\frac{dy}{dx} = \frac{\dot{y}}{\dot{x}}, \quad x = \dot{x}t, \quad \frac{dx}{dt} = \frac{dx}{dt}.$$

Now we still assume that Max's origin is fixed (not moving) relative to Joe's; therefore x is a constant and $dx/dt = 0$, we will find the

$$dx/dt = dx/dt'$$

and therefore:

$$d^2x/dt^2 = d^2x/dt'^2,$$

therefore we know that Eq. (11.4a) becomes

$$m_1(d^2x/dt^2)^{1/2} = F_{x_1},$$

(We also suppose that forces measured by Joe and Max are equal.) Thus the acceleration times the mass is the same as the other follows. We have also found the formula $F_x = F_{x_1}$, i.e., substituting from Eq. (11.1), we find that

$$F_x = F_{x_1}.$$

The other two forces will be Max appear the same; he can prove Newton's law but with different constants m and they will still be right. That proves that (11.4)

There is no unique way to define the origin of the world; because the laws will appear the same, from one user position, they are observer.

This is also true: if there is a piece of equipment in one place and a certain kind of machinery in it, the same equipment in another place will behave in the same way. Why? Because one machine, when analyzed by Joe, has exactly the same equations as the other one, analyzed by Joe. Since the equations are the same, the phenomenon happen. That is, the behavior of equipment in a new position behaves the same as it did in the old position, as the proof that the equations when replaced in space does not change themselves. Therefore we say that the law of physics are invariant for translational displacements, symmetrical in the sense that the laws do not change when we make a translation of our coordinates. Of course it is quite obvious intuitively. That is to say, it is interesting and enlightening to discuss the mathematics of it.

11-1 Rotations

The above is the first of a series of ever more complicated propositions concerning the symmetry of a physical law. The next proposition is: let us again make no difference in where we choose the axes. In other words, if we build a piece of equipment in some place and we do it properly, and nearby we build the same kind of apparatus but turn it up at an angle, will it operate in the same way? Obviously it will not if it is a Grandfather clock, for example. If a pendulum clock stands upright, it works fine, but if it is tilted, the pendulum falls against one side of the case and nothing happens. The theorem is even false in the case of the pendulum clock, unless we include the earth, which is pulling on the pendulum. Therefore we can make a proposition about pendulum clocks if we believe in the symmetry of physical law for rotation: something else is involved in the operation of a pendulum clock besides the mechanics of the clock, something outside it that we should look for. We may say perhaps no pendulum in space will not work the same way when located at different places relative to the mysterious source of gravitation, perhaps the earth. Indeed, we know that a pendulum clock will not work in space. For example, would not tick either, because there is no effective force, and on Mars it would go at a different rate. Pendulum clocks do involve something more: but just the mechanics itself may involve something on the outside. Once we recognize this factor, we see that we must turn the earth along with the apparatus. Otherwise we do not have to worry about Earth, it's best to do the one simply with a moment of rotation, so you can't bring into the problem, does now again in the new position the same as it did before. When we are rotating in space our bodies, a change changing, obviously. To change does not seem to be necessary more, but in the new position we seem to be in the same condition as in the old. This has a certain tendency to continue one, because it is true that in the new initial position the laws are the same as in the original position, but it is not true that we can a song to change the same laws as it does when we are not carrying it. If we perform sufficiently delicate experiments, we can tell that the earth is rotating, but not how it is going around. In other words, we cannot locate the angular position, but we can tell that it is changing.

Now we must discuss the effect of angular orientation upon physical laws. Let us find out who has the same symmetries with Joe and Mrs. Works-ager. This time, to avoid needless complication, we shall suppose that Joe and Mrs. Mac had the same initial position (we have already discussed). However, he moved by translation in another plane. Assume that Mrs.'s new axes rotated relative to Joe's by an angle θ . Two coordinate systems are shown in Fig. 11-2, which is restricted to two dimensions. Consider any point P having coordinates (x, y) in Joe's system and (x', y') in Mrs.'s system. We shall begin, as in the previous case, by expressing the coordinates x' and y' in terms of x , y , and θ . To do this we first drop perpendiculars from P to all four axes and draw all perpendiculars to xy . Inspection of the figure shows that x' can be written as the sum of two lengths along the x axis and y' as the difference of two longitudes along xk . All these lengths are expressed

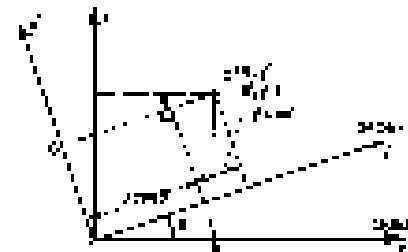

Fig. 11-2. Two coordinate systems having different angular orientation.

in terms of α , β , and δ in equation (11.5), at which we have added an equation for the third dimension:

$$\begin{aligned} x' &= x \cos \theta + z \sin \theta \\ y' &= y \cos \theta - z \sin \theta \\ z' &= z \end{aligned} \quad (11.5)$$

The next step is to analyze the relationship of forces as seen by the two observers, choosing the same generalized coordinates as before, i.e. x and z , which are already been analyzed as having components F_x and F_z (as seen by \mathbf{O}), by setting up a parallel of motion, located at point P in Fig. 11-2. For simplicity, let us move both sets of axes so that the origin is at P , as shown in Fig. 11-3. This sees the components of \mathbf{F} along his axes as $F_{x'}$ and $F_{z'}$. F_x has components along both the x' and z' axes, and F_z likewise has components along both these axes. To express F_x in terms of $F_{x'}$ and $F_{z'}$, we shall then consider F_x along the x axis, and in a like manner we can express F_y in terms of $F_{x'}$ and $F_{z'}$. The results are

$$\begin{aligned} F_x &= F_{x'} \cos \beta - F_{z'} \sin \beta \\ F_y &= F_{x'} \sin \beta - F_{z'} \cos \beta \\ F_z &= F_{z'} \end{aligned} \quad (11.6)$$

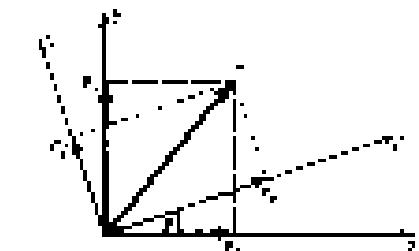

Fig. 11-3. Components of a force in the two systems.

It is interesting to note an accident of sorts, which is of extreme importance: the formulas (11.5) and (11.6) for components of \mathbf{F} and components of \mathbf{F}_x , respectively, are of identical type.

As before, Newton's laws are assumed to be true in both systems, and are repeated in equations (11.7). The question, again, is whether \mathbf{F} can satisfy Newton's laws—will the results be correct for the system of rotated axes? In other words, if we compare (1) Eqs. (11.5) and (11.6) give the right magnitude of the components, (2) is it of right direction?

$$\begin{aligned} m(\ddot{x}'^2/\partial t^2) &= F_{x'} \\ m(\ddot{y}'^2/\partial t^2) &= F_y \\ m(\ddot{z}'^2/\partial t^2) &= F_z \end{aligned} \quad (11.7)$$

To do this comparison, we calculate the left-hand sides independently, and compare the results. To calculate the left sides, we multiply equations (11.5) by m , \ddot{z} , and the product twice with respect to time, assuming the angle β to be constant. This gives

$$\begin{aligned} m(\ddot{x}'^2/\partial t^2) &= m(\dot{x}^2/\partial t^2)\cos^2 \beta - m(\dot{z}^2/\partial t^2)\sin^2 \beta \\ m(\ddot{y}'^2/\partial t^2) &= m(\dot{x}^2/\partial t^2)\cos^2 \beta - m(\dot{z}^2/\partial t^2)\sin^2 \beta \\ m(\ddot{z}'^2/\partial t^2) &= m(\dot{z}^2/\partial t^2) \end{aligned} \quad (11.8)$$

We take out the right sides of equations (11.7) by multiplying equation (11.7) into equations (11.6). This gives

$$\begin{aligned} F_{x'} &= m(\dot{x}^2/\partial t^2)\cos^2 \beta - m(\dot{z}^2/\partial t^2)\sin^2 \beta \\ F_y &= m(\dot{x}^2/\partial t^2)\sin^2 \beta - m(\dot{z}^2/\partial t^2)\cos^2 \beta \\ F_z &= m(\dot{z}^2/\partial t^2) \end{aligned} \quad (11.9)$$

Remark: The left sides of Eqs. (11.8) and (11.9) are identical, so we conclude that if Newton's laws are correct in one set of axes, they are also valid in another set of axes. This result, which has long been established for bivariate kinematics of axes, however, is not surprising. That means that all axes in a particular space are unique, but of course they can be more convenient for certain practical problems. For example, it is useful to have gravity along one axis, but this is not physically necessary. Second, a massive thin ring piece of equipment which is completely self-contained, with all the forces generating its motion completely inside the enclosure, would make the same when turned on its side.

11-4 Vectors

Newton's second law, because the other laws of physics so far we know today have the two properties which we call *invariance* (or *covariance*) under translation of coordinates and of time. These properties are so important that a mathematical technique has been developed to take advantage of them by writing and using physical laws.

The foregoing may yet appear considerably “weird” mathematical work. To test out the details of it in more detail, let us consider questions 2 and 3, more difficult mathematics machinery has been devised. This system, called “vector analysis,” simplifies the task of this chapter; strictly speaking, however, this is a chapter on the symmetry of physical laws. By the methods of the vector analysis we want to do everything required for achieving the results that we sought, but in practice we should like to do things more easily and rapidly, so we discuss the vector techniques.

We begin by noting some characteristics of two kinds of quantities that are important in physics. (Actually there are more than two, but we'll start out with two.) One of them, like the number of people in a flock, we call an *intensive quantity*, or an *independent quantity*, or a *scalar*. Temperature is an example of such a quantity. Other quantities that are independent of places do take a value, for instance velocity; we have a step back of which way a bird is going, not just its speed. Measuring the force also over direction, across displacement when, for example, going from one place to another in space, we can take track of time between, even if we only also in time where it went, we need to specify a coordinate.

All quantities that carry a dimension, like a step in space, are called *vectors*.

A vector is given by numbers. In order to represent a step in space say from the origin to some particular point, b , whose location is (x, y, z) , we really need three numbers, but we are going to invent a single mathematical symbol, \mathbf{v} , which is to be any other mathematical symbol we have on hand.¹ It is not a single number, it is systematically three numbers (x, y, z) . The three free numbers \mathbf{v} not really only three numbers, because it is better to use a different coordinate system. In these numbers \mathbf{v} could be changed to (x', y', z') . However, we must be able to our mathematics to jump around so we are going to make the same move to represent \mathbf{v} , the three numbers (x, y, z) and the three numbers (x', y', z') . Last is, we use the same move to represent the first set of three numbers for one coordinate system, into the second set of three numbers if we are going to other coordinate system. This has the advantage that when we change the coordinate system, we do not have to change the letters of our equations. That is, if we equate \mathbf{v} to (x, y, z) , and then use another system, we have to change to (x', y', z') . We shall just write \mathbf{v} , with the understanding that it represents (x, y, z) if we use one set of axes, or (x', y', z') if we use another set of axes, and so on. The three numbers which describe the quantity in a given coordinate system are called the *components* of the vector in a direction of the coordinate axes of that system. That is, we use the same symbol for the three letters that is a symbol for the same object, or even from different ways. The way that we can say “ \mathbf{v} is a quantity,” implies a physical reality and the reality of “ \mathbf{v} ,” x , y , z , x' , y' , z' depend on the coefficients in terms of which we measure \mathbf{v} , the symbol \mathbf{v} will represent the something no matter how we put the axes.

Now suppose there is another direction of pointing \mathbf{v} , say, any other coordinate system, also three numbers associated with \mathbf{v} , like (x_1, y_1, z_1) . Then these numbers change to three other numbers by a certain, mathematically true, as we change the axes. It must be the same rule that relates (x, y, z) to (x_1, y_1, z_1) . In other words, any physical quantity agrees with transformations which transform us to the components of a step in space is a vector. An equation like

$$\mathbf{F} = \mathbf{v}$$

would thus be true in any coordinate system if it were true in one. This is what

¹ In type code this is represented by boldface characters but I don't know if it works?

of course, counts for the other components.

$$F_x = a, \quad F_y = b, \quad F_z = c.$$

or, alternatively, for

$$F_x = a', \quad F_y = b', \quad F_z = c'.$$

The fact that a physical relationship can be expressed as a vector equation tells us the relationship is unchanged by a mere rotation of the coordinate system. That is, the reason why vectors are so useful in physics.

Now let us examine some of the properties of vectors. As examples of vectors we may mention velocity, momentum, force, and acceleration. For many purposes it is convenient to represent a vector quantity by an arrow that indicates the direction in which it is going. Why can we represent that way? Because it has the static mechanical transformation properties of a "step in space." We then represent it as a diagram as if it were a step, using a scale such that one unit of force, or one Newton, corresponds to a certain convenient length. Once we have done this, a force can be represented as length, because an equation like

$$\mathbf{F} = k\mathbf{r},$$

where k is some constant, is a perfectly legitimate equation. Thus we can always represent forces by lines, which is very convenient, however, since we've drawn the line we no longer need the axes. Of course, we can quickly calculate the three components as they change from time to time. However, because force is not a covariant quantity,

1.1-4 Vector algebra

Now we must describe the laws, or rules, for combining vectors to form new ones. The first such combination is the addition of two vector quantities. But \mathbf{a} is a vector object in some particular coordinate system, but the three components (a_x, a_y, a_z) , and that is another vector which has the three components (b_x, b_y, b_z) . Now let us invent three new numbers, $a_1 = b_x, a_2 = b_y, a_3 = b_z$. Do these form a vector? "Well," we might say, "they are three numbers, and every three numbers form a vector!" No, not every three numbers form a vector! In order for it to be a vector, not only must there be three numbers, but these must be associated with a coordinate system in such a way that if we turn the coordinate system, the three numbers "relocate" on each other, get "mixed up" in each other, by the precise laws we have already described. So the question is, "Can we make the coordinate system so that (a_x, a_y, a_z) become (a_1, a_2, a_3) and (b_x, b_y, b_z) become (b_1, b_2, b_3) ?" What do $(a_1 + b_1, a_2 + b_2, a_3 + b_3)$ become? Do they become $(a_x + b_x, a_y + b_y, a_z + b_z)$ or not? This exercise, of course, you remember the coordinate transformations of Eq. (11.2) except that we call it a *Möbius transformation*. If we apply these transformations to a_1, a_2, a_3 and b_1, b_2, b_3 to get $a_1 + b_1$, we find that the transformed $a_1 + b_1$ is *indeed* the same as $a_x + b_x$. When a and b are "added together" in this sense, they will form a vector which we may call c . We could write this as

$$\mathbf{c} = \mathbf{a} + \mathbf{b}$$

Now comes the interesting property:

$$\mathbf{c} = \mathbf{b} + \mathbf{a}.$$

so we can add vectors one at a time in components. That is,

$$\mathbf{a} + (\mathbf{b} + \mathbf{c}) = (\mathbf{a} + \mathbf{b}) + \mathbf{c}.$$

We can add vectors in any order.

What is the geometric significance of $\mathbf{a} + \mathbf{b}^2$? Suppose that \mathbf{a} and \mathbf{b} was represented by lines on a sheet of paper, what would it look like? This is shown in Fig.

Fig. 11-4. We see that we can add the components of \mathbf{b} to those of \mathbf{a} and conveniently place \mathbf{c} in such a way as to represent the components of \mathbf{b} as $-\mathbf{b}$, thus representing the components of \mathbf{a} in the system formed by \mathbf{b} . Since \mathbf{b} is just "this" force, really, it has a true meaning; this is done merely by putting the "tail" of \mathbf{b} at the "head" of \mathbf{a} , the arrow from the "tail" of \mathbf{a} to the "head" of \mathbf{b} being the vector \mathbf{c} . Of course, if we add \mathbf{a} to \mathbf{b} the other way around, we would get the same result as in the "tail" of \mathbf{b} by the parallelogram process of Fig. 11-2, yet the same result does. Note that vectors can be added in this way without changing their magnitudes.

Suppose we multiply a vector by a number n , what does this mean? We define n to mean a new vector whose components are $n a_x$, $n a_y$, and $n a_z$. We have no problem for horizontal vectors, but in 3D?

Now let us consider vector subtraction. We may define subtraction in the same way as addition, but instead of adding, we subtract the a portions. So we might define subvector by defining a new vector $\mathbf{a} - \mathbf{b} = \mathbf{a} + (-\mathbf{b})$ and then we would add the components. It comes to the same thing. The result is shown in Fig. 11-5. This figure shows $\mathbf{d} = \mathbf{a} - \mathbf{b} = \mathbf{a} + (-\mathbf{b})$; we can see that the difference $\mathbf{a} - \mathbf{b}$ is to be found very easily from \mathbf{a} and \mathbf{b} by using the commutative relation $\mathbf{a} + \mathbf{b} = \mathbf{b} + \mathbf{a}$. Thus the difference is even easier to find than the sum $\mathbf{a} + \mathbf{b}$, just like the vector sum $\mathbf{a} + \mathbf{b}$, in Fig. 11-2!

Now we discuss velocity. "Velocity is a vector." Position is given by the three coordinates (x, y, z) , what is the velocity? The velocity is given by dx/dt , dy/dt , and dz/dt is it a vector or not? We can find out by differentiating the expression of Eq. (11-1) to see if v is a vector in the right way. We see that the components dx/dt and dy/dt do transform according to the same laws as x and y , and therefore the "velocities" dx/dt and dy/dt are velocity vectors. We can write the velocity in an interesting way as

$$\mathbf{v} = \dot{x} \mathbf{i} + \dot{y} \mathbf{j} + \dot{z} \mathbf{k}.$$

What the velocities \dot{x} , \dot{y} , and \dot{z} are is a vector, can be understood more plausibly. How far does a particle move in a short time Δt ? Answer: Δr , so if a particle is "there" at one instant and "there" at another instant, then the vector difference in the position $\Delta \mathbf{r} = \mathbf{r}_2 - \mathbf{r}_1$, which is in the direction of motion. Given in Fig. 11-6, suppose by the time interval $\Delta t = t_2 - t_1$ is the "average velocity" vector

In other words, by vector velocity we mean the limit, as Δt goes to 0, of the displacement over the time interval Δt , i.e., $\Delta \mathbf{r}/\Delta t$. In terms of \mathbf{r} defined by (11-1)

$$\mathbf{v} = \lim_{\Delta t \rightarrow 0} \frac{\Delta \mathbf{r}}{\Delta t} = \frac{d\mathbf{r}}{dt} = \dot{x} \mathbf{i} + \dot{y} \mathbf{j} + \dot{z} \mathbf{k}. \quad (11-10)$$

This velocity is a vector because it is the difference of two vectors. It is also the definition of velocity because its components \dot{x} , \dot{y} , and \dot{z} are, in fact, dx/dt , dy/dt , and dz/dt . To sum this argument: that if we differentiate any vector with respect to time we produce a new vector. So we have several ways of obtaining new vectors: (1) multiply by a constant, (2) difference of two vectors with respect to time, (3) add two vectors.

11-6 Newton's Laws in vector form

In order to write Newton's laws in vector form, we have to project our x -axis, y -axis, and z -axis on the center of mass. This is the "inertial frame" for velocity vector, and it is easy to demonstrate that its components are the second derivatives of x , y , and z with respect to time:

$$\mathbf{a} = \frac{d^2 \mathbf{r}}{dt^2} = \left(\frac{d^2}{dt^2} (x) \right) \mathbf{i} + \left(\frac{d^2}{dt^2} (y) \right) \mathbf{j} + \left(\frac{d^2}{dt^2} (z) \right) \mathbf{k}, \quad (11-11)$$

$$a_x = \frac{d^2 x}{dt^2} = \ddot{x}, \quad a_y = \frac{d^2 y}{dt^2} = \ddot{y}, \quad a_z = \frac{d^2 z}{dt^2} = \ddot{z}, \quad \mathbf{a} = \ddot{x} \mathbf{i} + \ddot{y} \mathbf{j} + \ddot{z} \mathbf{k}. \quad (11-12)$$

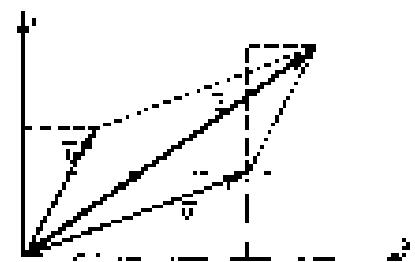

Fig. 11-4. The addition of vectors.

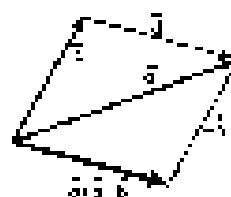

Fig. 11-5. The subtraction of vectors.

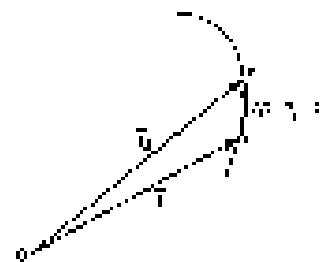

Fig. 11-6. The displacement of a particle in a short time interval $\Delta t = t_2 - t_1$.

With this definition, then, Newton's law can be written in this way:

$$m \ddot{\mathbf{r}} = \mathbf{F} \quad (11.1)$$

$$\text{or} \quad m\ddot{\mathbf{r}}(t)/t^2 = \mathbf{T}. \quad (11.1a)$$

Now the problem of deriving the equations of Newton's laws under rotation, or curvilinear motion, is reduced to taking vector differentiation just there. Since then \mathbf{F} is a vector, $m\ddot{\mathbf{r}}$ is also a vector; so if \mathbf{r} is a vector, then, since we know acceleration is a vector, Eq. (11.1a) will hold in the same as in any coordinate system. Writing it in a form which does not explicitly mention \mathbf{r}_x , \mathbf{r}_y , and \mathbf{r}_z has the advantage that from now on we need not write three axes every time we write Newton's equations or other laws of physics. We have scalar tools like one law, but really, of course, it is the free law for any particular set of axes, because any vector equation involves the statement that each of the components is equal.

The first law, the acceleration is the rate of change of the vector velocity, helps us to calculate the acceleration in our curvilinear coordinate circumstances. Suppose, for instance, that a particle is moving on some complicated curve (Fig. 11-7) and that at a given instant, it had a certain velocity \mathbf{v}_1 , but that when we go to another instant t_2 a little later, it has a different velocity \mathbf{v}_2 . What is the answer? Answer: Acceleration is the difference in the velocity caused by the same time interval, so we need the difference of the two velocities. How do we get the difference of the velocities? To do that two ways, let Δt be the time interval between t_1 and t_2 ; then $\Delta \mathbf{v}$ is the difference of the two vectors, right? Not! That only works when the ratio of the vectors is 1 : the set is closed! It has no meaning if we move the vector around when they are then in fact not closed, since about. We have to draw a new diagram to subtract the vectors. In Fig. 11-8, \mathbf{v}_1 and \mathbf{v}_2 and $\Delta \mathbf{v}$ drawn parallel to their components in Fig. 11-7, and now we can discuss the subtraction. If you try the subtraction is simply $\Delta \mathbf{v}/\Delta t$. It is interesting to note that we can compute the velocity difference out of the $\Delta \mathbf{v}$'s, without much of a calculation, by using the angle α between \mathbf{v}_1 and \mathbf{v}_2 to the path and α_1 of right angles to the path, as indicated in Fig. 11-8. The acceleration tangent to the path is, of course, just the change in the length of the vector, i.e., the change in magnitude:

$$a_r = d|\mathbf{v}|/dt. \quad (11.1b)$$

The other component of acceleration, at right angles to the curve, is easy to calculate, using Figs. 11-7 and 11-8. In the short time Δt let the change in angle between \mathbf{v}_1 and \mathbf{v}_2 be the small angle $\Delta\alpha$. If the magnitude of the velocity is called v , then of course

$$\Delta\alpha = 1.48$$

and the acceleration, a , will be

$$a_\theta = v^2/\Delta\alpha$$

Now we need to know $v/\Delta\alpha$, which can be found this way. If, at the beginning, the curve is supposed to be a circle of a certain radius R , then in Δt the distance s is, of course, $v\Delta t$, where v is the speed,

$$\Delta s = v\sin(\Delta\alpha/R), \quad \text{or} \quad \Delta s/\Delta\alpha = v/R.$$

Therefore, we find

$$a_\theta = v^2/R, \quad (11.1c)$$

as we have seen before.

11-7 Scalar product of vectors

Now let us end this talk further the properties of vectors. It is very important that the length of a vector in space would be the same in any coordinate system, and so, if a particular step $\Delta \mathbf{r}$ is represented by $\Delta_x, \Delta_y, \dots$ in one coordinate system,

and by x', y', z' the other components of system, since the orientation of world to the same in both form

$$r = \sqrt{x^2 + y^2 + z^2}$$

we also

$$r' = \sqrt{x'^2 + y'^2 + z'^2}.$$

So what we wish to verify is that these two quantities are equal. It is much more convenient now to take the square root, so that we'll want the square of the distance from the origin:

$$x^2 + y^2 + z^2 = x'^2 + y'^2 + z'^2. \quad (11.18)$$

If had better see if we substitute Eq. (11.8) we do indeed find that it is. So we see that there are no hidden difficulties with summing the squares of the components that is, let us find out whether

Something new is involved. We can introduce a new quantity, a function of a , b , and c , to be a scalar, *spherical angle*, in which two or three vectors which is the same as been systems. But at a later we can make a scalar. We have to find a general rule to that, i.e., a scalar value. The rule is to the case we consider add the squares of the components. Let me now define a new thing, often you will call it a dot. This is not a vector, but a scalar; it is a number that is the same in all coordinate systems, and it is defined to be the sum of the squares of the three components of the vector:

$$a \cdot b = a_x^2 + a_y^2 + a_z^2. \quad (11.19)$$

Now you say "But with what does?" It does not depend on because the vector is the same in every set of axes. So we have a new kind of quantity, a new kind of scalar, called "a scalar product." If we now define the following quantity for any two vectors a and b :

$$a \cdot b = a_x b_x + a_y b_y + a_z b_z. \quad (11.20)$$

we find that this quantity, calculated in the primed and unprimed systems, also have the same. To prove it we note that it is true of a_x , b_x and c_x since $a_x = a + b_x$. Therefore the sum of the squares $(a_x - b_x)^2 + (a_y - b_y)^2 + (a_z - b_z)^2$ will be invisible to

$$(a_x - b_x)^2 + (a_y - b_y)^2 + (a_z - b_z)^2 = (a_x - b_x)^2 + (a_y - b_y)^2 + (a_z - b_z)^2 + (b_x - b_x)^2 + (b_y - b_y)^2 + (b_z - b_z)^2. \quad (11.21)$$

Both sides of this equation are expanded, there will be cross products of just the type appearing in Eq. (11.20), as well as the sums of squares of the components of a and b . The expansion of terms of the form of Eq. (11.18) then shows there are no power terms (a , b) involved also.

The quantity $a \cdot b$ is called the scalar product of two vectors a and b , and it has many interesting and useful properties. For instance, it is easily proved that

$$a \cdot (b + c) = a \cdot b + a \cdot c. \quad (11.22)$$

Also, there is a simple geometrical way to calculate $a \cdot b$, without having to calculate the components a_x and b_x . $a \cdot b$ is the cosine of the angle θ between a and the length of b times the cosine of the angle between a and b . Why? Suppose that we choose a special coordinate system in which the x -axis lies along a ; in these coordinates, the only component of a that will be there is a_x , which is of course the whole length of a . Thus Eq. (11.18) reduces to $a \cdot b = a_x b$; for this reason, this is the length of a times the component of b in the direction of a , that is, b_x :

$$a \cdot b = ab \cos \theta.$$

Therefore, in this special coordinate system, we have proved that $a \cdot b$ is the

length it takes the longer path times (c/s) . But (c/s) is unique to one coordinate system, so it must be off, because ω is independent of the coordinate system. That is our argument.

What good is the dot product? Are there any cases in physics where we need it? Yes, we need it all the time. For instance, in Chapter 4 the kinetic energy was called $\frac{1}{2}mv^2$, but if the object is moving in space it should be the velocity squared in the direction the y -axis has, and the x -direction, and w . In formula for kinetic energy accounting for both the x and y is

$$K.E. = \frac{1}{2}m(v_x^2 + v_y^2) = \frac{1}{2}m(v_x^2 + v_y^2 + v_z^2) \quad (11.22)$$

Energy does not have dimension. Momentum has dimension kg , is a vector, and it is the mass times the velocity vector.

Another example of a dot product is the work done by a force when some thing is pushed from one place to the other. We have no yet defined work, but it is equivalent to the energy change, the weights used, when a box is pushed along a distance s :

$$\text{Work} = F \cdot s \quad (11.23)$$

It is sometimes very convenient to talk about the component of a vector in a certain direction (say the vertical direction, because that is the direction of gravity). For such purposes, it is useful to invent what we call a unit vector in the direction that we want to study. By a unit vector we mean one whose dot product with itself is equal to unity. If we call this unit vector even if $|F| = 1$ new, or we want the component of some vector \mathbf{v} in the direction of \mathbf{i} , we see that the dot product $\mathbf{v} \cdot \mathbf{i}$ will be a nice value, the component v_i of \mathbf{v} in the direction of \mathbf{i} . There is a nice way to get the component to zero; it permits us to get all the components and to write a rather amazingly simple. Suppose that in a given system of coordinates, \mathbf{i} , \mathbf{j} , and \mathbf{k} are defined. If we take \mathbf{i} as a vector in the direction of \mathbf{i} , \mathbf{j} and \mathbf{k} perpendicular to the direction of \mathbf{i} , and \mathbf{k} a unit vector in the direction of \mathbf{k} . Note that that $i \cdot i = 1$. What is $j \cdot j$? When two vectors are at right angles, their dot product is zero. Thus,

$$\begin{aligned} \mathbf{i} \cdot \mathbf{i} &= 1 \\ \mathbf{i} \cdot \mathbf{j} &= 0 \quad \mathbf{j} \cdot \mathbf{i} = 1 \\ \mathbf{i} \cdot \mathbf{k} &= 0 \quad \mathbf{j} \cdot \mathbf{k} = 0 \quad \mathbf{k} \cdot \mathbf{i} = 1 \end{aligned} \quad (11.24)$$

Now with these definitions, any vector whatever can be written this way:

$$\mathbf{v} = a\mathbf{i} + b\mathbf{j} + c\mathbf{k} \quad (11.25)$$

By this, we go from the components of a vector to the vector itself.

The properties of vectors is by no means complete. However, rather than try to go more deeply into the subject now, we shall first learn to use it physically since it comes up in the next few discussions. Then, when we have properly mastered the basic material, we shall find it easier to perceive more clearly if we do not go without getting too confused. We shall later find that it is useful to define another kind of product of two vectors, \mathbf{a} and the vector \mathbf{b} , $a \times b$, and written as $\mathbf{a} \times \mathbf{b}$. However, we shall postpone a discussion of such matters as a little while.

Characteristics of Force

12-1 What is a force?

Although it is interesting and worth while to study the physical laws, simply because they help us to understand and use the future more and more successfully, one in a while we might ask, "What does *law* really mean?" The meaning of *law* is a concept in a subject that has interested and troubled philosophers from time immemorial, and the meaning of classical laws is even more interesting, because it is generally believed that these laws represent some kind of real knowledge. The meaning of knowledge is a deep problem in epistemology, and it is always important to ask, "What does it mean?"

Let us ask, "What is the meaning of the physical laws of Newton, which you will learn?" or "What is the meaning of force, mass, and acceleration?" Well, we can say it very easily. The meaning of mass, and we can always assume it, is if we know the meaning of position and time. We shall not discuss those meanings, but shall concentrate on the new concept of force. The answer is quite simple. "If a body is accelerating, then there is a force on it." That is what Newton's law says; so the most precise and beautiful definition of force imaginable might simply be to say that force is the cause of the mass times the acceleration. Suppose we have a law which says that the conservation of momentum is valid if the sum of all the external forces is zero; then the question arises, "What does it mean, that the sum of all the external forces is zero?" A reasonable way to define this situation would be, "When the total momentum is constant, then the sum of the external forces is zero." There must be something wrong with that, because it is just not saying anything new. If we have defined a function of time, which shows that the force is equal to the mass times the acceleration, and then define the force to be the mass times the acceleration, we have sound but nothing. We could also define force to mean the following: object with no force acting upon it can do no more with greater velocity in a straight line. If we can move an object at constant velocity in a straight line, if we can move an object at constant velocity in a straight line, then we say that there is no force on it. Now such things hardly come up in the subject of physics, because many other things are going on at once. The Newtonian programme, however, seems to be a most precise definition of force, and one that appeals to the mathematician; nevertheless, it is completely useless, because no practical experimenter can measure force by definition. One might sit in somewhere all day long and define words at will, but to find out what happens when two bodies push against each other, or when a weight is hung on a spring, is another matter altogether, because the way the bodies behave is something completely outside any device of definition.

For example, if we want to choose to say that an object left to itself keeps its position, one does not move, even when we see something drizzling, we can't say that, just like it is a "force" a grain's chance of change of position. Now we have to add in new law, everything changes if except when a grain is moving. Yes, see, that would be analogous to the above definition of force, and it would contain no information. The real content of Newton's law is this, that the law is supposed to have some predictive properties, or utility, to the best of our part, but the specific inessential properties that the force has were not completely described by Newton or by anybody else, and therefore the physical law, $F = ma$, is an incomplete law. It means that if we study the mass times the acceleration and call the product the force, i.e., if we study the derivative force as a program

12-2 What is a force?

12-2 Attractors

12-3 Multicenter forces

12-4 Fundamental forces, I

12-5 Pseudo forces

12-6 Nuclear forces

of interest. Then we shall find that forces have some simplicity, the law is a great simplification, and, in fact, it is a very simple kind of the forces we experience.

Now the next example of a set forces may be the component of gravitation which was given by Newton, and in stating the law he announced the relation, "Who is the Lord?" If there were nothing but gravity, then the consequences of this law and the forces law (second law of motion) would be a complete theory. But there is much more than gravitation, and we want to use Newton's law in many different situations. Therefore in order to proceed we need to tell something about the properties of force.

For example, in dealing with forces the first assumption is always made that the forces is equal in size to the weight of one particle. There is present, that if we find a force total is not equal to zero we also has something at the simplest model that is source of the force. This seems, even here, like a formalism from the case of the second law, but it is really of a new type of the most important characteristics of force is that it has a material origin, and this is not just a definition.

Newton's original statement about the forces that the forces between interacting bodies are equal and opposite—action equals reaction, can rule of thumb is extremely true. In fact the law $F = ma$ is not exactly true; if it is exact, definitely we could have, say, no "absolute" gravitation, but it is not.

The student may object, "I do not like this approximation. I should like to have everything clear and exactly in fact." Let us make the point. In any science is a basic subject, in which everything is definite." If you make a very precise definition of force, you will never get it. Just because Newton's Second Law is not exact, and second, because in order to make strict physical laws you must understand that they are all some kind of approximation.

This simple idea is approached as an illustration, outside, an object ... was ... an object? All "things" are always moving. "Will" just take a chair, for example? As moreover they say that you know that they do not know what they are talking about me, now. What is a chair? Well, a chair is a certain thing ... is there ... certain? The same question arises if you want to name to chair—no more atoms, but a few ... carries out front you described at the chair; so, to define it in principle, to say exactly what it is, is not obtainable, unless atoms are ... or which atoms are there, or when atoms are placed, but saying of the chair is impossible. So the mass of a chair can be defined only approximately. In the same way, in fact, the mass of a single object is impossible, because there are not any single, infinitesimal regions in the world—every system is a mixture of a lot of things, so we can define only by a series of approximations and generalizations.

The trick is the qualifications. To an excellent approximation of we hope are part in (9-4). The number of atoms in the chair does not change in a minute, and if you are not the place. We may define as the chair is a definite thing, in the same way we say ... than the chair contains a "fence" is an absolute. Fishhook, if we are not too precise. One may be dissatisfied with the philosophical view of nature that classifies living beings. The energy is always increasing the accuracy of the approximation, and may prefer a mathematical definition, but mathematics definiteness can never reach to the real world. A mathematical definition will be given to the objects in which the logic can be followed, is incomplete, but the physical world is complex, as we have indicated, a number of examples such as (9-5) the room objects and capable of motion. When we try to isolate objects out of a collection of motion, it is impossible to do so, because we know which is which when one describes is the object? The forces on a single thing directly involves determining, and if we have a system of elements along the real world, that real system, at least for the present day, must involve approximations of some kind.

This system is, and unless the rest of mathematics is set in everything else we define, we can not say what we are talking about, or the language of mathematics. Let me do not care, to our what we are talking about. The point is that the laws, the constants, and the regions independent of what "it" is. If we have any other set of objects that obey the same system of axioms as Euclid's,

geometry, that if we make new definitions and follow them out with correct logic, all the consequences will be correct, and it makes no difference what the subject was. In nature, however, when we draw a line or establish a line by using a light beam and a telescope, as we do in surveying, one is measuring a line in the sense of Euclid's. Now, we're not doing an approximation; the trees don't have some wiggles, but a geometrical line has no wiggles, and so, whether Euclidean geometry can be used for surveying or not is a physical question, not a mathematical question. However, from an experimental standpoint, from a mathematical standpoint, we need to know whether the laws of Euclid apply to the kind of geometry that we use in surveying, and so we make a hypothesis that it does, and it works pretty well, but it is not precise, because our surveying lines are not really geometrical lines. Whether or not those lines of Euclid which are really abstract, applying to the lines of experience, is a question for experience; it is not a question that can be answered by other means.

In the same way, we cannot just call $F = ma$ a definition, deduced by surveying purely mathematically, and make mechanics a mathematical theory, with mechanics is a description of nature. By establishing suitable postulates, it is always possible to create a system of mathematics, just as Euclid did, but when we turn to mathematics of this sort, here we cannot be sure we have to find out whether the axioms are valid for the objects of nature. Thus we immediately get involved with these complicated and "fuzzy" objects of nature, but with approximations ever increasing in accuracy.

18-2 Trivia

The foregoing considerations show that a lot of understanding of Newton's law is equivalent to measurement forces, and it's the purpose of this chapter to continue such a discussion, as a kind of completion of Newton's law. We have already studied the definitions of acceleration and velocity vectors, but now we have to study the properties of force, and as a chapter, in the beginning chapters, we have very little; however, there are quite a number of things.

To begin with a practical topic, let us consider the case of an airplane flying through the air. What is the law for that force? Surely there is a law for every force; we might have a law of gravitation, hardly think that the law for this force will be simple. Let us suppose that when a drag is on an airplane flying through the air, the air will drag over the wings, the overwing, the under wing changes going on around the fuselage, and many other complications, and you see that there is not going to be a simple law. On the other hand, it is a remarkable fact that the drag force on an airplane is approximately a constant times the square of the velocity, or $F \propto v^2$.

Now what is the status of such a law, is it analogous to $F = ma$? Not at all, because in the first place this law is an empirical thing, but it is not even roughly the case in a wind tunnel. You say, "What? ... my might be empirical too." This is not the case that there is a difference. The difference is just that it is empirical, but that is the only standard name this law is the result of an enormous complexity of cause and effect, fundamentally, a simple thing. If we continue to study a more and more measuring mass and more accuracy, the law " $F \propto v^2$ " continues to become more and more realistic, i.e., true. In other words, as we gradually increase the drag on an airplane were and more closely, we find out that it is "true" and "false," and then more closely we study it, and the more accurately we make it, the more it agrees with the law. I think however, as in that case, we consider it not to result from a simple, fundamental process, which agrees with our original surmise. For example, if the velocity is zero, the law, as low that is, is ordinary simple, is zero flying, as when the airplane is dragged slowly through the air, but the air changes, and the drag increases depends more nearly linearly on the velocity. To take another example, the frictional force on a bullet is almost in anything that is moving slowly through a vacuum, independent of velocity, is proportional to the velocity, but for reasons so that that the fluid swirls around (bullet does not fall well) and so drag, the drag becomes more nearly proportional to the square of the velocity ($F \propto v^2$), and

If the velocity continues to increase, then, even this law begins to fail. People who say, "Well the coefficient changes slightly," are dodging the issue. Second, there are other great complexities involved in this force on the airplane. A wing is not fixed as a force on the wings, it acts on the frame, and so on? Instead, this can be done, "What are forces on about the wings, how fast there is, but then we have to get special laws for the force on the wings, and so on." It's an amazing fact that the force on the wing depends upon the other wings; in other words, if we take the airplane apart and put just one wing in the air, then the force is not the same as if the rest of the plane were there. The reason of course is the effect of the wind. As this jet goes forward the air hits the front and changes the force on the wings. It seems a miracle that there is such a simple, rough, empirical law that can be used in the design of airplanes, which is not in the same class as the laws of physics, and further study of it will only make it more and more complicated. A study of this coefficient depends on the shape of the front of the airplane because it is, I think, frustrating. There just is no simple way for determining the coefficient. It is one of the choices of the airplane. In contrast, the law of gravitation is simple, and further study only indicates its greater complexity.

We have just discussed two cases of friction, resulting from fast movement in air and slow movement in a liquid. There is another kind of friction, called the *sliding friction*, which occurs when one solid body slides on another. In this case a force is needed to maintain motion. This is called a *frictional force*, and in English, then, it is not complicated. After both surfaces of contact are irregular, or an atomic level. Then, at many points of contact, when the atoms seem to hang together, and then as the sliding body is pulled along, the atoms snap apart. A vibration causes something like that to happen. Basically the mechanism of this friction was thought to be very simple, but the surfaces were merely full of irregularities and the friction originated in sliding one side over the other but it cannot be, for there is no loss of energy in that process, whereas power is in fact consumed. The mechanism of power here is that as the slider moves over the bumps the bumps deform and then generate waves and deformation until, of course, the heat in the heat bath. Now it is very remarkable that again, empirically, this friction can be expressed approximately by a simple law. This law is that the force needed to overcome friction and to drag one object over another depends upon the normal force, that is, perpendicular to the surface between the two surfaces that are in contact. As really, in a fairly good approximation, the frictional force is proportional to this normal force, and has a more or less constant coefficient, denoted by μ ,

$$F = \mu N. \quad (12.3)$$

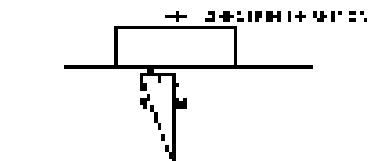

Fig. 12-1. The relation between frictional force and the normal force is often correct.

where μ is called the coefficient of friction (Fig. 12-1). Although the coefficient is not exactly constant, the formula is a good empirical rule for ordinary circumstances the majority of time. You will be needed it in your practical engineering circumstances. If the normal force or the speed of motion gets too big, the law fails because of the excessive heat generated. It is important to realize that each of these empirical laws has its limitations, beyond which it does not really work.

Let the formula $F = \mu N$ approximately correct can be demonstrated by a simple experiment. We set up a block, inclined at a small angle θ , and place a block of weight W on the block. We then tilt the plane at a larger angle, until the block just begins to slide down the incline. The component of the weight down along the plane is $W \sin \theta$, and this must equal the frictional force F when the block is sliding uniformly. The component of the weight normal to the plane is $W \cos \theta$, and this is the normal force N . With these values, the coefficient becomes $\mu = \tan \theta / \cos \theta$, from which we get $\mu = \sin \theta / \cos^2 \theta - 1/\cos \theta$. If this were exactly true, an object would start to slide at some definite incline angle. If the same block is loaded by putting extra weight on it, then, although W is increased, all the forces in the formula are increased in the same proportion, and μ cannot be. If a block contains the loaded block W will slide again at the same slope. When the angle θ is decreased by $\pi/2$ with the angle of slope, it is found

and with the greater weight the block will slide down the same slope. This will be true even when one weight is many times as great as the other, so we conclude that the coefficient of friction is independent of the weight.

In performing this experiment it is inevitable that when the block is tilted so as to begin sliding, the block does not glide smoothly but is jerking friction. At one place it may stop, at another it may move with acceleration. This behavior indicates that the coefficient of friction is only roughly constant and varies from place to place along the plane. The same erratic behavior is observed whether the block is loaded or not. Such variations are caused by different degrees of smoothness or cleanliness of the plane, and perhaps small ridges or other fungi, and on the tables that the purported values of μ for "steel on steel," "copper on copper," and the like, etc., also, because they ignore the surface contamination, which really determines μ . The friction is never due to "copper on copper" but to the impurities clinging to the copper.

The concept of the law described above, i.e., friction is roughly independent of the velocity, many people believe it's the friction is so enormous as just something started (static friction) exceeds the force required to keep it sliding (sliding friction). But with two metals it is very hard to allow any difference. The opinion probably arises from experiments where small bits of oil or lubricant are present, or when blocks, for example, are supported by springs or other devices suggesting that they appear to bind.

It is quite difficult to do rigorous quantitative experiments in friction, since the laws of friction are still not analyzed very well. It is one of the numerous engineering rules of thumb, a semiempirical. Although $F = \mu N$ is fairly reasonable since the surfaces are smoothened, moreover, for this form of the law is not really understood. To show that the coefficient μ is really independent of velocity requires some delicate experiments. You measure the apparent friction, i.e., much reduced if the lower surface vibrates very fast. When this experiment is done at very high speed, care must be taken that the object does not vibrate relative to one another, since apparent decrease of the friction is "high speed" can often due to vibrations. At any rate, this friction law is another of those semiempirical laws that are not thoroughly understood, and in view of all the work that has been done it is surprising the more understanding of this phenomenon has not come about. At the present time, to date, it is impossible even to estimate the coefficient of friction to over 10% substance.

It was pointed out above that a means of reducing the sliding friction is to have such as copper on copper will tend to stickiness, because the surfaces in contact are not pure copper but are mixtures of oxides and other impurities. If we try to get a relatively pure copper, if we clean and polish the surfaces, or put the materials in a vacuum, and take their conceivable reaction, we still do not get μ . For if we tilt the copper and clean copper in position, the slider will not let off—the two pieces of copper stick together! The coefficient μ , which is negligible less than unity for reasonably good surfaces, becomes several times μ_0 ! The reason for this "magical" behavior is that when the atoms in contact are all of the same kind, there is no way for the atoms to "know" that they are in different pieces of copper. When there are other atoms in the oxide or oxides and more complicated skin surface layers of contamination between the atoms, "holes" when they are not on opposite ends. When we consider that μ is forces between atoms then hold them together together as a solid, it should become clear that it is impossible to get the right coefficient of friction for your needs.

The next demonstration can be obtained in a simple device made by covering with a flat glass plate and a glass handle. If the handle is placed on the plate and pulled along with a long string or wire, slides freely and can be held. The coefficient of friction, it is a little irregular, but it is a coefficient. If we now cover the glass plate and the bottom of the cylinder and pull again we find that it binds, and if we look closely we shall find scratches, because the weight tries to lift the glass over the other continents of the surface, and the weight is unable to get control; the contact is too poor that it holds tight and needs extra pulling as much. But the glass is soon worn off; then it is makes scratches.

12-1 Molecular forces

We shall next discuss the characteristics of molecular forces. These are forces between the atoms, and are the ultimate origin of friction. Molecular forces have never been satisfactorily explained from a single "classical" physical theory quantum mechanics is too cumbersome to do this. Empirically, however, the force between atoms is illustrated schematically in Fig. 12-2 where the force F between two atoms is plotted as a function of the distance r between them. Here are different cases. In the water molecule, for example, the negative charges are more on the oxygen, and the mean positions of the negative charges and of the positive charges are not at the same point; consequently, another molecule nearby feels a relatively large force, which is called a dipole-dipole force. However, for many systems the net forces are very much better balanced, in particular for oxygen gas, which is perfectly symmetrical. In this case, although the negative charges and the positive charges are dispersed over the molecule, the distribution is such that the center of the negative charges and the center of the plus charges coincide. A molecule where the centers do not coincide is called a polar molecule, and charge carries the separation between centers is called the dipole moment. A nonpolar molecule is one in which the sum of all the charges is zero. For all uncharged molecules, in which all the electrical forces are neutralized, it nevertheless turns out that the force at any large distance r is an attraction and varies inversely as the seventh power of the distance, $\sim 1/r^7$, where k is a constant that depends on the molecules. Why this is we shall learn only when we learn quantum mechanics. Why there are dipole forces for polar molecules. What else is in molecules? But about they repel with a very large repulsion; this is what stops a stone falling through the floor.

These molecular forces can be demonstrated in a fairly direct way, and often is in a physics experiment with a given glass number; one has to make own wet, carefully ground and lapped surfaces which are very accurately flat, so that the surfaces can be brought very close together. An example of such surfaces is the Johnson-Miles block, used in machine shops as standards for making coordinate measurements. One such block is slid over another very fine 10^{-3} in. and the friction is lifted, so that the two surfaces cannot be lifted by the molecular forces, excepting the direct attraction between the atoms on one block for the atoms on the other block.

Now these molecular forces of attraction are still not fundamental in the sense that gravitation is fundamental; they are due to the vastly complex interactions of all the electrons and nuclei in one molecule with all the electrons and nuclei in another. Any simplification from this to get approximate or even some of complications, so we will have just get the fundamental phenomena.

Since the molecular forces is due to a large of atoms and nuclei, when molecules, as shown in Fig. 12-2, we can think up cases in which all the atoms are held together by their attractions and held apart by the repulsion that sets in when they are too close together. At a certain distance d where the graph in Fig. 12-2 crosses the axis the forces are zero, which means that they are all canceled, so that the molecules are just distance apart from one another. If the molecules are pushed closer together than the distance d they all show a repulsion represented by the portion of the graph above the axis. To pull the molecules out slightly except initially requires a great force, because the molecular repulsion rapidly becomes very great at distances less than d . If, however, you pull slightly apart them at a slight attraction, which increases as the separation increases. If they are pulled sufficiently far apart, they will separate permanently—the bond is broken.

These molecules are pulled only a very small distance down, or pulled only a correspondingly distance further than the corresponding distance along the curve of Fig. 12-2 is also very small, and can even be approximated by a straight line. Therefore, in more strict language, if the displacement x is not too great the force is proportional to the displacement. This principle is known as Hooke's law, or the law of elasticity, which says that the force in a body which tries to restore the body

Fig. 12-2. The force between two atoms as a function of their distance of separation.

to its original position when it is deformed is proportional to the distortion. This law, of course, holds true only if the elastic limit is not exceeded; when the force is too large, the body will no longer spring back, depending on the kind of distortion. The amount of force too much depends upon the material. For instance, for drawing a nail the force is very small, but for steel, is relatively large. Hook's law can be easily demonstrated with a long coil spring, made of steel and suspended vertically. A suitable weight hangs on the lower end of the spring produces a fine twist. If enough of the iron, δ , of the wire which results in a small vertical deflection in each turn one sees a proportionality between displacement and force. If the total elongation increased, say, by 10%, the weight is increased, as is found, but still about eight of 100 grams, so a stretch of 10% produces an additional elongation that is very nearly equal to the stretch that was measured for the first 10% increase. This is instant ratio. If force F is displaced δ by δ in length when the spring is stretched, we have Hook's law for springs.

13.4 Fundamental forces: Part I

We shall now discuss the only remaining forces that are fundamental. We shall begin with the attractive force between two electrically charged objects. We shall call it electrostatic force. Objects carry electric charges when composed simply of electrons or protons. They are called ionized electrically charged. There is an electrical force between them, and if the magnitudes of the charges are q_1 and q_2 , respectively, the force is given in the form of the Coulomb law between the two charges. If the charges are like, that is, like signs of quantization, but opposite charges the force is repulsive and the sign of quantization is reversed. The charges q_1 and q_2 can be numerically either positive or negative, and in any specific application of the formula we drop the sign of the force will come out right if the signs given the proper plus or minus sign; the force is directed along the line between the two charges. The constant in the formula depends somewhat upon constants used for the force, the charge, and the distance. In current practice the charge is measured in coulombs, the distance in meters, and the force in newtons. The inverse to get the force from coulombs directly in newtons, the constant factor for reduced reasons is written. Also it takes the numerical value

$$k_e = 8.99 \times 10^{9} \text{ N m}^2/\text{coul}^2 \text{ meter}^2$$

or

$$k_{\text{electro}} = 8.99 \times 10^9 \text{ N m}^2/\text{coul}^2$$

This Coulomb law for static charge is

$$F = k_e q_1 q_2 / (4 \pi \epsilon_0 r^2) \quad (13.2)$$

In some countries the charge of all is the charge of a single electron, which is 1.6×10^{-19} coulombs. In working with electrical forces between two similar particles, rather than with large charges, many people prefer the combination $q_1 q_2 / 4 \pi \epsilon_0 r^2$, in which r is defined as the charge or separation. This combination occurs frequently, and to simplify calculations it has been defined by the symbol ϵ_0 , its numerical value in coulombs squared units being 8.85×10^{-12} . The advantage of using the constant in this form is that the force between two electrons at a distance can then be written simply as e^2 / r^2 with e in meters, without all the Coulomb constants. Electrical forces are much more complicated than this simple formula. It is not a direct law, formula gives the force between two objects only when the objects are standing still. We shall consider the more general case shortly.

In addition to forces of the three fundamental kinds are such forces as friction, but the attraction force of the gravitational force, an interesting and very important concept, has been developed. Since at first sight the forces are not much more complicated than is indicated by the first equation above, one would less well true only with the interacting bodies are standing still, as expected

method is general to deal with the very complex forces that occur when the bodies start to move. It is conditioned, say, because it has been that an approach known as the concept of a "field" is adopted. For the sake of simplicity of this type, to illustrate the situation, say, electrical force, suppose we have two electric charges, q_1 and q_2 , located at points P and R , respectively. Then the force between them may be given by

$$F = \frac{q_1 q_2}{4\pi \epsilon_0 r^2} \hat{r} \quad (12.1)$$

To analyze this force by means of the field concept, we say that the charge q_1 at P produces a "condition" at R , such that when no charge q_2 is placed at R it "feels" the force. This is, however, always relative, of describing it, since the force F on q_2 at R can be written in another way. It is multiplied by a quantity E that would be there were no q_2 , were there no q_1 (provided we keep all the other charges in the right places). To be the "condition" produced by q_1 , we say, call E is the *electric field* produced at R by q_1 . It is a vector. The form is for the electric field E that is produced at R by a charge q_1 at P is the charge q_1 times ϵ_0 is constant, divided by r^2 (i.e., the distance from P to R), and it is along in the direction of the radius vector (the radial vector is directed by its own length). The expression for E is thus

$$E = \frac{q_1}{4\pi \epsilon_0 r^2} \hat{r} \quad (12.2)$$

We can write

$$F = q_2 E \quad (12.3)$$

which represents the force, the field, and the particle in the field. This is the point of all this. The physics is developed analysis, not the point. One part says that something produces a field. The other part says that something is acted on by the field. By allowing us to look at the two parts independently, the separation of the *analysis* simplifies the calculation of a problem in many situations. If more charges are present, we look first at the total electric field produced at R by all the charges and then, knowing the charge, one by placing at R , we find the force on it.

In the case of gravitation, we can do exactly the same thing. In this case, where $m_1 g = F$ (or, $m_1 g = m_1 m_2 G / r^2$), we can ignore the gravitational force, and focus the force on a body in a gravitational field. The mass of that body takes the field. The force on m_1 is the mass requires the field G produced by m_2 ; that is, $F = m_1 g$. Then the field G produced by a body of mass m_2 is $G = -m_2 g/r^2$ and it is scattered radially, as in the electrical case.

In spite of how it might at first seem, the separation of one part from another is not a trifling. I would be hard-pressed to say anything of writing the *grav. Eng.* if the laws of force were simple, but the laws of force are so complicated that it turns out that the field's basic quality is it is *united* independent of the objects which create them. One can do something like separate charge and produce an effect, a field, at a distance, from that source initially. To change the field keeps track of all the past effects of the interaction between two particles is not instantaneous. It is desirable to do this way to remember what happened previously. If the forces depend some of time depends upon where a particle was previously, which in turn, can run into difficulty to keep track of what were the positions, and that is the character of a field. So when the forces get more complicated, the field becomes more and more difficult to determine because it is a sum of an artificial separation.

In analyzing forces by the use of fields, we need two kinds of laws pertaining to fields. The first is "no response to a field," and then gives the equations of motion. For example, the law of response of a mass to a gravitational field is that the force is equal to the mass times the magnitude of field, or, if there is also a charge on the body, the response of the body to the field is to be charged up to match against the electric field. The second part of the rule of nature in these situations is to formulate the laws which determine the strength of the field and how it is generated. These laws are determined in the next chapter. We can learn more about them in due time, but shall write down a few things about them now.

First, the most remarkable fact of all, which is very easily and often can be easily understood, is that the total electric field produced by a number of sources is the vector sum of the electric fields produced by the individual sources separately. In other words, if we have numerous charges making a field, and if all by itself one of them would make the field E_1 , another would make the field E_2 , and so on, then we simply add the various E 's up to get the total field. This principle can be expressed as

$$E = E_1 + E_2 + E_3 + \dots \quad (12.6)$$

or, in view of the definition given above,

$$E = \sum_i \frac{q_i r_i}{4\pi\epsilon_0 r_i^2} \quad (12.7)$$

Can the same methods be applied to gravitation? The force between two masses m_1 and m_2 was expressed by Newton as $F = Gm_1 m_2/r^2$. But according to the field concept we may say that m_1 creates a field C in all the surrounding space, such that the force on m_2 is given by

$$F = m_2 C. \quad (12.8)$$

By complete analogy with Coulomb's law,

$$C = -Gm_1 r^{-2} \quad (12.9)$$

and the gravitational field produced by several masses is

$$C = C_1 + C_2 + C_3 + \dots \quad (12.10)$$

In Chapter 7, in working out a case of stationary motion, we used this principle in reverse. We simply added up the total forces to get the resultant force on a plane. If we divide out the mass of the planet in question, we get Eq. (12.10).

Equations (12.6) and (12.10) express what is known as the principle of superposition of fields. This principle exists for the total field due to all the sources in the sum of the fields due to each source. So far as we know today, the electrical field is an absolutely guaranteed law, while it is true even when the force law is complicated because of the nature of the charges. There are experimental tests, but more careful analysis has always shown these to be due to the overlooking of certain moving charges. However, although the principle of superposition applies exactly for electrical forces, it is not true for gravity if the field is too strong, and Newton's equation (12.10) is only approximate, according to Einstein's gravity, at all theory.

Directly related to electrical force is another kind, called magnetic force, and this too is analyzed in terms of the field. Some of the qualitative relations between electrical and magnetic forces can be illustrated by an experiment with an electron-ray tube (Fig. 12-3). At one end of such a tube is a source that emits a stream of electrons. Within the tube the electrons are forced along the electrons to a high speed and hitting some of them in a metal plate — >> a fluorescent screen at the other end of the tube. A spot of light glows at the center of the screen where the electrons strike and this enables us to trace the electron path. On the way to the screen the electrons pass through a narrow space between a pair of parallel metal plates, which are arranged, say, vertically. A voltage can be applied across the plates, + + at one plate and - - at the other plate. When such a voltage is present, there is an electric field between the plates.

The first part of the experiment is to apply a negative voltage to the lower plate while electrons from a filament have passed on the upper plate. Since like charges repel, the light spot on the screen invariably shifts upward. (We could also say this in another way: that the electron field, the field, has responded by deflecting upward.) When, however, the voltage is made large enough, very soon the light spot on the screen now jumps below the center, showing that the electrons in the beam were repelled by those in the plate above them. (Or we could say again

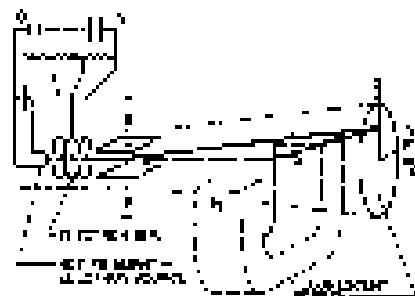

Fig. 12-3. An electron-beam tube.

then the electrons had "responded" to the field, which is new in its cause (see Appendix).

The second part of the experiment is to disconnect the voltage from the plates and see the effect of a magnetic field on the electron beam. This is done by means of a horseshoe magnet, whose poles are far enough apart to cover or less than the tube. Suppose we hold the magnet below the tube in the same vertical position, as in Fig. 11, with its poles up over part of the space between. We note that the light spot is deflected, say, upward, as the magnet approaches the tube from below. As it appears to us, the magnet repels the electron beam. However, it is not that simple, for if we move the magnet without reversing the poles side-to-side, and come approach the tube from above, the spot will move toward the magnet but it is now repelled instead. It appears to be attracted to the tube. Now we start again, returning the magnet to its original U position and moving it below the tube, as before. Yes, the spot is still deflected upward; but now with the magnet 180 degrees around a vertical axis, i.e., the it is off in the H position but the poles are reversed side-to-side. Hehoh! the spot does jump around, and stays down, even if we move the magnet up & down from above, as before.

To understand this peculiar behavior, we have to keep in mind a combination of forces. We explain it thus: Across the magnet there are pole to the side, there is a transverse field. It is left, but a dipole field which is always out of line and goes in opposite (what we could call) $\rightarrow\leftarrow$ and $\downarrow\uparrow$ and $\times\times$ and $\circ\circ$. Ingoing or ingoing will not change the direction of the field, but reversing the poles side-to-side did reverse its direction. For example, if the electron velocity were horizontal in the generator, and the magnetic field were also horizontally \downarrow in the y -direction, the magnetic force on the moving electron would be in the x -direction, i.e., $0\hat{x} + 0\hat{y} + 1\hat{z}$, depending on whether the field sees in the position a negative polarization.

Although we shall not soon present force law the correct law of force between charges moving in an arbitrary field, E and B , relative to the other, because it is too complicated, we can give one aspect of it: the simple law of the force of dipole moments. The force on a charged object depends upon its motion. If, \vec{v} , is the object's constant velocity in a given place, then in some sense, this is taken to be proportional to the charge and moment being what we call the electric field. Within the object itself the force F_E is different, and the correction, the net "spur" of force, due to the dipole moment on the object, has of right negative v and to cancel vector quantity which we call the magnetic induction \vec{B} . If the components of the electric field E and the magnetic induction B are respectively, (E_x, E_y) and (B_x, B_y) , and if the velocity v has the components (v_x, v_y) , then the total electric and magnetic force on a moving charge q has the components:

$$\begin{aligned} F_x &= q(E_x + v_x B_y - v_y B_x) \\ F_y &= q(E_y + v_x B_x + v_y B_y) \\ F_z &= q(B_x) \end{aligned} \quad (12.11)$$

If, for instance, the only component of the magnetic field were B_x , and the only component of the velocity were v_x , then the only component of the magnetic force would be a force in the z -direction, at right angles to both B and v .

12-5 Lorentz forces

The next kind of force we shall discuss might be called a particle force. In Chapter 12 we discussed the relationship between two persons, Joe and Moe, who live different lives in a system. Let us suppose that the positions of a particle as measured by Joe are x and by Moe are x' ; then the laws are as follows:

$$x = x' + S_x \quad x' = x'_0 + v_x t \quad v_x = \dot{x},$$

where S is the displacement of Moe's system relative to Joe's. If we suppose that,

the law of inertia is broken. For example, the day before May 9, 1961, first the

$$m_1 \ddot{x}_1 = m_2 \dot{y}_2 - m_3 \dot{x}_2$$

Previously, we considered the case where α was constant, i.e., found that α made no difference in the laws of motion, since $\alpha = 0$ if the body, therefore, the laws of physics were the same in both systems. But another case we can take is that $\alpha = \alpha(t)$, where α is a uniform velocity in a straight line. Then α is not constant, and $\alpha(t) \neq 0$, even if α is a constant. However, the acceleration $\alpha^2/\sqrt{1-\alpha^2}$ is still constant by $\alpha^2/\sqrt{1-\alpha^2} = C$. This violates the law that $m_1 \ddot{x}_1$ in (12.4), namely, that "the laws are the same." But with uniform velocity the laws of physics are, however, still the same when we are moving still. That is the Galilean transformation. But we wish to discuss the interesting case where α is still time varying, say $\alpha = \alpha(t)$. Then $\ddot{x}_1 = m_1 \alpha^2/\sqrt{1-\alpha^2} = m_1 \alpha$ is uniform acceleration; or in a still more complete case, the acceleration might be a function of time. This means that although the laws of force from the point of view of α would look like

$$m_1 \frac{d^2 x_1}{dt^2} = F_1,$$

the laws of forces as looked upon by Mac would appear as

$$m_1 \frac{d^2 x_1}{dt^2} - F_1 = m_1 \alpha.$$

In other words Mac's coordinate system is accelerating with respect to α , i.e., the exact form of force in (12.4). Mac will have to adjust his laws so that (12.4) is able to get Newton's laws to work. In this world, however, appears mysteriously a new force or unknown origin which arises, of course, because Mac has the wrong coordinate system. This is an example of a pseudo force, other examples occur in coordinate systems that are rotating.

Another example of pseudo force is what is often called "centrifugal force." An observer in a rotating, rigid mass system, e.g., in a rotating bus, will find mysterious forces, not accounted for by any known origin, in some "throwing things outward toward the walls." These forces are due merely to the fact that the observer does not have Newton's coordinate system, which is the complex coordinate system.

Pseudo forces can be illustrated by an interesting experiment in which we push a man or a sled along a table with a rubber band. Generally, all men will observe it on the table, but because of the horizontal acceleration there is also a pseudo force acting horizontally and in a direction opposite to the main action. The resultant of gravity and pseudo force makes an angle with the surface, and during the acceleration the surface of the water will be perpendicular to the resultant force, i.e., it makes an angle with the table, with the same sine. Consequently in the rearward side of the sled, when the person on the sled steps off, he falls sideways because of friction, the pseudo force is reversed, and the water runs faster on the forward side of the sled (Fig. 12-4).

The very important lesson to pseudo forces is that they are always proportional to the mass, the same is true of grav. up. The possibility exists, therefore, to "gravitate only" a pseudo force. It is not possible to "gravitate" grav. down due simply to the fact that we do not have the right coordinate system. After all, we can always push a box proportional to the mass, i.e., pushing the box back & acceler器ing. For this reason man and part of the car is moving still on the coordinate system fixed to the door or the box with a certain force that is proportional to his mass. But if there were no earth at all, i.e., the box were standing still, the man inside would float in space. On the other hand, if there were no earth at all and something were pulling the box along with an acceleration a , then the man in the box, according physics, would find a person from which would pull him to the door, just as gravity does.

Fig. 12-4. Illustration of a pseudo force.

Between galileo's theory and general relativity, we have an additional criterion, that the forces of acceleration, the pseudo forces, cannot be distinguished from forces of gravity. It is not precisely a tell-tale mark of a given force to gravity and how much is pseudo force.

It might seem off-light to consider gravity to be a pseudo force. In fact, we are all held down because we are accelerating upward, but how about the people in Mississippi? At the other side of the earth, are they accelerating too? Einstein found the "gravitational" force of a particle to be only a "weight" at a time, and was led by his considerations to suggest that the geometry of the world is more complicated than einstein's flat spacetime. The reason is that it is only qualitatively, and does not present or convey anything more than the general idea. To give a corroborating or how gravitation could be the result of pseudo forces, we present an illustration, which is rarely presented in college relativity, the ball situation. Suppose we were to live in two dimensions, and knew nothing of a third. We think we are on a plane, but suppose we are really at the surface of a sphere. And suppose that we start an object along the ground, with no forces other than "where will it go?" It will appear to go in a straight line, but it will remain on the surface of a sphere, so the shortest distance between two points is along a great circle, not a geodesic (a great circle). If we start another object similarly, but in another direction, it goes along another great circle. Because we think we are on a plane, we expect that the two bodies will continue to diverge linearly with time; but instead, separation will show that if they go far enough they move closer together again, as though they were attracting each other. (If they are not attracting each other, there's not something "weird" about it's geometry.) This particular illustration does not describe correctly the way in which "real" geometry is "weird," but it illustrates that if we discern the geometry sufficiently it is possible that all acceleration is due to non-zero pseudo forces, that is the general idea of the Einsteinian theory of gravitation.

12-6 Nuclear forces

We can end this chapter with a brief discussion of the last other known forces, which are called *nuclear forces*. These forces are within the nuclei of atoms and although they are much discussed, no one has ever calculated the force between two nuclei, and indeed present there is no known law for nuclear forces. These forces have very long range, perhaps just about the same size as of the nucleus, perhaps 10^{-11} centimeter. With particles so small and at such a tiny distance, only the quantum-mechanical laws are valid, not the Newtonian laws. In nuclear analysis we no longer talk in terms of forces, and in fact we can replace the force concept with a concept of the energy of interaction of two particles, a subject that will be discussed later. Any formula that can be written for nuclear forces is a rather crude approximation often times many components; one might be something as follows: forces with two nucleons do not vary free wells as the square of the distance, but are exponentially converging in distance, expressed by $F = C e^{-kx}/x^2$, where the distance x_0 is of the order of 10^{-12} centimeter. In other words, the forces disappear as soon as the particles are any greater distance apart, though they are very strong with the 10^{-11} centimeter range. So far as they are understood today, the laws of nuclear forces are very complex; we do not understand them in any simple way, and the whole problem of calculating the fundamental machinery behind nuclear forces is unsolved. New experiments have led to the discovery of numerous strange particles, the *mesons*, for example, but the origin of these forces remains unsolved.

Work and Potential Energy (1)

13-1 Energy of a falling body

In Chapter 4 we discussed the conservation of energy. In the discussion, we did not consider a case but it is of course of great interest to see how a body above that energy is at first conserved in accordance with that law. For clarity we shall start with the simplest possible example, one that develops further and harder examples.

The simplest example of the conservation of energy is a body falling vertically, one that moves only in the vertical direction. An object with mass m , height h , and initial mass of energy, starts with a kinetic energy $\frac{1}{2}mv^2$ (or K.E.) the v is written during the fall, and a potential energy mass M in P.E., which soon becomes zero:

$$\frac{mv^2}{2} - \frac{mg\delta}{E_0} = 0 \quad (13.1)$$

Now we would like to know that this statement is true. What do we mean, since it is true? From Newton's Second Law we can easily tell how the object moves, and it is easy to find out how the velocity varies with time namely, just if the mass proportionally with the time, and that the height varies as the square of the time. So if we measure the height from a certain point where the object is stationary, it is easy to see that the height increases in proportion to the square of the velocity times a number of constants. However, let us look at it a little more closely.

Let us find out directly from Newton's Second Law how the law is energy. Could this be, by taking derivative of the kinetic energy with respect to time and then using Newton's law? When we calculate $\frac{d}{dt}$ with respect to time, we obtain:

$$\frac{d}{dt} \left(\frac{1}{2}mv^2 \right) = m v \frac{dv}{dt} = m \frac{v}{dt} \quad (13.2)$$

since m is a constant. But from Newton's Second Law $m \frac{dv}{dt} = F$, so that

$$m \frac{v}{dt} = F \quad (13.3)$$

In general, it will not be able to $F = v$, but in our simplified case it is true, it is to be found: thus the velocity

Now in our simple example the force is constant, equal to $-mg$, a vertical force (the minus sign means that it acts downward), and the velocity, of course, is the rate of change of the vertical position, or length δ , with time. Let's substitute the value of the kinetic energy $\frac{1}{2}mv^2$ and the value of the force, in the law of change of something (that is the time δ of change of length). Therefore we find that the change in potential energy and in the quantity $m\frac{v}{dt}$ are equal, and opposite, so that the sum of the two quantities remains constant (13.2).

We have shown, from Newton's second law of motion, that energy is conserved for constant forces when we take the place far enough high so the kinetic energy zero. Now let's think is this finding still true when forces can be general, and thus advance our understanding. Does it work only for a freely falling body or is it more general? We expect from our discussion of the previous section of energy

13-1 Energy of a falling body

13-2 Work Done by gravity

13-3 Conservation of energy

13-4 Gravitational field of large objects

Let's consider what it would take for an object moving from one point to another in some kind of trajectory γ , under the influence of gravity (Fig. 13-1). If the object moves with a certain velocity v from the height H , then the time t that it should take to fall right, i.e., from the velocity v to zero, is given after γ by the vertical. We would like to understand why our law is still correct. Let us focus the same analysis, this time the time rate of change of the kinetic energy. This will again bear directly on why velocity is the rate of change of the magnitude of the momentum, i.e., the law of conservation of momentum (the tangential force F_t). This

$$\frac{dP}{dt} = m \frac{dv}{dt} = F_t.$$

Now, the speed is the rate of change of distance along the curve, $s(t)$, and the magnitude of F_t is proportional to $m g$ times the derivative of $s(t)$ along the path to the vertical distance ds . In other words,

$$F_t = -m g \sin \gamma = -m g \frac{ds}{dt},$$

so that

$$m \frac{dv}{dt} = -m g \left(\frac{ds}{dt} \right) \left(\frac{ds}{dt} \right) = -m g \frac{ds}{dt},$$

since $v = ds/dt$. Thus, we get (neglecting m) dP/dt is equal to the rate of change of v , as before.

In order to understand exactly how the conservation of energy works in general situations, we shall now derive a number of concepts which will help us to do so.

First, we discuss the rate of change of kinetic energy in general motion along γ . The best strategy is through components:

$$T = \tfrac{1}{2} m (v_x^2 + v_y^2 + v_z^2).$$

When we differentiate with respect to time, we get three trivial products:

$$\frac{dT}{dt} = \frac{1}{2} \left(\frac{\partial T}{\partial x} + \frac{\partial T}{\partial y} + \frac{\partial T}{\partial z} \right) \frac{dx}{dt} + \frac{1}{2} \left(\frac{\partial T}{\partial x} + \frac{\partial T}{\partial y} + \frac{\partial T}{\partial z} \right) \frac{dy}{dt} + \frac{1}{2} \left(\frac{\partial T}{\partial x} + \frac{\partial T}{\partial y} + \frac{\partial T}{\partial z} \right) \frac{dz}{dt}. \quad (13.1)$$

But each $\partial T / \partial x$ is the force F_x acting on m projected in the x -direction. Thus the right side of Eq. 13.1 is $(v_x F_x + v_y F_y + v_z F_z)$. We recall from vector analysis and mechanics that $F = \mathbf{F} \cdot \mathbf{v}$, therefore

$$dT/dt = \mathbf{F} \cdot \mathbf{v}. \quad (13.2)$$

This result can be derived more quickly as follows: if \mathbf{v} and \mathbf{F} are two vectors, both of which may depend upon the time, the derivative of $\mathbf{v} \cdot \mathbf{F}$ is, in general,

$$(d\mathbf{v} \cdot \mathbf{F})/dt = v_x (dv_x/dt) + v_y (dv_y/dt) + v_z (dv_z/dt). \quad (13.3)$$

We can use this in the form $\mathbf{v} = \mathbf{b} + \mathbf{r}$:

$$\frac{d(\mathbf{v} \cdot \mathbf{F})}{dt} = \frac{d(\mathbf{b} \cdot \mathbf{F})}{dt} + \frac{d(\mathbf{r} \cdot \mathbf{F})}{dt} = b_x \frac{db_x}{dt} + b_y \frac{db_y}{dt} + b_z \frac{db_z}{dt} + v_x \frac{dr_x}{dt} + v_y \frac{dr_y}{dt} + v_z \frac{dr_z}{dt}. \quad (13.4)$$

Because the forces of F_x , F_y , and F_z may in general be so important at times, we have been given to the importance of the equations such as $F_x v_x + F_y v_y + F_z v_z$, as the $\mathbf{v} \cdot \mathbf{F}$ component, called kinetic energy. $F \cdot v$ is called power: the force acting on an object times the velocity v of the object (not a "that" product) is the power being delivered to the object by that force. We note here, as we have noted before, the rate of change of kinetic energy, which is equal to the power expended by the force, along γ .

However, to study the conservation of energy, we want to analyze this still more closely. Let us see if the change in kinetic energy is always short circuit. If we multiply both sides of Eq. 13.3 by dt we find that the differential change in

the kinetic energy is the force "dot" the initial distance traveled:

$$dE_k = F \cdot ds \quad (1.1.6)$$

These units agree, we get:

$$dE_k = \int_{s_0}^s F \cdot ds \quad (1.1.7)$$

What does this mean? It means that if an object is moving in any order the influence of a force, using an arc as kind of curved path, then the change in K.E. when it goes from one point to another along the curve is equal to the integral of the component of the force along the curve. And the differential application of this, the tangent becomes just $F \cos \theta$, from one point to the other. This is very similar to what we saw in the last chapter, the work done by the forces. We see immediately that power equals work done per second. We also see that it's only a component of force is the difference of kinetic energy contributes to the work done. From a simple example the forces were only vertical, and had only a single component, say F_x , equal to $-mg$. But after 20 m the power would in these circumstances fall to 0, it's impossible for example in P.A.W., which can never turn $dE_k/dt + F_x ds + \dots ds$, has nothing left of it but $F_x ds = -mg ds$, because no other components of force are zero. The same, in our simple case,

$$\int_{s_0}^s F \cdot ds = \int_{s_0}^s mg ds = m g (s_s - s_0) \quad (1.1.8)$$

or again we find that it's only the vertical forces from which the object falls that contribute to the potential energy.

As we've about mass, since forces are measured in newtons, and we multiply by a distance in order to obtain work, work is measured in newton-meters (J), but people do not like to say newton-meters, they prefer to say joules (J). A centimetre meter is called a joule, work is measured in joules. Power, then, is joules per second and that is also called a watt (W). If we multiply work by time, the result is the work done. The work done by the electric company in our house, technically, is stored in the walls after the time. That is where we get things like biomass energy, 1000 w to three 3000 watt, or 3.6×10^9 joules.

Now we take another example of the law of conservation of energy. Consider an object which initially has kinetic energy and is moving very fast and is also going against the Earth's field. It says. At first the total kinetic energy is not zero, but at the end it is zero, there is work done by the forces, because whenever the object hits the earth there is always a component of force in a direction opposite to that of the motion and the energy is readily lost. The new law makes mass on the road of a planet swinging in a curved plane in a gravitational field with no friction. Work happens here as well, because when the mass is going up the force is downward, and when it is coming down, the force is also downward. Thus P.A.W. has one sign going up and another sign coming down. At each corresponding point of the movement, and upward paths the values of F are not necessarily equal in magnitude of opposite sign, so the net result of the integrations is zero for this case. This is the kinetic energy with all of the new comes back to the form as it had when it left, that is the principle of the conservation of energy. (Note that when there are friction forces the conservation of energy seems at first sight to be untrue. Without friction a ball loses energy. I think not, in fact the ball is accelerated to an object when it rubs against with friction, and at the moment we supposedly don't know that.)

1.1.1 Work done by gravity

The next problem to be discussed, is much more difficult than the above; it has to do with the case when the forces are not constant or simply vertical, as they were in the cases we have worked out. We want to consider a planet, for example, moving around the sun, or a satellite in the space around the earth.

We can't just consider the motion of an object which starts at some point 1 and falls, say, straight toward the sun or toward the earth (Fig. 13-2). Will there be a loss of conservation of energy if this occurs? The only difference is that in this case, the force is always nonconservative; it is not just a constant. As we know, the force is GMm/r^2 times the mass m , where M is the mass here. However, since the body falls toward the earth, the kinetic energy increases as the distance fallen increases, just as it does when we do our work about the variation of force with weight. The question is whether it is possible to fall so that the potential energy is lost from us, a different function of distance away from the earth, so that conservation of energy will still be true.

This one-dimensional case is easy to see. Let's see how much the change in the kinetic energy is equal to the integral "contribution of potential to the system," $-GMm/r^2$ times the displacement Δr :

Fig. 13-2. A small mass moves under the influence of gravity toward a large mass M .

$$T_2 - T_1 = - \int_{r_1}^{r_2} GMm \frac{dr}{r^2}. \quad (13.11)$$

There are no obvious reasons for this case because the force and the displacement are in the same direction. It is easy to integrate dr/r^2 ; the result is $-1/r$, so Eq. (13.11) becomes

$$T_2 - T_1 = +GMm \left(\frac{1}{r_2} - \frac{1}{r_1} \right). \quad (13.12)$$

This we have a different formula for potential energy. Equation (13.12) tells us that the quantity $(GMm)^{-1} = GMm/r$ calculated at point 1, at point 2, or at any other place, has a constant value.

We now have the formula for the potential energy in a gravitational field for vertical motion. Now we have an interesting problem. Can we make a vertical revolution in a gravitational field? The gravity isn't the same in different places; it is an $1/r^2$ term; distances are not constant strengths. Could we do something like this using a fixed, frictionless track, start at some point, and lift the object out to some other point? Then move it around and come back to the first point, then cover its return distance, then move out to a certain place and pull it out some other way, so that when we bring it back to the starting point a certain amount of work has been done by the gravitational force, and the kinetic energy of the object is increased? Can we design the curve so that it comes back moving a little faster than it did before, so that it goes around a few and a half and a full circle as potential motion? Since perpendicular motion is impossible we might wind out that this is also impossible. We ought to discover the following proposition: since there is no friction the object cannot come back with neither higher nor lower velocity; it should be able to keep going around and around any closed path. Since in another way, we never seem work to go the revolution a complete cycle should be zero for gravity forces, unless if it is not zero when get energy out by going around. If the work turns out to be less than zero, so that we get less speed when we go around one way, then we surely go around the other way, because the forces, of course, depend only upon the position, not upon the direction. That way is fine, the other way would be minus, so unless it is zero we will get perpetual motion by going around forever only.

Is the work really zero? Let us try to demonstrate that it is. First we shall explain more or less why it is zero, and then we shall examine it a little better mathematically. Suppose that we use a simple path, such as that shown in Fig. 13-3, in which a small mass is carried from point 1 to point 2, and then is made to go around a circle to 3, back to 1, then to 3, 4, 7, and 8, and finally back to 1. All of the arcs are either "purely radial" or circular with M as the center. How much work is done in carrying out around this path? Between points 1 and 2, $\Delta r = 2R\pi$ times the difference of $1/r$ between 1 and 2, plus

$$\Delta r_{12} = \int_{r_1}^{r_2} R dr = \int_{r_1}^{r_2} -GMm \frac{dr}{r^2} = -GMm \left(\frac{1}{r_2} - \frac{1}{r_1} \right).$$

Fig. 13-3. A closed path in a gravitational field.

From 2 to 3 the force is constant at right angles to the curve, so that $\nabla E_{\text{int}} = 0$. The work done is again

$$W_{3,4} = \int_{r_3}^{r_4} \mathbf{F} \cdot d\mathbf{s} = -GMm \left(\frac{1}{r_3} - \frac{1}{r_4} \right).$$

In the same fashion, we find that $W_{4,5} = 0$, $W_{5,6} = -GMm(1/r_5 - 1/r_6)$, $W_{6,7} = 0$, $W_{7,8} = -GMm(1/r_7 - 1/r_8)$, and $W_{8,3} = 0$. Thus

$$W = GMm \left(\frac{1}{r_1} - \frac{1}{r_2} + \frac{1}{r_3} - \frac{1}{r_4} + \frac{1}{r_5} - \frac{1}{r_6} + \frac{1}{r_7} - \frac{1}{r_8} \right).$$

But we note that $r_3 = r_1$, $r_4 = r_2$, and $r_5 = r_7$. Therefore $W = 0$.

Of course we can wonder whether this is the general answer. What if we have a nonconservative force? Even on a real curve, first of all, we might like to assert that a real curve cannot always be approximated sufficiently well by a series of rectangles (as in Fig. 13-4), and then therefore, even Q.E.D., how without analytic, it is not apparent at first that the work done going around even a small triangle is zero. Let us imagine one of the triangles, as shown in Fig. 13-4. Is the work done in going from a to b much larger than in going from b to c ? (The work done going directly from a to c ! Suppose that the force is acting in a certain direction; let us have the triangle such that the "force" is in this direction, just as an example. We also suppose that the triangle is so small that the force is essentially constant over the entire triangle. What is the work done in going from a to b ? It is

$$W_{a,b} = \int_a^b \mathbf{F} \cdot d\mathbf{s} = F_x dx,$$

since the force is constant. Now let us calculate the work done in going around once the three sides of the triangle. Our first side, a to b , the force is perpendicular to it, so that here the work is zero. On the horizontal side b ,

$$W_{b,c} = \int_b^c \mathbf{F} \cdot d\mathbf{s} = F_x dx.$$

Then we see that the work done in going along the sides of a small triangle is the same as that done only on a line, because zero. It is equal to zero. We have proved previously that the answer is zero for any path composed of a series of matches like those of Fig. 13-3, and also that we do the same work if we go across the surface instead of going along the matches (or along to the molecules, for fine enough) and we can always move them very freely; therefore, the work done in going around any path is a gravitational field is zero.

This is a very nice little result. And it's no surprising work if you already know about planetary motion. It tells us that when a planet moves around the sun (without any other objects around, no other forces) it moves in such a manner that the square of the speed is proportional to some constant divided by the radius to the sun, plus always the same at every point on the orbit. For example, the closer the planet is to the sun, the faster it is going, but by how much? By the following argument: if instead of letting the planet go around the sun, we were to change the direction but not the magnitude of its velocity and make it move radially, e.g. that we let it fall from some especial radius to the center of interest, the new speed would be the same as the speed it has in the actual orbit, because this is just another example of a complicated path. So long as we come back to the same distance, the kinetic energy will be the same. So, whether the motion is the usual, unrestricted one, or is changed in direction by channels, by frictionless constraints, the kinetic energy will follow the same, and its value at a point will be the same.

Thus, when we make a numerical analysis of the motion of the planet in its orbit, as we did earlier, we can check whether or not we are making appreciable errors by calculating this constant quantity, the energy, at every step, and it doesn't change. For the unit of T to E , the energy does change⁷ as changes by

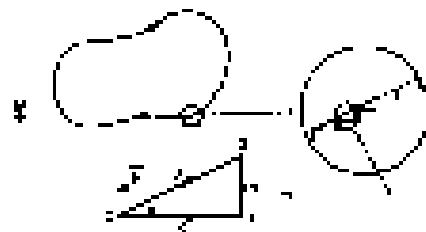

Fig. 13-4. A "messy" closed path, showing a magnified segment of it approximated by a series of vertical and horizontal steps, and an enlarged view of one step.

⁷ The energy is $(1/2)mv^2 + U$ in the general form.

some 1.5 percent. From the beginning to the end. Why? Either because the spring is not linear, or there are other frictional effects, or else because we made a slight mistake somewhere in our work.

Is it reasonable that energy is constant over the oscillation of a mass on a spring? When we consider the mass from its balanced position, the restoring force is proportional to the displacement. In those circumstances, can we think out a law for conservation of energy? Yes, because the work done by such a force is

$$W = \int_{x_1}^{x_2} F(x) dx = \int_{x_1}^{x_2} -kx dx = -\frac{1}{2} kx^2. \quad (13.1)$$

Therefore, for a mass on a spring we have that the kinetic energy of the oscillating mass plus $\frac{1}{2} kx^2$ is a constant. Let us see how this works. We pull the mass down; it is extending still and so it's speed is zero. But at equilibrium, $x=0$, its potential energy is zero. Energy, the sum of kinetic energy, decreases. Now we release the mass and things begin to happen (the mass will be horizontal). But as any instant the kinetic plus potential energy must be a constant. For example, when the mass is on its way up, the initial equilibrium point, the position is again zero but the k when it's at its highest x^2 , and it's going more, v^2 it gets less k^2 , and so on. So the balance $1/2 v^2 + kx^2$ is maintained as the mass goes up and down. Thus we have another rule now. i.e., the potential energy for a spring is $\frac{1}{2} kx^2$. If the force is $F = -kx$.

13-4 Harmonics of Energy

Now we go on to the topic of a consideration of what happens when there are several numbers of objects. Suppose we have the complicated problem of many objects, which we label $i = 1, 2, 3, \dots$, all exerting gravitational pulls on each other. What happens then? We recall once that if we add the total energies of all the particles, we can always keep away all forms of particle motion gravitational potential energy. Gravity, the total is a constant.

$$\sum_i \text{kinetic}_i = \sum_i \text{pot}_i = \frac{\text{constant}}{r_{ij}} \quad \text{since} \quad (13.1)$$

How do we prove it? We differentiate both sides with respect to time and get $\dot{m}_i \ddot{r}_{ij}$. We're not differentiating pot_i , we're taking the derivative of the velocity. So it's the forces, just as in Eq. (13.1). We replace those forces by the law of force that we know from Newton's law of gravity and then we notice that what is left is the same as the time derivative of

$$\sum_i \frac{G m_i m_j}{r_{ij}},$$

The time derivative of the kinetic energy is

$$\begin{aligned} \frac{d}{dt} \sum_i \text{kinetic}_i &= \sum_i m_i v_i \cdot \frac{dv_i}{dt} \\ &= \sum_i \dot{m}_i v_i \\ &= \sum_i \left(\sum_j \frac{-G m_i m_j}{r_{ij}^2} \right) v_i. \end{aligned} \quad (13.2)$$

The time derivative of the potential energy is

$$\frac{d}{dt} \sum_i \text{pot}_i = \sum_i \left(\frac{-G m_i m_j}{r_{ij}^2} \right) \left(\frac{dr_{ij}}{dt} \right).$$

But

$$r_{ij} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2},$$

so that

$$\begin{aligned}\frac{dr_{ij}}{dt} &= \frac{1}{2r_{ij}}[2(r_i - r_j)\left(\frac{dv_i}{dt} - \frac{dv_j}{dt}\right) \\ &\quad - 2v_i \cdot v_j\left(\frac{dv_i}{dt} - \frac{dv_j}{dt}\right) \\ &\quad + 2(r_i - r_j)\left(\frac{dz_i}{dt} - \frac{dz_j}{dt}\right)] \\ &= r_{ij} \cdot \frac{v_i - v_j}{r_{ij}} \\ &= r_{ij} \cdot \frac{v_i}{r_{ij}} + r_{ij} \cdot \frac{v_j}{r_{ij}},\end{aligned}$$

since $v_{iz} = -v_{jz}$ while $r_{iz} = r_{jz}$. Thus

$$\frac{d}{dt} \sum_{1 \leq i < j \leq n} \frac{Gm_i m_j}{r_{ij}} = \sum_{i,j} \left[\frac{(mv_i m_j v_{iz})_i v_j}{r_{ij}^2} + \frac{(Gm_i m_j v_{iz})_i v_j}{r_{ij}^2} \right]. \quad (13.16)$$

Now we must note carefully what \sum , \sum_i , and $\sum_{i,j}$ mean. In Eq. (13.15), $\sum_i \sum_j$ means that i takes on all values $i = 1, 2, 3, \dots$ in turn, and for each value of i , the index j takes on all values except i . Thus if $i = 3$, j takes on the values $1, 2, 4, \dots$.

In Eq. (13.16), on the other hand, \sum means that given values of i and j occur only once. Thus the particle pair 1 and 2 contributes only one term to the sum. To keep track of this, we might agree to let i range over all values $1, 2, 3, \dots$, and for each i let j range only over values greater than i . Thus if $i = 1$, j could only have value 2, 3, 4, ... But we notice that for each i, j value there are two contributions to the sum, one involving v_i and the other v_j , and that these terms have the same superposition as that of Eq. (13.14), where all values of i and j (except $i = j$) are taken in the sum. Therefore, by matching the terms one by one, we see that Eqs. (13.16) and (13.15) are precisely the same, but of opposite sign, so that the time derivative of the kinetic plus potential energy is indeed zero. Thus we see that, for many objects, the kinetic energy is the sum of the contributions from each individual object, and that the potential energy is also simple, it being also just a sum of contributions, the energies between all the pairs. We can understand why it should be the energy of every pair this way: suppose that we want to find the total amount of work that must be done to bring the objects to certain distances from each other. We may do this in several steps, bringing them in from infinity where there is no force, one by one. First we bring in number one, which requires no work, since no other objects are yet present to exert force on it. Next we bring in number two, which does take some work, namely $W_{12} = -Gm_1 m_2 / r_{12}$. Now, and this is an important point, suppose we bring in the next object to position three. At any instant the force on number 3 can be written as the sum of two forces: the force exerted by number 1 and that exerted by number 2. Therefore the work done is the sum of the work done by both, because if F_3 can be resolved into the sum of two forces,

$$\mathbf{F}_3 = \mathbf{F}_{31} + \mathbf{F}_{32},$$

then the work is

$$\int \mathbf{F}_3 \cdot d\mathbf{s} = \int \mathbf{F}_{31} \cdot d\mathbf{s} + \int \mathbf{F}_{32} \cdot d\mathbf{s} = W_{13} + W_{23}.$$

That is, the work done is the sum of the work done against the first force and the second force, as if each acted independently. Proceeding in this way, we see that the total work required to assemble the given configuration of objects is precisely the value given in Eq. (13.14) as the potential energy. It is because gravity obeys the principle of superposition of forces that we can write the potential energy as a sum over each pair of particles.

13-4 Gravitational field of large objects

Now we wish to calculate the fields which are met in a few physical circumstances involving distributions of mass. We have not so far considered contributions of mass, only of force, so it is interesting to consider the forces which they can produce by more than just one particle. First we shall find the gravitational force due to a mass that is produced by a plane sheet of constant density in extent. The force on a unit mass at the given point P , produced by this sheet of mass (Fig. 13-5), will of course be directed toward the sheet. Let the distance of the point from the sheet be a , and let the constant mass per unit area of the sheet sheet be σ . We shall suppose it to be constant. This is a uniform sheet of mass σa^2 . Now, when small dudm is produced by the mass dm lying between p and $p + dp$ from the point C of the sheet nearest point P . Answer: $dC = Gdm/r^2$. But this force is directed along r , and we know this, only the component of dC we want when we add all the little vector dC 's to produce C . The y -component of dC is

$$dC_y = G \frac{dm}{r^2} \cos \theta = G \frac{dm}{r^2},$$

Fig. 13-5. The gravitational force F on a mass m produced by an infinite plane sheet of matter.

Now all contributions which are at the same distance r from P will yield the same dC_y , so we may at once write for dm the total mass in the ring between p and $p + dp$, namely $dm = \sigma 2\pi p dp$ ($2\pi p dp$ is the area of a ring of radius p and width dp , if $dp \ll p$). Thus

$$dC_y = G\sigma 2\pi p \frac{dm}{p^2}.$$

But, since $r^2 = p^2 + a^2$, $dm = r dr$. Therefore,

$$C_y = 2\pi G\sigma \int_p^\infty \frac{dr}{r^2} = 2\pi G\sigma \left(\frac{1}{p} - \frac{1}{r} \right) = 2\pi G\sigma. \quad (13.7)$$

Thus the $G\sigma$ is independent of distance a . Why? Have we made a mistake? One might think that the farther away we go, the weaker the force would be. But no! If we are close, most of the matter is pulling at an unfavorable angle; if we are far away, most of the matter is situated quite favorably to exert a pull toward the plane. A simple diagram the matter which is most effective lies in a certain range. When we are farther away the force is smaller by the inverse square, but in the same range, in the same angle, there is much more matter, larger by just the square of the distance. This analysis can be made rigorous by just noticing that the differential contribution to any given force is in fact independent of the distance because of the reciprocal variation of the strength of the force from a given mass, and the amount of mass included in the force, with changing distance. The force is not really constant, of course, because when we go on the other side of the sheet it becomes $-$ in sign.

We have also, in effect, solved an electrical problem: if we have an electrically charged sheet, with an infinitesimal of charge per unit area, then the electric field at a point a is, outside the sheet, $E = \sigma/2\epsilon_0$, and is in the outward direction of the sheet if positively charged, and inward if the sheet is negatively charged. To prove this, we merely note that the gravity, $(2\pi G\sigma)/a$, is due to the conductivity.

Now suppose that we have two plates, with a positive charge $+q$ on one and a negative charge $-q$ on another at a distance a from the first. What is the field? Outside the two plates it is zero. Why? Because one side is at the other repels the force being withdrawn of charge, so that it has to move out. Also, the force between the two plates is clearly taken as q/q as two sheets one side, namely $E = q/4\pi\epsilon_0 a^2$, and is directed from the positive plate to the negative one.

Now we come to a most interesting and important problem, whose solution we have been assuming all the time, but now, that the force produced by the earth is a pull, and the surface of the earth it is the same as if all the mass of the earth were located in its center. The validity of this assumption is not obvious, because when we are close, some of the mass is very close to us and some is further away.

and so on. When we add the effects all together, it seems a miracle that the net force is exactly the same as we would get if we put all the mass in the middle!

We now decide to be convinced of this miracle. In order to do so, however, we shall consider a thin spherical shell instead of the whole earth. Let the total mass of the shell be m , and let us calculate the potential energy of a particle of mass m' at a distance R away from the sphere (Fig. 13-6) and show that the potential energy is the same as it would be if the mass m were a point at the center. (The potential energy is easier to work with than is the field because we do not have to worry about angles; we merely add the potential energies of all the pieces of mass.) If we call x the distance of a certain plane section from the center, then all the mass that is in a slice dx is at the same distance x from P , and the potential energy due to this ring is $-Gm'm\mu dx/x$. How much mass is in the small slice dx ? An amount

$$dm = 2\pi\mu x dx = \frac{2\pi\mu x dx}{\sin\theta} = 2\pi\mu dx,$$

where $\mu = m/(4\pi R^2)$ is the surface density of mass on the spherical shell. (It is a general rule that the area of a zone of a sphere is proportional to its axial width.) Therefore the potential energy due to dm is

$$\delta W = -\frac{Gm'm\mu}{x} = -\frac{Gm'm\mu dx}{x}.$$

But we see that

$$\begin{aligned} r^2 &= x^2 + (R-x)^2 = x^2 + x^2 - 2Rx = R^2 - 2Rx \\ &= x^2 + R^2 - 2Rx. \end{aligned}$$

Thus

$$2r dx = -2R dx$$

so

$$\frac{dx}{r} = \frac{dx}{R}.$$

Therefore,

$$\delta W = -\frac{Gm'm\mu dx}{R},$$

and so

$$\begin{aligned} W &= -\frac{Gm'm\mu}{R} \int_{R-x}^{R+x} dr \\ &= -\frac{Gm'm\mu}{R} dx = -\frac{Gm'(4\pi x^2\mu)}{R} \\ &= \frac{Gm'm}{R}. \end{aligned} \tag{13.18}$$

Thus, for a thin spherical shell, the potential energy of a mass m' external to the shell, is the same as though the mass m of the shell were concentrated at its center. The earth can be imagined as a series of spherical shells, each one of which contributes an energy which depends only on its mass and the distance from the center; adding them all together we get the total mass, and therefore the earth acts as though all the material were at the center.

But notice what happens if our point is on the inside of the shell. Making the same calculation, but with P on the inside, we still get the difference of the two r 's, but now in the form $x + R$ ($x = R$) = $2R$, or twice the distance from the center. In other words, W comes out to be $W = -Gm'm/a$, which is independent of R and independent of position, i.e., the same energy no matter where we are inside. Therefore no force; no work is done when we move about inside. If the potential energy is the same no matter where an object is placed inside the sphere, there can be no force on it. So there is no force inside, there is only a force outside, and the force outside is the same as though the mass were all at the center.

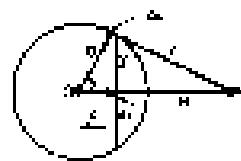

Fig. 13-6. A thin spherical shell of mass or charge.

Work and Potential Energy (continued)

14.1 Work

In the preceding chapter we have presented a great many new ideas and results that play a central role in physics. These ideas are so important that it seems worthwhile to devote a whole chapter to a closer examination of them. In the present chapter we shall not repeat the "proofs" or the specific tricks by which the results were obtained, but shall concentrate instead upon a discussion of the ideas themselves.

In learning any subject of a technical nature where mathematics plays a role, one is confronted with the task of understanding and solving, usually, in the extremely large body of facts and laws. Let us imagine by way of example something which can be "proved" or "shown" to rest between them. It is easy to confuse the proof itself with the result which it establishes. Clearly, the important thing is to know and to remember is the relationship, not the proof. In any particular case, however, we can safely say that it can be shown that "such and such is true," if we can show it. In almost all cases, the particular "such" that is most interesting, that is, the interest lies in its being done quickly and easily on the computer or on paper, and so that it will be as simple looking as possible. Consequently, the proof may look deceptively simple. This is fact. In fact, you might have worked for hours trying different ways of calculating the same thing until you found the easiest way, so as to be able to show that it can be done in the shortest amount of time. The thing to be remembered when seeing a proof, is that the proof is off, but for the it can be shown that such and such is true. Of course, if the proof involves some mathematical procedure or "tricks" that one has not seen before, then you should try to get back to the basic theory, turn to the mathematics, and re-investigate.

It is certain that at all the examinations that I have taken up to now, as well as this, nothing has been remembered from me from where the author studied freshman physics. Quite the contrary, he merely remembers what was done, since such is true, and to explain how it can be shown he uses a demonstration of the human kind. Anyone who has really learned a subject ought to know how to follow a similar procedure, but it is not necessarily the point. That is why, in this section, we shall avoid the words of the various statements made previously and simply summarize the results.

The first idea that has to be discussed is work when a force. The classical word "work" is not the word in the ordinary sense of "the labor of the workman," but by a different idea. Physical work is expressed as $\int F \cdot ds$, called "the line integral of F dot ds ," which means that if the force F , for instance, is in one direction and the object on which the force is working is displaced in a certain direction, then only the component of force in the direction of the displacement counts as work. If the direction of the force were constant and the displacement were a straight line, then the work done in moving the object distance through that distance is only the component of force along ds in ds . That is, "Work times Distance" here, as really means only the component of force in the direction of the displacement times the displacement. As you, naturally, the component of displacement in the direction of force times F . It is evident that a work whatever is done by a force which is at right angles to the displacement.

Now if the vector displacement is resolved into components. In other words, if the actual displacement is ds and we write to consider it "vertically" as a component of displacement dy in the y -direction, dz in the z -direction, and dx

14.1 Work

14.2 Conservation motion

14.3 Conservative forces

14.4 Nonconservative forces

14.5 Potentials and fields

In an equilibrium, when the work done in carrying an object from one place to another can be calculated in three parts, i.e. calculating the work done along x , along y , and along z . The work done in going along x involves only the component of force, namely F_x , and so on, so the work is $F_x \Delta x - F_y \Delta y - F_z \Delta z$. When the force is not constant, and we have to consider curved motion, then we must follow the path in a series of little steps, and the work done in carrying the object along x , y , z would take us until as it goes to zero. This is the meaning of the "line integral."

Everything we have just said is contained in the formula $W = \int F \cdot ds$. It is all very well to say that it is a mathematical formula, but it is important to understand what it means, so what some of the consequences are.

The word "work" in physics has a meaning quite different from that of the word as it is used in ordinary circumstances that it may be close, yet still. But there are some peculiar circumstances in which it appears not to be the same. For example, according to the physical definition of work, it does not have a hundred pound weight off the ground for a while. Is it doing no work? None of us even one knows. Let us begin to see why this, and because harder, as if he were running up a flight of stairs. Yet running upstairs is considered as doing work for running downstairs, we do not see all the work according to physics. In simply holding an object in a fixed position, no work is done. I think the physical definition of work differs more in psychological definition, for reasons we shall shortly examine.

It is a fact that when one holds a weight he does no "physiological" work. Why should he sweat? Why would he need to concentrate hard to hold the weight up? Why is the machinery inside him operating at full force, giving his heart, his lungs up? Actually, he might as well be holding up with an effort by suspending it on a table, then the table, quietly and calmly, without the supply of energy, is able to hold it. This is the way of the static weight. The physiological situation is something like the following. There are two kinds of muscles in the human body and, in other animals, too, called smooth muscle and the type of muscle we have in our arms, for example, which is under voluntary control. The other kind, called smooth muscle, is like the muscle of the heart muscle, or the stomach, the greater omentum muscle that closes the fist. The smooth muscles are not very strong, but they can make their job. If we try to hold, for example, a six pound fish to hang, to catch it, it will hold a position under load for hours and hours without getting tired, because it is very much easier to not having to a weight of "pounds" into a certain position, and the skeleton just does this, keeping it with no work being done, more work being performed by the brain. The fact then we have to generate effort to hold up a weight is simply due to the design of smooth muscle. What happens is that when we use voluntary muscles then, the brain gives a little twitch and then relaxes, so that when we hold something the enormous volleys of nerve impulses are coming to the muscle. Large numbers of impulses are maintaining the weight while the brain relaxes. We can see this, of course, when we hold a heavy weight and get tired, we begin to shake. The reason is that the volleys are coming continually, and the muscle is tired and not reacting, restlessly... Why such a inefficient system? Which we know exactly why, but evolution has not been able to evolve just smooth muscle. Smooth muscle would be much more effective for holding up weights because you could just stand there and it would kick in, there would be no work, the less work energy would be required. However, it has the disadvantage that it is very slow-operating.

Returning now to physics, we may ask why we want to calculate the work done. The answer is that it is interesting and useful to do so, since the work done on a particle is the resultant of all the forces acting on it. It's easily related to the change in kinetic energy of that particle. That is, if an object is being pushed, it picks up speed, and

$$K.E. = \frac{1}{2} m v^2$$

14-1 Constrained motion

Another interesting feature of forces and work is this. Suppose that we have a string in a curved path, and a particle that must move along the track, for some reason. If we now have a particle, with a string and a weight, the string connects the weight to some fixed point about the pivot point. The pivot point may be changed by pulling the string "tilt a yard," so that the part of the weight is along two circles of different radii. These are examples of what we call *geometric constraint*.

In motion with a fixed track, constrained motion is done by the constraint because the forces of constraint are always at right angles to the motion. By the "Principle of Least Action," the same thing is true which is applied to the object directly by the one pulling itself—the tension force with the tends or the tension in the string.

The forces involved in the motion of a particle on a slope moving under the influence of gravity are quite complicated since there is a normal force, a gravitational force, and so on. However, if we take into account the law of conservation of energy and the law involving work alone, we get the right result. This seems rather strange because it is not strictly the right way to do it; we should use the resulting force. However, the work done by the gravity force, force \mathbf{F}_g , will turn out to be the change in the kinetic energy, because the work done by the conservative force of the forces is zero (Fig. 14-1).

The important feature here is that the forces can be analyzed as the sum of the various "pieces." Then the work done by the resultant force in going along a certain curve is the sum of the works done by the various "independent" forces, into which the forces are resolved. Thus if we analyze the forces as being the vector sum of several effects of gravitational, normal, frictional, etc., then, as in the assumption of a frictional and the "parametrization" of all forces in any other way than we wish to split them, then the work done by the net force is equal to the sum of the works done by all the parts in it, which we have divided the force in making the analysis.

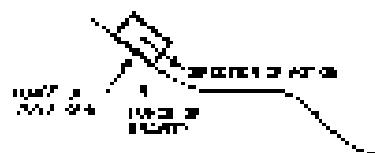

Fig. 14-1. Forces acting on a sliding body (no friction).

14-2 Conservative forces

To introduce these we start with a lot of gravity, for example, which have a very remarkable property which we call "conservative" (we will find this involved, it is again one of those crazy words!). If we calculate how much work is done by a force in moving an object from one point to another along some curved path, in general the work depends upon the curve, but in gravity's case it does not. If it does not depend upon the curve, we say that the force is a conservative force. In other words, if the integral of the force times the distance in going from position 1 to position 2 in Fig. 14-2 is evaluated along curve 4 and then along 5, we get the same number of joules, and this is true for the pair of points in every case, and if the same procedure is taken with pairs of points we have them say the force is conservative. In such circumstances, the work integral along from 1 to 2 can be evaluated in a simple manner, and we can give a formula for the result. Ordinarily it is not this easy, because we also have to specify the curve, and why we have a case where the work does not depend upon the curve, then, of course, the work depends only upon the positions of 1 and 2.

To demonstrate this, let's consider the following. We take a "fixed" point P , at an arbitrary location (Fig. 14-3). Then, the work U_{12} (along curve 1) from 1 to 2, which we want to calculate, can be evaluated as the work done in going from 1 to P plus the work done in going from P to 2, because the forces are conservative and the work does not depend upon the curve. Now, the work done in going from position P to a particular position of 2 is a function of that position of 2 itself. Of course it really depends on P also, but we have an arbitrary point P does not妨碍 our analysis. If that is done, then the work done in going from point P to point 2 is some function of the final position of 2. It depends upon where 2 is, if we go somewhere else, we get a different answer.

We shall call this function of position = $U(x_2, y_2, z_2)$, and when we want to refer to some particular point 2 whose coordinates are (x_2, y_2, z_2) , we shall write $U(2)$.

Fig. 14-2. Possible paths between two points in a field of force.

is an abbreviation for $\mathbf{U}(x_1, y_1, z_1)$. The work done in going from point 1 to point P can be written also by using the other form along the integral, referring to the $d\mathbf{r}_1$. That is, the same curve in going from 1 to P is known. The work done in going from the point P to 1:

$$\int_1^P \mathbf{F} \cdot d\mathbf{r} = \int_{\mathbf{r}_P}^{\mathbf{r}_1} (-\mathbf{F}) \cdot d\mathbf{r} = - \int_P^1 \mathbf{F} \cdot d\mathbf{r}$$

The total work done in going from P to 1 is $-\mathcal{U}(P)$, and from P to 1 the work is $\mathcal{U}(P)$. Therefore the integral from 1 to P is equal to $-\mathcal{U}(P)$ plus $(-\mathcal{U}(P))$ backwards, i.e. $-\mathcal{U}(P) + \mathcal{U}(P)$.

$$\begin{aligned} \mathcal{U}(P) &= - \int_P^1 \mathbf{F} \cdot d\mathbf{r} = \mathcal{U}(1) = - \int_1^P \mathbf{F} \cdot d\mathbf{r} \\ &= \int_1^P \mathbf{F} \cdot d\mathbf{r} = \mathcal{U}(1) - \mathcal{U}(P) \end{aligned} \quad (14.1)$$

The quantity $\mathcal{U}(P) - \mathcal{U}(1)$ is called the change in the potential energy, and we call \mathcal{U} the potential energy. We say, "when the object is located at position 2, it has potential energy $\mathcal{U}(2)$ and at position 1 it has potential energy $\mathcal{U}(1)$. If it is located at position P, it has zero potential energy." If we had used another potential, say \mathcal{U}' , instead of \mathcal{U} , we would get $\mathcal{U}'(P)$ and we shall leave it to you to convince yourself that the potential energy is changed only by the addition of a constant. Since the numerical value of energy depends only upon changes, it does not matter if we add a constant to the potential energy. Thus the point 1 is arbitrary.

Now, we have the following two propositions: (1) that the work done by a conservative plus the non-conservative force of the problem, i.e., (2) and non-conservative forces, is zero; (2) that the work done is minus the change in a function \mathcal{U} which we call the potential energy. As a consequence of these two, we arrive at the proposition that if any conservative force has no non-conservative part, its potential energy is conserved invariant.

$$\mathbf{F} + \mathbf{V} = \text{constant}. \quad (14.2)$$

Let us now discuss the formulae for non-potential energy for a number of cases. If we have a gravitational field, it follows, if we are not going to neglect non-conservative forces, the work done is minus the change in a function \mathcal{U} which we call the potential energy. As a consequence of these two, we arrive at the proposition that if any conservative force has no non-conservative part, its potential energy is conserved invariant.

$$\mathbf{F}_G = m\mathbf{g}, \quad (14.3)$$

and the point P which corresponds to zero potential energy happens to be any point in the plane $z = 0$. We could also choose $z = L$ for, the potential energy is zero $= 0$ if we had chosen to—all the results would, of course, be the same in our analysis except that the value of the potential energy at $z = 0$ would be $-mgL$. It may be an infinitesimal, because only difference in potential energy is small.

The energy needed to complete a linear spring a distance x from an equilibrium point is

$$\mathcal{U}(x) = \frac{1}{2}kx^2 \quad (14.4)$$

and the value of potential energy is at the position $x = 0$, the equilibrium position of the spring. A given weight will stay constant as we wish.

The potential energy of a capacitor at point x is, as we know, a capacitor (see Eq. 1.1)

$$\mathcal{U}(x) = Q^2/2C \quad (14.5)$$

The constant has been chosen here so that the potential is zero at infinity. Of course, this choice certainly applies to electric charges, because it is the same law.

$$Q_{\infty} = q_1 q_2 / 4\pi\epsilon_0 r_{\infty} \quad (14.6)$$

Now let us actually use all of these formulas, to see whether we understand what "means". Please! This has always been to show a rocket away from the

can't go out far if it leaves? Because if the kinetic plus potential energy must be constant; when it "leaves," it will be no longer of finite energy, and since it is just barely going, it can't be radius of the curve, size of its mass. The kinetic plus potential energy is then initially given by $\frac{1}{2}mv^2 + GMm/r$. On the end of the motion the two energies must be equal. The kinetic energy is taken to be zero at the end of the motion, because it is supposed to be just barely falling away at essentially zero speed, and so potential energy is exactly divided by infinity, which is zero. So everything is now in our control that $v^2 = rGM$; the square of the velocity must be $2GM/r$. Our GGM is what we call the acceleration of gravity g . Thus

$$v^2 = 2gr$$

At what speed must a satellite travel, in order to keep going around the earth? We worked this out long ago and found that $v^2 = GM/r$. Therefore, if you want to leave the earth, you must $\sqrt{2GM/r}$ be velocity you need to just go around the earth near the surface. We know, in other words, *not to touch things*, because initial speed is the square of the velocity to leave the earth or the distance around it. Therefore, the first thing that we have to do is to find v in m/s we have to go and to go around the earth, which requires a speed of five miles per second. This next time, we have to send a satellite away from the earth perpendicularly. It's required twice the energy, or about seven miles per second.

Now, continuing our discussion of the characteristics of potential energy, let us consider the interaction of two molecules, or two atoms, like oxygen atoms for instance. When they are very far apart, the force is one of attraction, which scales up like inverse seventh power of the distance, and when they are close together there is a very large repulsion. If we integrate the inverse seventh power to find the work done, we find that the potential energy V , which is a function of the center distance between the two oxygen atoms, varies as the inverse sixth power of the distance r in general.

If we sketch the curve of the potential energy $V(r)$ as in Fig. 14-2, we thus start at the point $r = \infty$ with an infinite negative potential, but if we come in sufficiently far, we reach a point where there is a minimum in potential energy. The minimum in potential energy is $-V_0$. If r comes closer to r_0 we start at V_0 and move a small distance, a very small distance, the next time, which is the change in potential energy when we move this distance, is nearly zero, because there is very little change in potential energy at the bottom of the curve. Thus the r_0 is the equilibrium point, and V_0 is the equilibrium potential. Another way to see this is the equilibrium point is that it takes work to move away from it in either direction. When the two oxygen atoms are seated down, so that no more energy can be extracted from the force between them, they are in the lowest energy state, and they will be. The expansion of this gas is why an oxygen cylinder looks when it is cold. When we heat it up, the atoms shake and move farther apart, and we can extract less and less work, but it still requires a certain amount of work to move, which is the potential energy difference between $r = r_0$ and $r = \infty$. When we try to push two masses very close together the energy goes up very rapidly, because the potential V of r .

The reason we bring this up is to make the idea of potential energy particularly suitable for mechanics, where the idea of energy is most natural. We find that although forces and velocities "divided" and "supplied" when we consider the many independent forces between particles, they do not represent any of the energy except potentials. Therefore we have curves of potential energy of one form, velocities another, but we can't do the same sort of curve for the forces between two masses, even if we try. Very people who are doing mechanics are thinking in terms of energy rather than of forces.

Next we note that if you're moving along a curve in an object of finite mass, then the maximum energy of the object is the sum of the potential energies from each of the separate forces. This is the same proposition that we mentioned before: because if the forces are proportional and additive in form, then the total force is the sum of the forces due to the partial

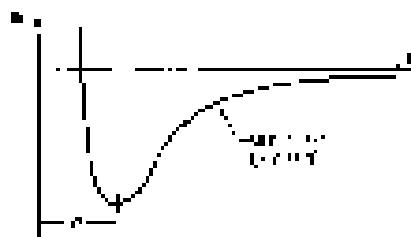

Fig. 14-2. The potential energy between two atoms as a function of the distance between them.

It does, and it can't be defined in any other terms. Changes in the potential energy is a *vector* of force *separately*. This total potential energy is the sum of all the little pieces.

We could generalize this to the case of a system of many objects, like a galaxy with many stars, like Jupiter, Saturn, Uranus, etc., oxygen, nitrogen, carbon, etc., which are acting with respect to one another in proportion to forces all of which are conservative. In these circumstances, the kinetic energy in the entire system is simply the sum of the kinetic energies of each of the particular atoms or planets or whatever, and the potential energy of the system is the sum, over the pairs of particles, of the potential energy of each pair. It's a single pair, so "length the vector" were not there. (This is not really true for Coulomb's forces, and the formula is somewhat more complicated; it certainly is not for Newtonian gravitation, and it is less accurate sometimes by molecular forces. For instance, since there's a repulsive energy, you'd have to make a more complex expression of the positions of the atoms than simply a sum of forces from particle 1, the special case of gravity, though...) The potential energy is the sum, overall, the same kind of - ∞ -infinity, as was indicated in Eq. (11.10). Equation (11.10) expressed mathematically the obvious consequence, that the total kinetic energy plus the total potential energy does not change with time. As the various planets travel around, and turn and twist and so on, as we calculate the total kinetic energy and the total potential energy we find that the total remains constant.

14-4 Nonconservative forces.

We have spent a considerable time discussing conservative forces, what about nonconservative forces? We said "like a dog: this is his domain, and outside the domain no nonconservative forces." As a matter of fact, the fundamental forces in nature appear to be conservative. It is *not* a consequence of Newton's laws. In fact, in Isaac Newton I may know, the forces would be more conservative, as Einstein apparently is. When we say "inertial reference frame," we are taking a modern view, in which it has been observed that all the deep forces, the forces between the galaxies, the major fundamental ones, are conservative.

In fact example, we analyze a system like the planet, galaxy or star cluster that we saw a picture of with the dependence of other all interacting, then if we do the for the total potential energy is simply the sum plus another term, etc., a minus sign, all pair of stars, and the result will be if the sum of the kinetic energies of all the individual stars. But the galaxies cluster as a whole is itself in space here, and the total forces of gravity from it and the other galaxies could be the sum of each single object. Then if forces were applied to it, some of those forces might add up causing it to move as a whole, and we would say "The center of the whole thing moves." On the other hand, some of the forces can be, so to speak, "wasted" in increasing the kinetic or potential energy of the "particle" alone. I.e., we suppose, for instance, the the action of these forces causes the whole cluster and makes the particles move faster. The total energy of the whole thing is still conserved, but not from the particle with a center of mass which is just the combination of previous kinetic, and just thinking of the kinetic energy of the motion, of the whole object as though it were a single particle, a weak assumption, this energy is not conserved, but this is due to a lack of appreciation of what it is that we see. And that is more or less the total energy of the system, kinetic plus potential, is a constant when we look closely enough.

When we study matter in the finest detail at the atomic level, it is not always easy to the total energy of a thing for two parts, kinetic energy and potential energy, and such separation is not always necessary. It is always always possible to do it, and it is very frequently necessary, possible and for the genuine electrostatic energy of the world is constant. Thus the total potential plus-kinetic energy, like the kinetic plus U constant, and if the "whole" is a system of isolated particles, the energy is constant if there are no external forces. But as we have seen, some of the kinetic and potential energy of a thing may be lost, for instance like internal molecular motions in the solid. So we do not make it. We know that in a glass of water everything is jiggling around, all the atoms are moving

of the atoms there is a certain kind of energy inside which we usually may not pay any attention to. We do not notice the motion of the atoms, which produces heat, and so we do not call it kinetic energy, but heat is certainly kind of one type. Internal potential energy may also be in the form of the form of electric energy; when we move positive charge is liberated because the potential energies of the atoms at the new position or arrangement are lower than in the old one. In fact, it is not entirely possible to beat "heat" being some kind of energy, for a time the potential goes on and goes over to chemical energy, so we sum the two together and say that the total kinetic and potential energy inside an object is partly heat, partly chemical energy, and so on. Anyway, all these different forms of internal energy are sometimes considered to "heat" energy in the way described above, so it will be make clear when we study thermodynamics.

As another example, when friction is present, it is not true that kinetic energy is lost, even though a sliding object stops and the kinetic energy seems to be lost. The kinetic energy is not lost because, of course, the atoms inside are juggling with a larger amount of kinetic energy than before, and although we cannot see that, we can measure it by determining the temperature. Of course if we disregard the heat energy, then the conversion of energy between will appear to be loss.

Another situation, in which energy conservation appears to be false is when we study only part of a wave. Below, the conservation of energy theorem will appear to be false, something is interacting with everything else in the outside and we neglect to take that interaction into account.

In classical mechanics potential energy involved only gravitation and electricity, but now we have nuclear energy and other energies also. Right, for example, weak forces are a new type of energy in the classical theory, but we can do, if we want, imagine that the energy of π^+ is the kinetic energy of a pion, and then our formula (14-1) would go like right:

14-5 Potentials and Fields

We shall now discuss a bit of the theory associated with potential energy and with the idea of a field. Suppose we have two large objects A and B and a third very small one which is attracted gravitationally by the two, with some resultant force \mathbf{F} . We have already noted in Chapter 13 that the gravitation of objects A and B can be written as the sum of three numbers G , each of which is dependent only upon the position of the particle:

$$\mathbf{F} = \mathbf{qC}$$

We can calculate gravitation, that is, by calculating that there is a certain vector \mathbf{C} at every position in space which "feels" up to a mass which we may place there, but which is free itself where you want to supply a mass for it to "feel" on it. \mathbf{C} has three components, and each of these components is a function of (x, y, z) , a location of position in space. Such a thing we call a field, and we say that the objects A and B generate the field, i.e., they "cause" the vector \mathbf{C} . When an object is placed below the horizon it is due to its mass times the value of the field vector at the point where the object is given.

We can also do the same with the potential energy, since the potential energy, defined as V of (14-1), can be written as $V = q\mathbf{q}\cdot\mathbf{C}$ (that is, the potential of the field). With a mass charge q at (x, y, z) the potential energy $V(q, p)$ of an object located at a point (x_1, y_1, z_1) in space can be written as a third function Φ which we may call the potential Φ . The integral $\int \mathbf{q}\cdot d\mathbf{s} = -q\int q\cdot d\mathbf{s} = -V$. There is only a plus factor between the two:

$$V = -\int q\cdot d\mathbf{s} = -q\int (x, y, z)\cdot d\mathbf{s} \quad (14-2)$$

By having the function $\Phi(x, y, z)$ at every point in space, we can immediately calculate the potential energy of a system at any point in space, namely, $V(x_1, y_1, z_1)$ and (x_2, y_2, z_2) —either a real business concern. But it is not really trivial, because it is somewhat difficult to describe the field by giving the field in

of Φ everywhere in space instead of having to give Φ a name and having to write three complicated equations of a vector function, we can also list all these for Φ in one. Furthermore, it is much easier to calculate Φ at any given component of \mathbf{E} when the field is produced by a number of charges, because the potential Φ is a scalar and is always odd, without worrying about direction. Also, the total Φ can be integrated easily from Φ , as we shall shortly see. Suppose we have point charges q_1, q_2, \dots, q_n at points $\mathbf{r}_1, \mathbf{r}_2, \dots$ and we wish to know the potential Φ at some arbitrary point \mathbf{r} . This is simply the sum of the potentials due to the individual charges taken singly and

$$\Phi(\mathbf{r}) = \sum -\frac{q_i}{r_i}, \quad i = 1, 2, \dots \quad (14.8)$$

In the last chapter we used this formula. But the potential is the sum of the potentials from all the different objects, to calculate the potential due to a spherical shell of charge by adding the contributions to the potential at a point from all parts of the shell. An example of this calculation is shown graphically in Fig. 14.4. It is negative, along the radius r to $r = \infty$ and decreasing as r increases. The radius a and then is constant inside the shell. Consider first that the potential is $-q/a$, where a is the radius of the shell, which is exactly the same as it would have been if all the q 's were located at the center. But it is not appropriate now by the same for inside the shell. Its potential is known to be $-q/a$, and is a constant. Then the potential is constant, there is no force, or rather the potential energy is constant; there is no force, because if we move an object from one place to another anywhere inside the sphere the work done by the force is exactly zero. Why? Because the work done in moving the object from one place to the other is equal to minus the change in the potential energy, so the work required to change the energy of the potential is zero. But the potential energy of the shell at any two points inside, so there is zero change in potential energy, and therefore the work is zero in going between any two points inside the shell. The only way the work can be zero for all directions of displacement is that there is no force at all.

This gives us a clue as to how we can obtain the force at the field given the potential of charge. We are supposed that the potential energy of an object is known at the position (x, y, z) and we want to know what the force on the object is. It will not do to know the potential at only this one point, as we shall see; it requires knowledge of the potential at neighboring points as well. Why? They can be calculated by summation of the forces. If we can do this, of course, we can also find the x and y components, and we will then know the whole force. Now, if we want to move the object a small distance Δr in the x direction, the force on the object would be the change ΔU in the force times Δr . If Δr is sufficiently small, this should equal the change in potential energy in going from one point to the other:

$$\Delta U = -\Delta V = F_x \Delta x. \quad (14.9)$$

We have nearly used the formula $\Delta U = -\Delta V$, but for a very short while how we divide by Δx and Δr and that the force is

$$F_x = -\partial V / \partial x. \quad (14.10)$$

Of course this is not exact. What we really want is the limit of (14.10) as the distances Δx and Δr get smaller, because it is only *approximately* right in the limit of infinitesimals Δx . This we recognize as the derivative of V with respect to x , and we will be defining the force in some "mathematical" way. F depends on x, y, z , and θ , and the mathematicians have invented a different symbol to remind us to be very careful when we use the unitless θ as a function, so as to distinguish that we are considering the field \mathbf{E} around some point x, y, z every "angle" of θ is being simply made a "backwards 0," or $\bar{\theta}$. ($\bar{\theta}$ should have been used to the beginning of calculus because we always want to cancel that off but we never seem to notice it with θ .) They write $\partial V / \partial x$ for "force," in "mathematical" terms, if they want to be very careful, they put a bar under θ and a tilde over V in the notation $\partial \tilde{V} / \partial \bar{\theta}$, etc., etc.

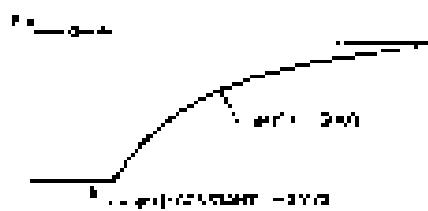

Fig. 14.4. Potential due to a spherical shell of radius a .

which we've "Take the derivative of U with respect to x , keeping y and z constant." Most often we leave out the remark about what is kept constant because it is usually evident from the context, so we usually do not use the $\partial/\partial x$ with the word x , instead always use $\partial/\partial x$ instead of d/dx because the latter is a derivative with some other variables kept constant. This is called a *partial derivative*; it is a derivative in which we vary only x .

Therefore, we find that the force in the x -direction is minus the partial derivative of U with respect to x :

$$F_x = -\partial U / \partial x \quad (14.12)$$

In a similar way, the force in the y -direction can be found by differentiating U with respect to y , keeping x and z constant, and the third component, of course, is the derivative with respect to z , keeping x and y constant:

$$F_y = -\partial U / \partial y, \quad F_z = -\partial U / \partial z. \quad (14.13)$$

This is the way to get from the potential energy to the force. We get the first from the potential in exactly the same way:

$$C_x = -\partial U / \partial x, \quad C_y = -\partial U / \partial y, \quad C_z = -\partial U / \partial z. \quad (14.14)$$

Incidentally, we don't mention this second notation, which we shall not actually use for quite a while; since C is a vector and has x , y , and z components, the symbolized $\partial U / \partial x$, $\partial U / \partial y$, and $\partial U / \partial z$ which produce the x , y , and z components are something like vectors. The xy -term, however, has an unusual significance, too, called "grad" or "gradient" which is a scalar quantity but an operator which makes a vector function scalar. It has the following "components": The x -component of this "grad" is $\partial/\partial x$, the y -component is $\partial/\partial y$, and the z -component is $\partial/\partial z$, and then we have the fact of writing our formulas this way:

$$\mathbf{F} = \mathbf{C} U, \quad \mathbf{C} = \text{grad } U. \quad (14.15)$$

Using Eq. 14.15 gives us a quick way of testing whether we have a true vector equation or not, but only Eq. 14.15 means precisely the same as Eqs. 14.12 and 14.13; it is just another way of writing them, and since we do not want to write three equations every time, we just write Eq. 15 instead.

One more example of fields and potentials has to do with the electrical case. In the case of electricity the force on a stationary object is the charge times the electric field: $\mathbf{F} = q\mathbf{E}$. (In general, of course, the x -component of force in an electrical problem is also a part which depends on the magnetic field.) It is easy to show from Eq. 13.10 that the force on a particle due to magnetic fields is always at right angles to its velocity, and also at right angles to the field. Since the force due to magnetism on a moving charge is at right angles to the velocity, no work is done by the magnetism on the moving charge because the motion is at right angles to the force. Therefore, in calculating the loss of kinetic energy in electric and magnetic fields we can disregard the contribution from the magnetic field, since it does not do any kinetic energy. We suppose that there is only an electric field. Then we can calculate the energy, or work done, in the same way as for gravity, and calculate a quantity ϕ which is minus the integral of $\mathbf{F} \cdot d\mathbf{s}$, first in the initial specified point in the path, where we make the calculation, and then the potential energy in an electric field is just charge times this quantity ϕ .

$$\phi(r) = \int_{r_0}^r \mathbf{E} \cdot d\mathbf{s}$$

Let us take, as an example, the case of two parallel metal plates, each with a surface charge of σ per unit area. This is called a parallel-plate capacitor. We learned previously that there is zero force outside the plates and that there is a uniform electric field between them, E , equal from 1 to 2 and of magnitude σ/ϵ_0 (Fig. 14-1). We would like to know how much work would be done in

carrying a charge from one plate to the other. The work would be the (force) · (the integral, which can be written as charge times the potential) value of units 1 coulombs times 1 volt = 1 joule.

$$W = \int_1^2 F \cdot ds = q(\phi_1 - \phi_2)$$

We can actually work out this integral because the force is constant, and if we call the separation of the plates d , then the integral is easy:

$$\int_1^2 F \cdot ds = W \int_{\phi_1}^{\phi_2} dx = Wd.$$

The difference in potential, $\phi_2 - \phi_1/d$, is called the voltage difference, and V is measured in volts. When we say a pair of plates is charged to a certain voltage, what we mean is that the difference in electrical potential of the two plates is equal to many volts. (For a capacitor made of two parallel plates carrying a surface charge (i.e., the voltage, or difference in potential, of the pair of plates is $V = Q/C_0$).

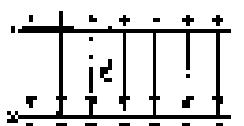

Fig. 14-5. Field between parallel plates.

The Special Theory of Relativity

15-1 The principle of relativity

For over 300 years no experiments of motion originated by Newton were performed in space; he could conceive, and the first time that either or in these laws was disagreed, one way to correct it was to disprove. Both the error and its correction were discovered by Galileo in 1602.

Newton's Second Law, which we have expressed by the equation

$$F = m a = m \frac{dv}{dt},$$

was tested with the first assumption that it is consistent, but we now know that this is not true, and can measure how it truly increases with velocity. In this it increased to much more than the value

$$m = \frac{m_0}{\sqrt{1 - v^2/c^2}} \quad (15.1)$$

where the "rest mass" m_0 represents the mass of a body that is not moving and c is the speed of light, which is about 3×10^8 cm/sec 2 or about 186,000 miles/sec.¹

For those who want to learn just one problem that does not cause problems, that is all there is to the theory of relativity—it just changes Newton's law by introducing a correction factor to the mass. From the formula, we find it easy to see that this mass increases very small in ordinary circumstances. If the velocity is even as great as that of a satellite, which goes around the earth at 5 mi/sec, then $m/m_0 = 5/(5c/300,000)$, putting this value into the formula shows that the correction to the mass is only one part in ten billion billion, which is easily impossible to observe. Actually, the correctness of the formula has been simply confirmed by the observation of many kinds of particles, moving at speeds close to exactly the speed of light. However, because the effect is really so small, it took a hundred years for it to be discovered theoretically before it was discovered experimentally. Empirically, at a sufficiently high velocity, the effect is very large, but it was not discovered that way. Therefore it is interesting to see how the Einsteins involved to develop a modification (at the time when it was first discovered) was brought up by a combination of experiments and physical reasoning. Contributions to the discovery were made by a number of people, the final result of whose work was Einstein's discovery.

The second major Einstein theory of relativity, this chapter is connected with the Special Theory of Relativity, which dates from 1905. In 1915 Einstein published an additional theory, called the General Theory of Relativity. This latter theory deals with the extension of the Special Theory to the case of the law of gravitation; we shall not discuss the General Theory here.

The principle of relativity was first stated by Newton in one of his axiomatics to the laws of motion: "The motions of bodies included in a given space are the same among themselves, whether that space is at rest or moves uniformly forward in a straight line." This means, for example, that if a space ship is moving along at a uniform speed, all experiments performed in the cockpit and within ρ distance in the space ship will appear the same as if the ship were not moving, provided, of course, that one does not look outside. That is the meaning of the stated principle of relativity. This is a simple enough idea, and the only question is whether it is true for all experiments performed inside a moving system the laws of physics

will appear the same to Jay as if the system were standing still. Let us first investigate whether Newton's laws appear the same in the moving system.

Suppose that Moe is moving in the x direction with a uniform velocity v , and he measures the position of Jones's x -axis at point, shown in Fig. 15-1. This defines the " x -distance" of the point in his coordinate system as x' . Jones is at rest, and measures the position of the same point, designating its x -distance in "his system" as x . The relationship of the coordinates in the two systems is clear from the diagram. After $v t$ Moe's origin has moved a distance $v t$, and if the two systems originally coincide,

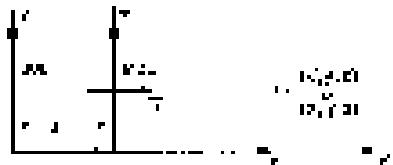

Fig. 15-1. Two coordinate systems in uniform relative motion along their x -axes.

If we substitute the coordinate law of conversion into Newton's laws we find that these laws transform to the static laws in the primed system, that is, the laws of Newton are of course true in a moving system as in a stationary system, and therefore it is impossible to tell, by carrying out such experiments, whether the system is moving or not.

The principle of relativity has been used in mechanics for a long time. It was employed by various people, in particular Huygen, to obtain the rule for the collision of billiard balls in which the same rule as we use it in Chapter 10 to discuss the conservation of momentum. In the past century, indeed, it was heightened as the result of investigations into the phenomena of electricity, magnetism, and light. A long series of such studies of these phenomena by many great scientists as in Maxwell's equations of the electromagnetic field, which describe electricity, magnetism, and light as one unified system. However, the Maxwell equations did not seem to obey the principle of relativity. That is, if we transform Maxwell's equations by the substitution of equations (15-1), both forces that we remain the same; therefore, in a moving space ship the electrical and optical phenomena should be different from those in a stationary ship. Thus one could use these optical phenomena to determine the speed of the ship; in particular, one could determine the absolute speed of the ship by looking outside. It applies to electrical means, however. One of the consequences of Maxwell's equations is that if there is a disturbance in the field such that light is generated, then electromagnetic waves go out in all directions equally and at the same speed c , or 186,000 miles/sec. Another consequence of the equations is that if the source of the disturbance is moving the light emitted goes through space at the same speed c . This is analogous to the case of sound. The speed of sound waves being obviously independent of the motion of the source.

Can the speed of the source of the waves, in the case of light, affect upon its traveling speed?

Suppose we are riding in a car that is going at a speed v , and light from the sun is going past the car with speed c . On the initial path the first equation of (15-1) gives

$$\frac{dx'}{dt} = \frac{dx}{dt} - v,$$

which means that according to the Galilean transformation the apparent speed of the passing light, as we measure it in the car, should not be c but $c - v$. For instance, if the car is going 100,000 miles/sec, and the light is going 186,000 miles/sec, then apparently the light going past the car should go 86,000 miles/sec. In any case, by measuring the speed of the light going past the car in the Galilean transformation, we can test if "light" can travel faster than c . A number of experiments were made in this group; they were performed to determine the velocity of the earth, but they all failed; they gave no velocity at all! We shall discuss one of these experiments in detail, to show exactly what was done and why was the law concerning light the matter, whereas something was wrong with the equations of physics. What could it be?

15-2 The Lorentz transformation

When the failure of the equations of physics in Newton's case came to light, the first thought that occurred was that the motion must be to the new Maxwell equations of electrodynamics, which were by 20 years older than him. I accepted almost without doubt that equations must be wrong or the thing to do was to change them in such a way that under the Galilean transformation the principle of relativity would be satisfied. When this was done, the new terms had to be put into the equations so the predictions of new electrodynamic laws did not exist at all when tested experimentally, so this attempt had to be abandoned. That is, probably because it appeared that Maxwell's laws of electrodynamics were correct, and the trouble must be sought elsewhere.

In the meantime H.A. Lorentz added a modification to his theory when he made the following substitution in the Maxwell's equations:

$$\begin{aligned} x' &= \frac{x - ct}{\sqrt{1 - v^2/c^2}} \\ y' &= y \\ z' &= z \\ t' &= \frac{t - vx/c^2}{\sqrt{1 - v^2/c^2}} \end{aligned} \quad (15.2)$$

namely, Maxwell's equations remain in the same form when this transformation is applied to them! Equations (15.2) are Lorentz's *contracting hypothesis*. Einstein, following a suggestion originally made by Poincaré, then proposed that all the physical laws should be of such a kind that they remain unchanged under a Lorentz transformation. In other words, we should change, not the laws of electrodynamics, but the laws of mechanics. Now that we change Newton's laws, then they will remain unchanged by the Lorentz transformation.⁴ If this goal is set, we can have to rewrite Newton's equations in such a way that the contraction becomes implemented. As it turned out, the only requirement is that the mass m in Newton's equations must be replaced by the form shown in Eq. (15.3). When this change is made, Newton's laws are the laws of electrodynamics now. Furthermore, if we use the Lorentz transformation, ... comparing Moe's measurements with ours, we should never be able to detect whether there is motion, because the form of the experiments will be the same in both coordinate systems!

It is interesting to observe what it means then we neglect the transformation between the coordinates and then with a new one, because the old one (Galilean) seems to be self-evident, and the new one (Lorentz) looks peculiar. We wish to know whether it is logically and experimentally possible that the new and not only the transformation is correct. A fact that alone is not enough to justify the laws of mechanics but, as Lorentz says, we also must compare the laws of gravity and force in order to make this confirmation. We shall focus on this in these laws and their implications for mechanics at some length, so we say in advance that the effort will be justified, since the results agree with experiment.

15-3 The Michelson-Morley experiment

As mentioned above, attempts were made to determine the speed of velocity of the earth through the hypothetical "ether" that was supposed to pervade all space. The most famous of these experiments is the performed by Michelson and Morley in 1887. It was 14 years later before the negative result of the experiment was finally explained by Lorentz.

The Michelson-Morley experiment was performed with an apparatus like that shown schematically in Fig. 15.2. This apparatus is essentially composed of a light source A , a partially silvered glass plate B , and two mirrors C and D , all mounted on a rigid base. The mirrors are placed at equal distances L from B . The plates E and F are used for mounting the A light and the beam splitter beam com-

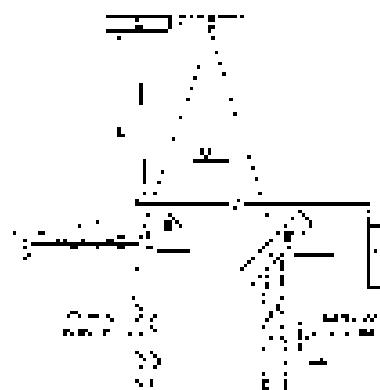

Fig. 15.2. Schematic diagram of the Michelson-Morley experiment.

travels in mutually perpendicular directions in the mirrors, where they are reflected back to B . On arriving back at B , the two beams are recombined as two separate parallel beams, B and C . If the time taken for the light to go from B to C and back is the same as the time from A to B and back, the emerging beams B and C will be in phase and will reinforce each other, but if the two times differ slightly, the beams will be slightly out of phase and interference will result. If the apparatus is "at rest" in the sense, the times should be precisely equal, but if it is moving toward the right with a velocity v , there should be a difference in the times. Let us calculate.

First, let us calculate the time required for the light to go from B to C and back. Let us say that the time for light to go from point B to point C is t_1 , and the time for the return trip is t_2 . Now, while the light is on its way from B to C , moreover, the apparatus moves a distance L , so the light must travel a distance $L + v t_1$ at the speed c . We can also express this distance as $c t_1$, so we have

$$ct_1 = L + vt_1 \quad \text{or} \quad t_1 = L/c - v/c$$

(This result is also obtained from the point of view that the velocity of light relative to the apparatus is $c - v$, so that one is the length L divided by $c - v$.) In a like manner, the time t_2 can be calculated. During this time the plane B travels a distance $v t_2$, so the total distance of the light is $L - v t_2$. Then we have

$$ct_2 = L - vt_2 \quad \text{or} \quad t_2 = L/c + v/c$$

Then the total time is

$$t_1 + t_2 = 2L/c + 2v/c = 2L/c(1 + v/c)$$

For convenience in later comparison of times we write this as

$$t_1 + t_2 = \frac{2L/c}{1 - v^2/c^2}. \quad (15.4)$$

Our second calculation will be of the time t_3 for the light to go from B to the mirror C' . As before, during time t_3 the mirror C' moves as the light accelerates to the position C' ; in the same time the light travels a distance $c t_3$ along the hypotenuse of a triangle, which is BC' . For this right triangle we have

$$(c t_3)^2 = L^2 + (v t_3)^2$$

or

$$L^2 = c^2 t_3^2 - v^2 t_3^2 = (c^2 - v^2) t_3^2,$$

from which we get

$$t_3 = L/\sqrt{c^2 - v^2},$$

For the return trip from C' the situation is the same, so we have. From the symmetry of the figure, therefore the return time is also the same, and the total time is $2t_3$. With a little rearrangement of the form we can write

$$2t_3 = \frac{2L}{\sqrt{c^2 - v^2}} = \frac{2L/c}{\sqrt{1 - v^2/c^2}}. \quad (15.5)$$

We are now able to compare the times taken by the two beams of light. In expressions (15.4) and (15.5) the same terms are identical, and represent the time that would be taken if the apparatus were at rest. In each denominator, the term v^2/c^2 will be small, unless this is comparable in size to v . The denominators represent the modifications in the times caused by the motion of the apparatus. And finally, since modification terms are not very great, the time to go to C' is less than the time to go back to C and back, even though the mirrors are equidistant from B , and C , we have v/c to increase. Total difference $\approx v/c$ percent.

There is another mechanical point arises—suppose the two lengths L are not exactly equal? In that we would expect some time effect. In that case we simply turn the apparatus 90 degrees, so that between the lines of motion and BC is perpendicular to the motion. Any small difference in lengths then becomes

diminution, and with we look for a shift in the interference fringes when we rotate the apparatus.

In carrying out the experiment, Michelson and Morley oriented the apparatus so that the line BC was nearly parallel to the Earth's motion, i.e., orbit, at certain times of the day and night. This is little speed is about 18 miles per second, and any "transversal" speed would have had that much in components of the day or night and no南北 speed during the year. The apparatus was finely sensitive to observe such an effect, but no time of the day was found. The velocity of the earth through the ether could not be detected. The result of the experiment was null.

The result of the Michelson-Morley experiment was very puzzling and somewhat disconcerting. This is first for failing a very basic of the important relativity from Lorentz. He suggested that material bodies contract when they are moving, and that this length-shrinking is only in the direction of the motion, and also that if the length is L_0 when a body is at rest, then when it moves with speed v parallel to its length, the new length, which we call L , is given by

$$L = L_0 \sqrt{1 - v^2/c^2} \quad (15.6)$$

When this modification is applied to the Michelson-Morley interferometer setup, the distance from B to C does not change, but the distance from B to E is shortened to $L_0 \sqrt{1 - v^2/c^2}$. Therefore $L_0 / (L_0 \sqrt{1 - v^2/c^2})$ is not changed, and the λ in Eq. (15.4) must be changed in accordance with Eq. (15.6). When this is done we obtain

$$\Delta t = \frac{(2L_0 \sqrt{1 - v^2/c^2})}{c} = \frac{2L_0}{c \sqrt{1 - v^2/c^2}} \quad (15.7)$$

Comparing Eq. (15.7) with Eq. (15.5), we see that $\Delta t = \tau_{\text{obs}} - \tau_{\text{exp}}$. If the apparatus rotates at the manner just described, we have a way of understanding why the Michelson-Morley experiment gives no result at all. Although the contraction hypothesis successfully accounted for the negative result of the experiment, it was open to the objective that it was invented for the express purpose of explaining away the difficulty, and was not utilized. However, it must other experiments to a similar set either with, or the different, however, it appears that nature was at the "conspiracy" to cover man by introducing some new phenomenon to make the experiment fail, he thought, would give it a measurement of c .

However, it is distinguished, as Poincaré pointed out, that, *provided conspiracy is still a law of nature*, Poincaré then proposed that there is still a law of nature, that it is not possible to determine in either way by any experiment, that is, there is no way to determine an absolute velocity.

15-4 Transformation of time

Is accepting our wavelet contraction idea as an analogy with the facts in other experiments is it reasonable. But everything is except provided that the wavelets are also modified in the manner proposed in the fourth, or the fifth section. So it turns out because the time t_0 , calculated for the trip from A to C and back, is not the same when calculated by a man performing the experiment in a moving spaceship as when calculated by a stationary observer who is watching the spaceship. To the man in the ship, the time is simply $2L_0/c$, but to the other observer it is $2L_0/c(1 - v^2/c^2)$ (Eq. 15.5). In other words, when the man looks the man in the spaceship lighting a cigarette, the screens appear to be slower (than normal), while to the other man, everything moves at a normal rate. So between them, the lighter the atom, but also the interatomic forces (which is called γ) must apparently slow down. That is, when the clock in the spaceship moves it slows down, as seen by the man in the ship; it takes $1/\gamma$ more "normal" seconds to the man in the ship.

This slowing of the clock in a moving system is a very peculiar phenomenon, and is worth an explanation. To begin to understand this, we have to watch the mechanics of the clock and see why it appears when it is moving. Since the β

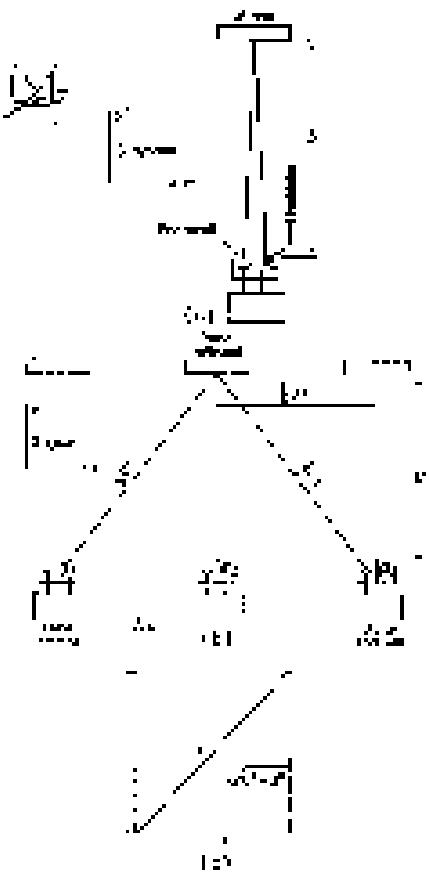

Fig. 15-2. (a) A "light clock" of two mirrors in the S system. (b) The same clock moving through the S' system. (c) Illustration of the diagonal path taken by the light beam in a moving "Twin" clock.

rather difficult, we shall take a very simple kind of clock. The one we choose is not a really kind of clock, but it will work if principles it is based upon are valid when a mirror is present, and, when we send a light signal between the mirrors, the light beam goes up and down, making a click every time it comes down, like a clock and ticking clock. We "bank" our twin clocks with exactly the same length, and synchronize them thereby starting them together, then they agree to agree thereafter, because they are the same in length, and light always travels with speed c . We give one of them, the S clock, no motion to take along in its space ship, and let it make the run perpendicular to the direction of motion of the ship; then the lengths of the rods will not change. How do we know that perpendicular lengths do not change? Two men can agree to make marks on each other's arms or necks. They pass each other. By symmetry, the two marks must come up the same way and change distance, since otherwise when they get together, to compare each other's neck with his own or below his other arm, he would really move it.

Now let us see what happens to the moving clock. Before the man does it, should he agree that it was a true constant clock, and when he goes along in the space ship, he will not see anything peculiar. If he did, he would know he was moving, if anything at all changed, because of the motion, he could tell he was moving. But the principle of relativity says this is impossible in a uniformly moving system, so nothing has changed. On the other hand, when the external observer looks at the clock with him, he sees that the light is going from center to mirror, & "nearly" taking a zig-zag path, since the rod is running sideways all the while. We have already analyzed such a zig-zag motion in connection with the Michelson-Morley experiment. I'm given to think the rod moves forward a distance proportional to $v t$, in Fig. 15-1, the distance the light travels in the same time is proportional to c , and the vector distance is therefore proportional to $\sqrt{c^2 - v^2} = c$.

That is, it takes a longer time for light to go round and back in the moving clock than in the stationary clock. Therefore the apparent time between clicks is longer for the moving clock, in this case, proportional to shown at the hypotenuse of the triangle (that is, the sum of the equivalent expressions in our equation). From the figure it is also apparent that the greater v is, the more slowly the moving clock appears to run. Not only does this particular kind of clock run more slowly, but if our theory of relativity is correct, any clock does, occurring on any principle whatsoever, would also appear to run slower, and in the same proportion—no matter who makes it. Why? This is why?

To answer the above question, suppose we had two identical clocks made only alike with tubes and gears, or perhaps based on radioactive decay, or something else. Then we adjust these clocks so they both run in precise synchronism with our fire-starts. When light goes up and back in the fire-starts and synchronizes them with a clock, the new model can complete some sort of cycle, which then simultaneously synchronizes by some similarly independent flash, a long, narrow signal. One of these clocks is taken into the space ship, along with the first kind. Perhaps this clock will not run slow, but will continue to keep the same time as its stationary twin part, and thus disagree with the other moving clock. At least, if that should happen, the man in the ship could use this mismatch between his two clocks to determine the speed of his ship, which we have been supposing is impossible. We now can draw a fitting picture of how every bit of the new clock that might cause the effect we simply knew and whatever the reason, it will appear to run slow, just like the first one.

Now if all moving clocks run slow, if for any reason changing time gives anything but a slower rate, we still just have to sit in a constant state. One thing may appear to be faster in a space ship. All the phenomena there— he needs time to eat, his thought processes, the time to raise to light a cigar, how long it takes to open his mouth, all these things must be slowed down in a space ship even, however, because all he is moving. The big experts and learned men sometimes say it is not quite certain that the time it takes for a cigar to develop will be the same in a space ship, but from the viewpoint of a modern physicist it is nearly impossible to imagine anything but the rate of time development to determine the speed of the ship!

A very interesting example of the working of time dilation is furnished by muons from cosmic-ray particles that disintegrate spontaneously after an average lifetime of 2.2×10^{-6} sec. They come to the earth from space, and can also be produced artificially in the laboratory. Some of them are created in mid-air, but the continuous disintegrations only after they encounter a mass to remain in c . It's clear that in its short lifetime a muon cannot travel, even at the speed of light, much more than 100 meters. But although the muons are released at the top of the atmosphere, some 10 kilometers up, they are usually found in a laboratory down here, in cosmic rays. How can this be? The answer is that different muons move at various speeds, some of which is a very close to the speed of light. While from their own point of view they only travel 2 meters, from our point of view they live considerably longer, i.e., much longer than they may reasonably expect. The factor by which the time is increased has already been given as $\gamma = \sqrt{1 - u^2/c^2}$. The γ -invariance factor is measured quite accurately for clusters of different velocities, and the values agree exactly with the formula.

We do not know *why* the theory, despite the γ 's, is valid, but we do know *why* or *where* the principle of relativity. That is to say, many of the predictions of relativity attempt to make predictions, even about things that otherwise we do not know much about. For example, before we knew anything about what matter is made of, it was not predicted that if it is moving at the speed of light, the speed it is all of time that it goes to is $c^2 = 1/c^2 = 0.73$ sec, and no prediction works—that is the kind thing about it.

15-5 The Lorentz contraction

Now it is return to the two-dimensional motion (15.2) and try to make better understanding of the relationship between the x -position and the (x', y', z') coordinates system, which we shall call the S' and S systems, or Joe and Mrs systems, respectively. We have already noted that the first equation is based on the Lorentz suggestion of synchronizing the two systems; how can we prove that a synchronization takes place? In the Michelson-Morley experiment we note apparent times were measured around 1900 m.s., but length by the principle of relativity, the null result of the experiment demands that the times must be equal, so, in order for the experiment to give a null result, the length of the $S'E$ must happen, by the requirement $\gamma(1 - u^2/c^2)$. What does this synchronization mean, a series of measurements made by Joe and Mrs? Suppose that Mrs, driving at the S' system in the x -direction, is measuring the x -coordinate of some point with a meter stick. She says the stick is a m. long, so he prints the distance is a' meters. From the viewpoint of Joe in the S system, however, Mrs is moving a longitudinal distance the "real" distance measured is $a\sqrt{1 - u^2/c^2}$ meters. Then if the S' system has traveled a distance a away from the S system, the S observer would say that the same point measured in his coordinates is at a distance $x = a\sqrt{1 - u^2/c^2} + a$ m.

$$x' = \frac{x - u t}{\sqrt{1 - u^2/c^2}},$$

which is the first equation of the Lorentz transformation.

15-6 simultaneity

In a non-inertial system, there are c different times. To make the simultaneous expression is introduced into the fourth equation of the Lorentz transforms. The most interesting term in this equation is the $u x'/c$ in the numerator, because that is quite new and unexpected. Now what does this mean? If we look at the situation carefully we see that events that occur at two separate places at the same time as seen by Mrs in S' , do not happen at the same time as viewed by Joe in S . If one event occurs at position x_1 at time t_1 , and the other occurs at position x_2 at time

Thus we find that the two corresponding times t_1 and t_2 differ by an amount

$$t_2 - t_1 = \frac{(v_{x_1} - v_{x_2})^2}{c^2}.$$

This time interval is called "Effect of simultaneity of a Galileo;" and to make the idea a little clearer let us consider the following experiment.

Suppose that a man moving in a space ship system S' has placed a clock at each end of the ship and is interested in making sure that the two start at the same time. How can the clocks be synchronized? There are many ways. One way involving very little calculation would be just to have exactly the same pulse between the clocks. Then from this a man would send a light signal which will go both ways at the same speed and will return at both clocks, clearly, at the same time. This signal arrives at all of the ship's clocks. He need to synchronize the clocks at the same time so he can synchronize his clock by the pulses of motion. Let us see whether an observer in system S would agree that the two are in synchronism. The man in S' sees light as follows: he sees because he does not know that he is moving. But the man in S reasons that since the ship is moving forward, the clock in the front end has gained time. The light signal, hence the light bulb to perform more to "keep up." In other words the clock, however, was advancing to meet the light signal so the distance was shorter. Therefore, the man in S needed the rear clock. But, although the man in S' thought that the signals traveled him separately. When the signals when a man in a space ship thinks the times at two locations are simultaneous, equal values of c in the coordinate system must correspond to different values of c in the other coordinate system.

13-4 Transformation

Let us see what she we can discover in the Lorentz transformation. It is interesting to note that the transformation between the x 's and x 's is analogous to that of the transformation between x 's and y 's that we studied in Chapter 11 for a relative of coordinates. We have

$$\begin{aligned} x' &= x \cos \theta - y \sin \theta, \\ y' &= y \cos \theta + x \sin \theta, \end{aligned} \quad (13.5)$$

in which the new x' means the old x and y' are the new y also in which the old x and y ; similarly, in the Lorentz transformation we find a new x which is a mixture of x and y , and a new y which is a mixture of x ' and y . So the Lorentz transformation is analogous to a rotation, only it is a "rotation" in space and time, which appears to be a curious concept. A check of the analogy is provided can be made by calculating the quantity

$$x'^2 - y'^2 + z'^2 = x^2 - y^2 + z^2 = c^2 t^2. \quad (13.6)$$

In this equation the first three terms on each side represent, in three-dimensional geometry, the square of the distance between a point and the origin (surface to a sphere) which remains unchanged (invariant) regardless of choice of the coordinate axes. Similarly, Eq. (13.6) shows that there is a certain combination which includes x , y , z that is invariant in a Lorentz transformation. Thus the analogy to a rotation is complete, and x 's and y 's are like unit vectors, i.e., quantities involving "components" which transform the same way as the coordinates and time, are transformed in connection with relativity.

Thus we continue our treatment of the idea of vectors which we have so far considered to have only space components, to include a time component. That is, we expect the them will be one \vec{v} with four components, three of which are the components of an ordinary vector, one with time well represented in the transformation, which is the analog of the time part.

This concept will be analyzed further in the next chapters, where we shall find that, if the ideas of the preceding paragraphs are applied to momentum, the transformation gives three space parts, that are: the ordinary momentum components, and a fourth component, the time part, which is the energy.

L5.9 Rekurrenzbedingungen

We are now ready to investigate, more generally, what form the laws of mechanics take under the Lorentz transformation. [We have thus far explained how length and time change, but not how we get the modified formulae for m (Eq. 291). We shall do this in the next chapter.] To see the varying stages of Einstein's modification of the Newtonian mechanics, we start with the Newtonian law that $\ddot{x}_i = \frac{d}{dt}(\dot{x}_i)$ is the rate of change of velocity x_i , or

$$F = \sigma_{\text{max}}^2$$

When I am in a C program, but after we use the `DEF` of this becomes

$$B = \sin \frac{\pi \omega t}{\sqrt{C^2 - I^2 \omega^2}}. \quad (15.10)$$

This is Einstein's modification of Newton's laws. Under this modification, if action and reaction are still equal (which they may not be in detail, but are in the long run), there will be conservation of momentum in the same way as before, but the quantity that is being conserved is not the old $m v$ with its constant mass, but instead \rightarrow the quantity given in (15.10), which has the modified mass. When this change is made in the form of a law of momentum, conservation of momentum still works.

Now let us see how momentum varies with speed. In Newtonian mechanics, it is proportional to the speed v , according to (15.10), over a considerable range of speed, but small compared to c . It is nearly the same in relativistic mechanics, because the significant modification differs only slightly from 1. But when v is almost equal to c , the square-root expression approaches zero, and the momentum therefore goes toward infinity.

Who happens? To consider, how does a body for a long time? In Newtonian mechanics the body increases picking up speed until it goes faster than light. But this is impossible in relativistic mechanics. In relativity, the body keeps picking up, not speed, but momentum, which can continuously increase because the mass is increasing. After a while there is practically no acceleration in the sense of a change of velocity, but the momentum continues to increase. Of course, whenever a force produces any small change in the velocity of a body, we say that the body has a great deal of inertia, and that is exactly what our formula for relativistic mass says (see Eq. 13.10). It says that the inertia is very great when v is nearly as great as c . As an example of this effect, to collect the high-speed electrons in the synchrotron that is used here at Caltech, we need a magnetic field that is 2000 times stronger than would be expected on the basis of Newton's laws. In other words, the mass of the electrons in the synchrotron is 2000 times as great as their normal mass, and it is greater than \sqrt{e} times of a proton. That is, it should be 2000 times m_p , so that $L = 1.6 \times 10^3$ must be $1.6 \times 10^3 m_p$, and that means that mc^2 differs from E by one part in 4,000,000, or that c differs from v by one part in 5,000,000, so the electrons are getting pretty close to the speed of light. If the electrons and light were born to gear from the synchronous (estimated at 100 feet away) and run out in Bridge Hall, who would arrive first? The light, of course, because light always travels faster.² How much earlier? That is not hard to tell; instead, we tell by what distance the light is ahead: it is about $1/2000$ of an inch, $\sim 3 \times 10^{-5}$ inch—of a piece of glass! When the electrons are going that lose their masses are electrons, but their speed cannot exceed the speed of light.

* The electrons would normally scatter from atoms under light because of the index of refraction of air. A permanent would make no losses.

Now let us look at some further consequences of relativistic change of mass. Consider the mass of all the molecules in a small unit of gas. When the gas is heated, the speed of the molecules is increased, and therefore the mass is also increased and the gas is heavier. An expression for this increase in the mass of mass, for example, when the velocity is small, can be found by expanding $m_0/\sqrt{1 - v^2/c^2} \approx m_0(1 + v^2/c^2)^{-1/2}$ as a power series. Using the form of expansion, we get

$$m_0(1 + v^2/c^2)^{-1/2} = m_0(1 + \frac{v^2/c^2}{2} + \frac{v^4/c^4}{8} + \dots).$$

We see clearly from the formula that the series converges rapidly when v is small, and the terms after the first two or three are negligible. So we can write

$$m \approx m_0 + M_{\text{kin}} \left(\frac{v^2}{c^2} \right) \quad (15.11)$$

in which the second term on the right expresses the increase of mass due to molecular velocity. When temperature increases the molecular propagation, so we can say that the increase in mass is proportional to the increase of temperature. But since $m_0 v^2$ is the kinetic energy in the non-relativistic Newtonian sense, we can also say that the increase in mass of all the molecules of gas is equal to the increase in kinetic energy divided by c^2 , or $M_{\text{kin}} = m_0 K_{\text{kin}}/c^2$.

15.4 Equivalence of mass and energy

The above observation led Einstein to the suggestion that the mass of a body can be expressed more simply than by the formula (15.1), if we say that the mass is equal to the total energy of content divided by c^2 . If Eq. (15.11) is multiplied by c^2 the result is

$$mc^2 = m_0 c^2 + M_{\text{kin}} c^2 + \dots \quad (15.12)$$

Here, the term on the left is called the total energy of the body, and we recognize the last term as the ordinary kinetic energy. Einstein interprets the long constant term, $m_0 c^2$, as part of the total energy of the body, as "rest energy," known as the "rest-mass."

Let us follow our own interpretation of meaning with respect to that the motion of a body without energy $m_0 c^2$. As an interesting result, we shall find the formula (15.12) for the conversion of mass to energy, which we have already assumed up to now. We start with the body at rest, when its energy is $m_0 c^2$. Then we apply a force to the body, which starts it moving and gives it kinetic energy; therefore, the total energy has increased. The new law of mechanics is implicit in the original assumption: as long as the force continues, the energy and the mass both continue to increase. We have already seen (Chapter 13) that the law of a type of energy with time varying force varies the velocity, v ,

$$\frac{dE}{dt} = F \cdot v. \quad (15.13)$$

We also have (Chapter 9, Eq. 9.1) that $F = \rho(x)v(x)$. When these relations are put together with the definition of E , Eq. (15.12) becomes

$$\frac{d(m_0 c^2)}{dt} = \rho(x) v(x) \frac{d(m_0 v)}{dt}. \quad (15.14)$$

We wish to solve this equation for $v(x)$. To do this we first use the technique just described of multiplying both sides by dm_0 , which changes the equation to

$$c^2 \left(\frac{dm_0}{dt} \right) \frac{dv}{dx} = \rho(x) v \frac{d(m_0 v)}{dt}. \quad (15.15)$$

We now let go one of the derivatives, which can be accomplished by integrating

both sides. The quantity $(\partial^{\mu} A_{\mu})/dt$ can be recognized as the time derivative of A^{μ} , and $(\partial^{\mu} A_{\mu}) - \partial A^{\mu}/\partial t$ is the time derivative of A^{μ} . But Eq. (15.17) is then simply

$$\partial^{\mu} (\frac{\partial A_{\mu}}{\partial t}) = \frac{\partial m^2 c^2}{\partial t}. \quad (15.18)$$

If the derivatives of two quantities are equal, the constants themselves differ at most by a constant, ϵ , i.e., C . This point is as before:

$$m^2 c^2 = m^2 c^2 + C. \quad (15.19)$$

We must again make the constant C massless initially. Since Eq. (15.19) must be true for all velocities, we can choose a special case where $v = 0$, and set $C = 0$; in this case the mass is m_0 . Substituting these values into Eq. (15.17) gives

$$m^2 c^2 = 0 + C.$$

We can now substitute values of C in Eq. (15.19), which becomes

$$m^2 c^2 = m^2 c^2 + m^2 c^2. \quad (15.20)$$

Dividing by c^2 and rearranging terms gives

$$m^2(1 - c^2/c^2) = m_0^2$$

from which we get

$$m = M_0 / \sqrt{1 - 1/c^2}. \quad (15.21)$$

This is the form of Eq. (15.1), and is exactly what is necessary for the agreement between mass and energy in Eq. (15.19).

Ordinarily these energy changes represent extremely slight changes in mass, because most of the time we cannot disentangle much energy from a given amount of mass-energy; but in an atomic bomb of explosive energy equivalent to 20 kilograms of TNT, for example, it can be shown that the difference between the initial and final masses is $\sim 10^{-13}$ g. The initial mass of the resulting neutron is m_1 because of the energy that was released, i.e., the released energy was a mass of 1 gram, according to the relationship $\Delta E = \Delta m c^2$. This famous "conservation of mass" may have been fully verified by experiments in which mass is annihilated—converted entirely to energy: an electron and a positron come together at rest, each with a rest mass m_1 . When they come together they annihilate and lose gamma-ray energy, each with the measured energy of $m_1 c^2$. This experiment provides a direct demonstration of the energy associated with the existence of the rest mass of a particle.

Relativistic Energy and Momentum

16-1 Reference and the philosopher

In this chapter we shall continue to discuss the principle of relativity of Einstein and Poincaré, as it affects our areas of physics and other because of human thought.

Twentieth-century philosophers seem of one mind in their view of the principle of relativity. According to the principle of relativity, the laws of physical phenomena must be the same for a fixed observer, as for an observer who has a uniform motion of translation relative to him, or "that we have no reason to precisely know, any means of discerning whether or not we are carried along at such a motion."

When this idea descended upon the world, it is said a great number of philosophers, particularly by "cocktail-party philosophers," who say, "Oh, it is very simple. Einstein's theory says all is relative!" In fact a surprising number of philosophers, not only those found at cocktail parties, but others, too, than philosophers, seem to think all is relative. A consequence of Einstein's theory is just now illustrated in an ad. In addition, they say, "It has been demonstrated in physics that phenomena depend upon your frame of reference." We can take a great deal but it is difficult to find out what it *means*. Probably the source of this idea lies were originally referred to were the coordinate systems which are in the very basis of the theory of relativity. So the fact that "things depend upon your frame of reference" is supposed to have had a profound effect on public thought. One might well wonder why *any* person, after all, that things depend upon one's point of view is an simple idea and certainly should have been necessary to go to all the trouble of the physical relativity theory in order to discover it. The whole matter depends upon his frame of reference is actually known to anybody who walks around because he sees an airplane and suddenly lost from the front and then from the back; this is nothing deeper than most of the philosophy which is said in the course from the theory of relativity than to comment that "A person looks different from the front than from the back." The old story about the elephant that several blind men describe in different ways is another example, perhaps, of the theory of relativity from the philosopher's point of view.

But actually there can be deeper things in the theory of relativity than just this single remark that "you can look different from the front than from the back." Of course relativity is deeper than this, because we can make definite predictions with it. I would say it is rather remarkable if we could predict the behavior of atoms from just a simple theory like this.

There is another school of philosophers who see very uncomfortable about the theory of relativity, yet it seems that one cannot live with our civilization seriously without ruling in something outside, and who would say "It is obvious that one cannot measure his velocity without looking outside. It is self-evident that it is impossible to talk about the velocity of a thing without looking outside. The physicists are quite simple for having thought otherwise, but it was just known from them that this is the case. If only the philosophers had realized what the problem were! The physicists had, so could have decided immediately by themselves that it is impossible to tell how fast one is moving without looking outside, and we could have had an immediate confirmation to ourselves." These philosophers are always with us, struggling in the periphery to try to tell us something but, they never really understood the subtleties and causes of the problem.

16-2 Relativity and the philosopher

16-2-1 The twin paradox

16-2-2 Transformation of velocities

16-2-3 Velocity-addition rules

16-2-4 Relativistic energy

Our inability to detect absolute motion is a result of experiment and not a result of plain thought, as we can easily illustrate. In the first place, Newton believed that it was true that one could not tell how fast one is moving with uniform velocity in a straight line. In fact, Newton himself was the author of this belief and one of earliest writers on the last topic was also an element of Newton's. Why then did the philosophers not make all this fuss about "all is relative?" or whatever is Newton's line? Because it was not until Maxwell's theory of electromagnetism was developed that a physicist knew that one could measure his velocity without looking outside; soon it was found that one could do this and could not.

Now if it were my definition, philosophy is necessary to one whom I do not be able to tell how fast he is moving almost looking outside. One of the consequences of relativity was the development of a philosophy which said "You can only define what you can measure." Since it is self-evident that one cannot measure a velocity without telling what he is measuring is relative to, therefore it is clear that there is no moving in absolute motion. The physicist should realize that one can only say about a thing "you can measure" by which the philosopher would mean that one can only define absolute velocity in the sense of what he can measure without looking outside; whether he is moving. Likewise, whether something is measurable is not something to be decided a priori. I might think he is moving that can be decided only by experiment. Given the fact that the velocity of light is 186,000 miles per second, one will find the few philosophers who will easily note that it is still evident that if light goes 186,000 miles per second and the car is going 100,000 miles, that the light can go 86,000 miles per second on the ground. This is a shocking fact to them, but very does with each, it is obvious that, when you have them a specific fact, that it is no problem.

Finally, there is even a philosopher who says that one cannot detect any motion except by looking outside. This is simply not true in physics. Thus, one can not provide a uniform motion in a straight line, but if he places a man who moves he would certainly know it, for everybody would be aware of the pull. There would be all kinds of "non-uniform" others. That, however, is a matter for the philosopher to determine without looking outside. Until a man moves, he does not know he. When this is said to a philosopher, he is very apter that he did not really understand it, because to him it seems impossible that one could be able to detect an motion about an axis without looking outside. If the philosopher is given enough of an excuse, he may come back and say, "I understand. We really do not have such a thing as absolute motion; we are really rotating relative to the stars, you see. And a some influence exerted by the stars on the object must cause the centrifugal force."

Now, let us see how we know that a man who has a car, at the present time, of telling whether there would have been centrifugal force if there were no stars and no other objects. We have not been able to do the experiment of removing all the people and cars, leaving the situation, so we simply do not know. We might, also, let the philosopher say "right." He comes back, therefore, to the philosopher and says, "It is necessary necessary that the world uniformly turn out to be the way uniform rotation means, nothing, it is only relative to the world." Then we say to him, "Now my friend, is not the uniform motion uniformity in a straight line, relative to the world, should produce no effects outside a car?" Now that the man is a little also interested in the relative, it becomes a question of question, and a question that can be answered only by experiment.

What then are the philosophical influences of the theory of relativity? If we continue his influences in the sense of a kind of one who had suggested one type to the physicist by the principle of relativity, we could describe some of them as follows. The first discovery is essentially that one does know which have been held for a very long time and which turn from very necessary to the "ignor be wrong." It was a shocking discovery, at once, and Newton's laws are it."

working, after all the years in which one seemed to be correct. Of course it is also true that the experiments were wrong, but that they were done was only a limited range of velocities, so small ones; the relativistic effects might not have been evident. But nevertheless, we now have a much more humble point of view of our physics; however, only thing one is wrong.

Secondly, if we come a bit of strange times such as the time goes slower when one moves, and so forth, whether we like them or do not like them is a nonscientific question. The only unscientific question is whether the Einstein's relativity was right or wrong experimentally. In other words, the "strange ideas" need only agree with experiment, and the only reason that we have to discuss the behavior of objects and so forth is to disprove it. But although the notion of the time dilation is strange, it is consistent with the way we measure time.

Finally, there is a third suggestion which is a little more technical but which seems good to be of importance: if you are only at other points, how are that to be read at the "beginning" of the time so, more specifically, to look for the ways in which the laws can be unchanged under a shift from the origin. When we develop the theory of motion, we never say the fundamental laws of motion are not changed when we rotate the coordinate system, and now we learn that they are not the "right" when we change the space and time variables in a suitable way, given by the Lorentz transformation. So this idea of finding the particular conditions under which the fundamental laws are not changed has proved to be a very useful one.

14.2 The relativity paradox

To continue our discussion of the theory of relativity and relativistic effects, we consider a famous story that "paradox" of Peter and his son who are supposed to be twins, born at the same time. When they are old enough to drive a car, say, Paul flies away at very high speed. Because Peter, who is left on the ground, sees Paul going so fast, all of Paul's clocks appear to go slower. His heart beats go slower, his thoughts go slower, everything goes slower, from Peter's point of view. Of course, Paul notices nothing unusual, but "he . . . accelerated and about ten minutes and then comes back, he is . . . older than Peter, the man on the ground! That is actually right, it is one of the consequences of the theory of relativity when two have every driven to that—less as the man who last longer when they are moving, so also will Paul last longer when he is moving. This is just this "paradox," only the people who believe that the principle of relativity means that all motion is relative; they say, "Well, look, you from the point of view of Paul, can't we say that Peter was moving and should therefore appear to age more slowly?" By symmetry, the only possible . . . is that Paul should be the same age when they meet." For in order for them to come back together and make the comparison, Paul must take, say, at the end of the trip and make a comparison of clocks or something, simply he has to come back, and the one whom comes back must be the man who was moving, and so know this, because he had to turn around. What he turned around? A kind of unusual things happened to his space ship—the rocks went off, things jammed against one wall and so on—while Peter left, etc.

At the very bottom, the only to know that the man who has felt the acceleration, who has seen things fall against the walls, and so on, is the one who would be the younger. Just > the difference between that in the "paradox" sense, and it is actually known. When we measured the fact that running man runs like human, we used as an example their straight-line motion in the atmosphere. The scientist also make measurement in a laboratory and cause them to go at a curve with a magnet, and even under the same field condition, they has varied as much for as they do when they are moving in a straight line. Although no one has arranged enough time especially on that we can get rid of the paradox, one could compare a magnet, which is left running with one can feel going around a magnetic field, and . . . would surely be found that the one that went around the circle last longer. Although we have not actually carried out an experiment using a magnet

circle. It is really not necessary, of course, because everything has longitude. Right. This may not satisfy those who insist that only single-fiber determinations will do, but we confidently predict the result of our experiment to watch Paul go to a complete circle.

16.2 Transformation of velocities

The main difference between the relativity of Einstein and the relativity of Newton is that the laws of transformation connecting the coordinates and times between different moving systems are different. In contrast, Isaac's motion law, the "law of motion," is:

$$\begin{aligned}x' &= \frac{x - vt}{\sqrt{1 - v^2/c^2}}, \\t' &= t, \\z' &= z, \\r' &= \frac{r - vx/c^2}{\sqrt{1 - v^2/c^2}}.\end{aligned}\quad (16.1)$$

These equations correspond to the relativity example now in which the relative velocity of the two observers is along their common x -axis. Only rectangular dimensions of motion are possible, but the time period. **Line 2** Transformation is called "coupled" with x' being split like this mixed up together. Why? **LT** continues to remain simpler form, since it contains all the essential features of the theory.

Let us now discuss more of the exact nature of this basic motion. First, it is interesting to ask: Are equations in moving—that is, here is a set of linear equations, four equations with four unknowns, and they can be solved in general, the x, y, z, t , in terms of x', y', z', t' . The result is very interesting, since it tells us how a system of coordinates "at rest" looks from the point of view of one who is "moving." Of course, since the motion can also be one of uniform velocity, the "rest" or "moving" can say if he wishes, but it is only then he follows who is moving and he himself who is at rest. And since he is moving in the opposite direction, he should see the same transformation, but with the opposite sign of velocity. That is precisely why we find by extrapolation, you don't have to think if he not come out that way, we would have real cause to worry!

$$\begin{aligned}x &= \frac{x' + vt'}{\sqrt{1 - v^2/c^2}}, \\y &= y', \\z &= z', \\t &= \frac{t' + vx/c^2}{\sqrt{1 - v^2/c^2}}.\end{aligned}\quad (16.2)$$

Next we discuss the interesting problem of the addition of velocities in relativity. We recall that one of the original postulates was that light travels c. 186,000 miles in all systems, even when they are in relative motion. This is a special case of the more general principle exemplified by the following. Suppose that an object made a space ship is flying at 100,000 miles/sec and the space ship itself is going at 100,000 miles/sec fast is the object made the space ship moving from the point of view of an observer outside? We might say no, say 200,000 miles/sec, which is more than the speed of light. This is very interesting, too, since it is required to be going faster than the speed of light. The general problem is as follows:

Let us suppose the the object made the ship from the point of view of the outside, is moving with velocity v , and that the space ship itself has a velocity u with respect to the ground. We want to know with what velocity v' the object is moving to the point of view of him in on the ground. This is, of course, still but a special case in which the motion is in the x -direction. There will also be a

transformation for velocities in the y -direction, or for any right angle can be worked out as needed. Make the same assumption, velocity is v_{xy} , which means that the displacement x is equal to the velocity times the time:

$$x' = v_{xy}t. \quad (16.1)$$

Now we have only one relation: who the position and time are from the point of view of the outside observer for the object which has the relation, if 6.2, between x' and t . So we simply substitute (16.1) into (16.2), and obtain

$$x' = \frac{v_{xy}t + vt}{\sqrt{1 - v^2/c^2}}. \quad (16.4)$$

At this we find x' expressed in terms of t . In order to get the velocity as seen by the observer, the outside, we must divide the distance by the time and by the factor c/v . So we must also take advantage to go from the outside, which is

$$z = \frac{t + v(x_{xy}/c)^2}{\sqrt{1 - v^2/c^2}}. \quad (16.5)$$

Now we must find the ratio of x to z , which is

$$x_2 = \frac{x}{z} = \frac{y + vt}{t + v(x_{xy}/c)^2}. \quad (16.6)$$

An important note having to do with. This is the law that we work the resultant velocity, i.e., "sum" of two velocities, is not just the algebraic sum of two velocities (we know that it wouldn't be so, we just in practice, but is "corrected" by $1/c^2$ term).

Now let us see what happens. Suppose that you are moving inside the space ship at the speed of light and that the space ship itself is going at the speed of light. This is impossible, but is the definition used in defining the γ factor.

$$\gamma = \frac{1}{\sqrt{1 - v^2/c^2}} = \frac{1}{\sqrt{1 - 1}} = \infty.$$

So, in reality, "half" and "light" does not mean "one," it makes only " $1/\gamma$." Of course low velocities can be dealt quite easily in the familiar way, because so long as the velocities are small compared with the speed of light we can forget about the $(1 - v^2/c^2)$ factor; but things are quite interesting at high velocity.

Let us take a limiting case, just for fun, suppose that inside the space ship the man was observing light itself. In other words, $v = c$, and yet the space ship is moving. How will it look to the man on the ground? The answer will be

$$x = \frac{s + t}{1 - sv/c} = s + \frac{t}{\gamma} = s.$$

Therefore, if something is moving at the speed of light inside the ship, it will appear to be moving at the speed of light from the point of view of the man on the ground. This is good, for it is, in fact, what the Einstein theory of relativity was designed to do in the first place—so it can't work.

Of course, there are cases in which the motion is not in the direction of the uniform translation. For example, here may be an object inside the ship which is not moving "properly" with the velocity v_x with respect to the ship, and the ship is moving "horizontally." Now, we simply go through the same thing only using v_x instead of v , with the result

$$y = y' + v_x t,$$

so that $v_{xy} = 0$,

$$x' = \frac{t}{\gamma} = \frac{t}{\sqrt{1 - v^2/c^2}} = t/c^2. \quad (16.7)$$

This is a sideways velocity v_y and not v_x , but $v_y^2 = v^2 - v_x^2$. We can obtain it by substituting and simplifying the measurement equations. But we can also get it directly from the principle of relativity for the following reason: it is always good to look again at what we can and cannot do. We know only that light always travels at the speed c in the laboratory. While a moving particle appears to travel at c , it goes at the speed v in the laboratory. While a moving particle moves with the same speed in the moving system. We found that the vertical component of the velocity in the moving system is less than that of light by the factor $\sqrt{1 - v^2/c^2}$ (see Eq. 15-2). But now suppose that we let a material particle go back and forth in a some "clock" having some "frequent" f_0 at some "natural frequency" of light (Fig. 16-1). Then when the particle has gone back and forth n times the light will have gone exactly n times. That is, the "frequency" of the moving clock will coincide with each other "below" the light clock. One goes up and down, the other moves to and fro. Because the speed of the emission of photons will be approximately the same, the particle must be slower than the corresponding speed by the same small fractional. That is why the square root appears in any velocity velocity.

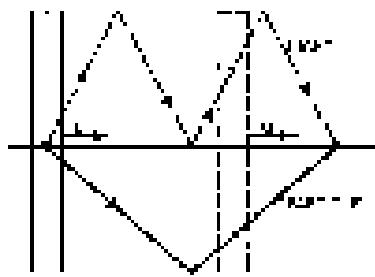

Fig. 16-1. Two diagrams showing how a light ray and particle below a moving clock.

16-4 Relativistic mass

You know or have test data that the mass of an object increases with velocity, but no demonstration of this was given, in the sense that we made no arguments to prove it. Now about the way clocks move we believe. However, we did prove that the consequence of this belief gives four very remarkable implications. The most interesting to us is this. (We have to say "a few other assumptions" because we cannot prove anything unless we have some laws which we assume to be true if we expect to make reasoning". Definitions.) Consider the case to study the transformation law of the total energy E of an object's motion, where we shall take nothing constant but the law of Newton. First we shall assume the conservation of momentum and energy. Also, we shall assume that the momentum of a particle which is moving in a straight line is always directed in the direction of the velocity. (However, we shall not assume that the momentum is necessarily along the velocity as Newton does, but only that it is scale parallel to velocity. We shall write the momentum vector as a coordinate function of the particle velocity.)

$$p = m v, \quad (16-5)$$

We put a condition on the coefficient to remind us that it is a function of velocity, and we shall agree to call the coefficient in the "rest" of expression where the velocity is zero. It is the rest mass that we would measure in the slow moving experiments with wave motion. Now we shall try to determine what the form of the mass must be. First, by arguing from the principle of causality into the laws of physics must be causal or have causal links between distant events.

Say you that we have two systems, like two particles, that are moving away and they are moving toward each other with exactly equal velocities. Their total momentum is zero. Now what happens? After the collision, their three pieces of motion must be exactly opposite to each other. Because if they are not exactly opposite, there will be a nonzero total vector momentum, and afterward it will not have been conserved. Also they must have the same speed, since after they exactly stop, all the energy is converted in the collision. So the digits of an electric charge or mass scale remain set, and the length between all the charges are the same length, all the speeds are equal. We can suppose that such causality can always be assumed. That is to say that causality, and that only speed could be used in such a collision. Next, we notice that the same particle can be visualized differently by turning the axes, and just for convenience we shift them the axes, so that the horizontal splits it evenly, as in Fig. 16-2(a). It is the same clock in motion, only with the axes "tilted".

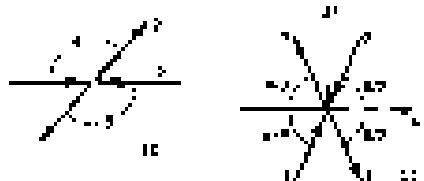

Fig. 16-2. Two stages of an elastic collision between equal objects moving at the same speed in opposite directions.

Now here is the trick: let me look at this collision from the point of view of someone riding along in a car that is moving at the speed equal to the horizontal component of the velocity of one particle. Then how does the collision look? It looks as though particle 1 is just going straight up because it has lost its horizontal component, and it comes straight down again afterwards in a shorter time than that our particle. That is, the collision appears as shown in Fig. 16.3(a). Particle 2, however, was going the other way, and so the impact appears to fly by at some terrible speed and at a smaller angle, but we see apparently that the angles before and after the collision are the same. So, the change of the horizontal component of the velocity of particle 2, and by so the vertical velocity of particle 1.

Now the question is, what is the vertical velocity v_{1y} ? If we knew that, we could get the momentum gain for the particle, assuming the law of conservation of momentum is the same. However, I think the horizontal component of the momentum is unchanged. It is the same before and after the collision for both particles and is zero for particle 1. So we must use the conservation law only for the horizontal velocity v_{1x} . Let us forget the particle theory, simply by focusing on the particle, looking the other way! If we look at the collision of big (6-kg) hammer to the 10-kg mass with speed $v_1 = v_0$, the same collision "turns over," as shown in Fig. 16.3(b). Now particle 2 is the one that goes up and down with equal speed and particle 1 has picked up the horizontal speed v_0 . Of course, now we know why the velocity v_{1y} is zero in $v_0 = v_{1y}$ (see Fig. 16.7). We know that the change in the vertical component of the velocity moving over time is

$$v_{1y} = \frac{v_0}{m_1} = \frac{v_0}{6\text{ kg}}.$$

(2), because it moves up and back down. The "slightly" moving particle has a initial velocity v_0 whose components we have found to be $v_{1x} = v_0/\sqrt{3}$, and $v_{1y} = v_0/2$. There is again recoil momentum, and this particle is therefore $\Delta p = -2m_2 v_0/3 = -v_0/3$ heavier, in accordance with our assumed law. (In 3) the horizontal component is always the mass corresponding to the magnitude of the velocity times the component of the velocity in the direction of interest. Thus in order for the total momentum to remain the vertical momenta must cancel and the ratio of the mass moving with speed v_0 and the mass moving with speed v_0 must therefore be

$$\frac{m_2}{m_1} = \sqrt{1 - v_{1x}^2/v_0^2}. \quad (16.9)$$

Let us take the limiting case that m_1 is infinitesimally small, very tiny indeed, so that the two objects are essentially equal. In this case, $m_1 = m_2$ and $m_1 = 1\text{ kg}$. Let's go ahead and do

$$\frac{m_2}{m_1} = \frac{m_2}{\sqrt{1 - v_{1x}^2/v_0^2}}. \quad (16.10)$$

From our earlier discussion, we know that if we want Eq. (16.8) to reduce to Eq. (16.9) it needs time for arbitrary values of v_0 , assuming that Eq. (16.10) is the right formula for the mass. Now that the velocity associated to Eq. (16.9) can be calculated from the right-hand side of (16.10)

$$v_0^2 = v_{1x}^2 + v_{1y}^2(1 - v_{1x}^2/v_0^2).$$

Now we find to make out automatically, although we need it only in (16.9) and not in (16.10).

Now, let us accept that momentum is conserved and that the mass depends upon the velocity according to (16.10) and prove that whatever we calculate. Let us consider what is commonly called an elastic collision. For simplicity, we can suppose that two pieces of mass m_1 and m_2 moving oppositely with equal speeds v_0 at first stick together to become some new, combined object, as shown in Fig. 16.4(a). The mass of this new object is $m_1 + m_2$, so we know $v_{1x} = -v_{2x}$. If we assume the conservation of momentum and the principle of relativity, we can demonstrate an interesting fact about the mass of the new object which has been formed. We compute the initial total velocity

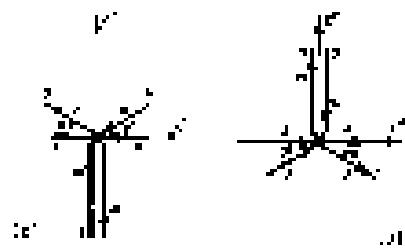

Fig. 16.3. Two views of the collision between moving cars.

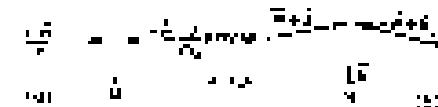

Fig. 16.4. Two views of an elastic collision between moving objects.

at right angles to it (we can do the same with other values of α , but it's easier to understand it with the horizontal velocity), then both objects move in directions parallel to an object's initial velocity, $v - p$. What we see is shown in Fig. 16-1(b). The composite object has an "run-down mass" M . Now object 1 moves with an upward component of velocity equal to the initial component which is proportionally equal to v , and so does object 2. After the collision we have the mass M moving upward with velocity v , considered as a small composite with the speed of $|v|$, and a mass m associated with it. Momentum must be conserved, so let us determine the momentum in the upward direction before and after the collision. Before the collision we have $v_1 = |v|$, and after the collision the "center" will be evidently $p_1 = Mv$, but p_2 is evidently the same as $m v$ because v is so small. These momenta must be equal because of the conservation of momentum, and therefore

$$Mv = mv \quad (16.11)$$

The mass of the whole object is shared when two objects move with equal and opposite velocities when they come together. You might say, "Yes, of course, that is the conservation of mass." But it "is not, of course" necessarily, because when two objects have exchanged mass, the masses m_1 and m_2 will be if they were exceeding still, yet they still contribute to the total M , not the mass they have taken standing still, just more. According to that may seem, in order for the conservation of mass to work when two objects come together, the mass that they form **must** be greater than the rest masses of the objects even though the objects are not after the collision!

16.5 Relativistic energy

In the last chapter we demonstrated that as a result of the dependence of the mass on velocity (see Newton's laws, the changes in the kinetic energy of an object resulting from the total work done by the forces on it), "total energy" can be

$$\Delta T = (m_1 + m_2)c^2 - \frac{m_1 c^2}{\sqrt{1 - v^2/c^2}} - m_2 c^2. \quad (16.12)$$

We can write further, and guessed that the total energy is the total mass times c^2 . Now we can take this definition.

Suggest that our two equally massive objects can still be "inside" M . For instance, a proton and a neutron are "stack together," but are still moving along, inside of M . Then, although we might at first suspect the mass M to be $2m_0$, we have found that it is not $2m_0$, but $m_1 + m_2$. Since $2m_0$ is when $v = 0$, but $m_1 + m_2$ are the rest masses of the things inside, the "new" mass of the composite object is equal to the kinetic energy brought in. This means, of course, that energy has flowed. In the last chapter we discussed the analogy of gas and showed that because the gas molecules are moving and moving atoms are heavier when we put energy into the gas its molecules move faster and the gas goes faster. In fact the argument is completely general, and our discussion of the inelastic collision shows that the mass \rightarrow time relationship is kinetic energy. In other words, "Two particles come together and sacrifice potential to any other form of energy (the pieces are closed doors to shrinking it)", being work against internal forces, or whatever, then it is true that the mass is not initially, but has been put in. We see that the conservation of mass which we have deduced above is equivalent to the conservation of energy, and therefore there is no place in the theory of relativity for strictly inelastic collisions, as there was in Newtonian mechanics. According to Newtonian mechanics ... is all right for two things to collide and so for a collision of mass $2m_0$, which is in many ways distinct from the one that would see a "summarizing them together slowly." Of course we know from the law of conservation of energy that there is more kinetic energy inside, but that does not alter the mass, according to Einstein's laws. That now we see that this is impossible: because of the kinetic energy involved in the collision, the resulting

object will be broken; therefore, it will be a different object. When we pull the object together, yet I may make something whose mass is large; when we pull them together forcefully, they may become something whose mass is small. Then the mass is different, we can not say it is different. So unless this, the conservation of energy must go along with the conservation of momentum in the theory of relativity.

This has interesting consequences. For example, suppose the we have an object whose mass M is moving and, and suppose something happens so that it flies into two equal pieces moving with speed c , so that they each have a mass m . Now suppose that these pieces contain enough material to slow them up until they stop; then they will have mass m . How much energy will they have given to the material after they have stopped? Each will give an amount $(m - m_0)^2/c^2$, by the famous theory of general relativity. This mass energy is left in the material as some form, as heat, potential energy, or whatever. Now $2m_0 = M$, so the total initial energy is $E = (M - 2m_0)c^2$. This is good for the usual calculations how much energy would be liberated under fusion in the atomic bomb. For example, although the fragments are not exactly equal, they are nearly equal. The mass of the atomic bombinium was known. It had been measured. One day -- see the atomic bomb which is split,裂變, atom, and so on, all were all known years ago. Today we do not know the masses while calculating one thing, we need the masses when the atoms裂變, or other words, heat, of and any one known. So by subtracting the two numbers one can calculate how much energy will be released. If one has a rock to split in "half". For this reason your old Einstein was to say the "father" of the atomic bomb is all the newspaper. Of course, all that means was that he could tell us ahead of time how much energy would be released if we had known what process would occur. The energy that should be released when an atom, or hydrogen undergoes fission was estimated about six months before the first direct test, and as such as the energy was in fact liberated, someone immediately wrote (and if Einstein's formula had not worked, they would have measured it anyway), and the nuclear energy measured it, they no longer needed the formula. Of course, we should credit him to him, but he also should credit the newspaper and many popular descriptions of what comes when in the history of physics and technology. The problem of how to get the thing to work is an effective and important one is a completely different matter.

The most important significant is chemistry. For instance, if we were to weight the carbon dioxide molecule and compare its mass with that of the carbon and the oxygen, we think that not much energy would be released when a hydrogen and oxygen form carbon dioxide. The only trouble here is that the substances in question are so small that it is relatively very difficult to do.

Now let me come to the question of whether we should add m_0^2 to the kinetic energy and say from now on that the total energy of the object is $E + m_0^2$. First, if we can still see the component pieces of new mass m_0 inside M , then we should say that some of the mass M of the compound object is the massless rest mass of the parts, part of it is kinetic energy of the parts, and part of it is potential energy of the parts. So we have discussed, it is quite possible of course to do such nuclear reactions just like the one we have treated above, in which when all the energy in the world, + or - goes over the mass. For instance, when E. K. Meissner distinguishes into two parts it does not necessarily do the $(E + m_0^2)$ but the idea that E is made out of m_0^2 is a useless idea, because it also distinguishes into E 's.

For this we have a situation: we cannot have to know what E and m_0 is made of inside; we cannot say that we identify individual particles, which of the energy is rest energy of the parts until which it is going to disintegrate. It is not convenient and also not possible to separate the total rest energy of an object into the energy of the individual pieces. Kinetic energy of the pieces, and potential energy of the pieces moreover, we simply ignore at the total energy of the particle. We "shut the engine" of energy by adding m_0^2 to a rest energy being, and say for the individual particle it increases in scaling times c^2 , and when the object is standing still, the energy is the mass of that object c^2 .

Typically, we find that the velocity v , momentum p , and total energy E are expressed in a rather simple way. That the mass in relation to speed c is the most reasonable one divided by $\sqrt{1 - v^2/c^2}$ (neglecting mass) is hardly useful. Instead, the following relations are easily proven, and turn out to be very useful:

$$E^2 - p^2 c^2 = m^2 c^4 \quad (16.15)$$

and

$$p_c = p_c/c \quad (16.16)$$

Space-Time

17-1 The geometry of spacetime

The theory of relativity shows us that the relationships of positions and times as measured in one coordinate system are different from what we would have expected in the Galilean intuition. This is very important, and we thoroughly understand the relations of space and time implied by the Lorentz transformation; and therefore we shall consider little matter more deeply in this chapter.

The Lorentz transform for between the positions and times (x, y, z, t) as measured by an observer "stationary at ∞ " and the corresponding coordinates and time (x', y', z') as measured inside a "moving" space ship, moving with velocity v , is:

$$\begin{aligned}x' &= \frac{x - vt}{\sqrt{1 - v^2/c^2}}, \\y' &= y, \\z' &= z, \\t' &= \frac{t - vx/c^2}{\sqrt{1 - v^2/c^2}}.\end{aligned}\quad (17.1)$$

Let us compare these equations with Eq. (10.5), which also relates measurements in two systems, one of which is in translation relative to the other:

$$\begin{aligned}x' &= x \cos \theta - y \sin \theta, \\y' &= y \cos \theta + x \sin \theta, \\z' &= z.\end{aligned}\quad (17.2)$$

In this particular case, x and y are increasing with time having an angle θ between the x' - and x -axes. In each case, we note that the "primed" quantities are "the result" of the "transformation," since the new x' is a mix of old x and y , and the new y' is also a mixture of x and y .

An analogy is useful: When we look at an object, there is no obvious thing we might call the "depth, width," and another we might call the "height." But the two being, width, and depth, are not fundamental properties of the object, however. If we step aside and look at the same thing from a different angle, we get a different width and a different depth, and we may develop some formulas for computing the new ones from the old ones and the angles involved. Equations (17.2) are those formulas. One might say that a given depth is a kind of "mixing" of all depth and all width. If it were impossible ever to move, and we always saw a given object from the same position, then this whole business would be unnecessary—we could always see the "true" width and the "true" depth, and they would agree in how quite different qualities, because one expects as a subtler optics, angle and the other involves a refraction, of the lens or even rotation, they would seem to be very different things and would never get mixed up. It is because we can walk around that we realize that depth and width, somehow or other, just two different facets of the same thing.

Can we look at the Lorentz transformation in the same way? Then also we have a mixture of positions and the time. A difference between a space measurement and a time measurement produces a new space measurement! In other words, in the space measurements of one man, there is mixed in a jolt of time, as seen by the other. One cannot seem to separate this fact. The "reality" of

17-1 The geometry of spacetime

17-2 Space-time intervals

17-3 Past, present, and future

17-4 More about four-vectors

17-5 Four-vector algebra

an object (as); we are looking at a situation where (speaking crudely and intuitively) even its "width" and its "depth" measure they depend upon how we look at it: when we move to a new position, our brain immediately reevaluates the width and the depth. This is not immediately recognizable, but it does, and this is what we mean by high speed, because we have had an effect on experience of going nearly as fast as light; to accelerate the fact that time and space are also of the same nature. It is as though we were always stuck in the position of having to think of just the width of something, not being able to move our heads independently one way or the other; if we could, we understand now, we would see some of the other man's face. We would say "horizontal," we speak a little bit.

Now we shall try to think of objects in a new kind of world, a space-time mixed together, in the same sense that the objects in our ordinary space world are real and can be looked at from different directions. We shall then consider the objects occupying space and having for a certain length of time occupy a kind of a "block" in this kind of world, and this we call at this "block" from different points of view when we are moving at different velocities. This, however, has the geometrical reality in which the "blocks" exist by occupying position and taking up a certain amount of time, is called gravitons. A given point (x_1, y_1, z_1, t_1) is called an isolated graviton. Imagine, for example, that we plot the positions horizontally, y and z in two other directions both initially at "right angles" and at "right angles" in the sense (1), and time, vertically. Now, how does a moving particle, say, look on such a diagram? If the particle is standing still, then it has a certain x , and the time goes on, it has the same x . In short, the same x space "path" is a line that runs parallel to the x -axis (Fig. 17-1(a)). On the other hand, if it drifts outward, then as the time goes on x increases (Fig. 17-1(b)). So, you know, for example, which starts to drift out and then slows down should have a motion something like that shown in Fig. 17-1(c). A particle, in other words, which is permanent and does not disintegrate is represented by a line in spacetime. A particle which disintegrates would be represented by a forked line, because it would turn into two other things, which would start from that point.

What about light? Light's speed in the space-time, and that would be represented by a line having a certain fixed slope (Fig. 17-1(d)).

Now according to our new idea, if a given event passes into a particle, say if it is suddenly dissevered at a certain speed, it points into our new axes what follows we have L and C , and this has nothing ever occurred at a certain value of x and a certain t , so if x and t then we would expect L.C., if this makes any sense, we just have to take a few pairs of ones and two there, and that will give us the new road. Our new x is our new system, as shown in Fig. 17-2(a). But this is wrong, because Eq. (17-1) is not exactly the same mathematical expression as Eq. (17-2). Note, for example, the difference in sign between the two, and the fact that one is written in terms of $\cos \theta$ and $\sin \theta$, while the other, i.e. written with algebraic quantities. Of course, it is not impossible that algebraic quantities could coincide, as cosine and sine, but actually they cannot, but still, the two expressions are very similar. As we shall see, it is not really possible to think of spacetime as a real, ordinary geometry, because of that difference in sign. In fact, although we shall not emphasize this point, it turns out that a man who is moving has to make an "axis" which are inclined equally to the light ray, using a "geometric" kind of projection parallel to the x and t axes, for his x and t as shown in Fig. 17-2(b). We shall not deal with the geometry, since it does not help much, it is easier to work with the x - y - z axes.

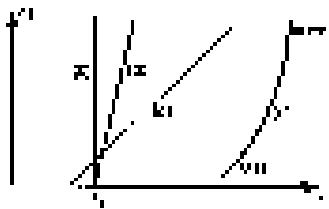

Fig. 17-1. Three particle paths in space-time: (a) a vertical line at $x = x_1$; (b) a particle with constant velocity $v = v_1$ and moves with constant velocity; (c) a particle which slows at high speed down.

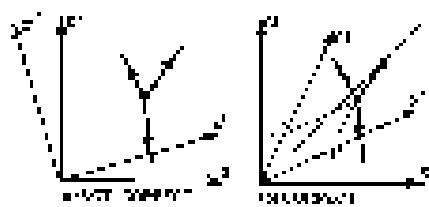

Fig. 17-2. Two views of a disintegrating particle.

17-3 Spacetime intervals

Although the geometry of spacetime is not based on the ordinary sense, there is a quantity which is very similar, but perhaps in certain respects. If this kind of geometry is right, there ought to be some functions of spacetime and time which are independent of the coordinate system. For example, under ordinary rotations, if we take two points, one at the origin, the x -axis, and the other on x -axis, the two systems would have the same x given the distance from

less to the other point is the same in both. That is one property that is independent of the particular way of measuring it. The square of the distance is $x^2 + y^2 + z^2$. Now what about spacetime? It is not hard to demonstrate that we have here, also, something which stays the same. Namely, the combination $x'^2 - x^2 - y^2 - z^2$ is the same before and after the transformation:

$$x'^2 - x^2 - y^2 - z^2 = x^2 + y^2 + z^2 - c^2. \quad (17.2)$$

This quantity is therefore something which, like the distance, is "real" in some sense. It is called the interval between the two space-time points, one of which is, in this case, at the origin. (Actually, of course, it is the interval squared, just as $x^2 + y^2 + z^2$ is the distance squared.) We give it a different name because it is in a different geometry, and the interval implying identity has some signs reversed and there is no unit.

Let us get rid of the c : this is an abuse if we are going to have a sensible system with c 's and y 's that can be unambiguous. One of the curiosities this could be caused by occurring with no experience would be to measure widths, say, by the range subtended in the eye and measure depth in a different way, like the sum of the angles needed to focus them, so that the angle would be measured in feet and the width in meters. Then one would get all enormously complicated messes of equations in making transformations such as (17.2), and would not be able to see the beauty and simplicity of the theory for a very simple technical reason, just the same thing is happening measured in two different units. Note that Eqs. (17.1) and (17.3) make c refer to that time and space unit equivalent; time becomes space; they should be measured in the same units. What distance is a "second"? It is easy to figure out from (17.1) what it is. It is 3×10^8 meters. The distance that light could cover in one second. In other words, if we were to measure all distances and times in the same units, seconds, then our unit of distance would be 3×10^8 meters, and the equations would be simpler. Or another way that we could make the units equal is to measure time in meters. What is a "meter" of time? A meter of time is the time it takes for light to go one meter, and so therefore $1/(3 \times 10^8)$ sec., or 0.3 billionths of a second.¹ We would like, in other words, to put all our equations in a system of units in which $c = 1$. If time and space are measured in the same units, as suggested, then the equations are obviously much simplified. They are

$$\begin{aligned} x' &= \frac{x - ct}{\sqrt{1 - \beta^2}}, \\ \gamma &= \frac{c}{v}, \\ \beta &= \frac{v}{c}, \\ \epsilon &= \frac{1 - \beta^2}{\sqrt{1 - \beta^2}}. \end{aligned} \quad (17.4)$$

$$t'^2 - x'^2 - y'^2 - z'^2 = t^2 - x^2 - y^2 - z^2. \quad (17.5)$$

Now we can drop the "light unit". But also we have this system with $c = 1$. We shall never be able to get our equations right again, the answer is called the impossible. It is much easier to remember them without the c 's in them, and it is always easy to put the c 's back, by looking after the dimensions. For instance, in $\sqrt{1 - \beta^2}$, we know that we cannot subtract a velocity squared, which has units, from the unity minus it, so we know that we must divide v^2 by c^2 in order to get the right answers, and this is the way to do it.

The difference between space-time and ordinary space, and the character of the interval as related to the distance, is very interesting. According to formula (17.5), if we consider a point which in a given coordinate system had zero time and only space, then the interval squared would be negative and we would have an imaginary interval, the square root of a negative number. Intervals can be either real or imaginary in the theory. The square of an interval may be still positive or negative, unlike distance, which has a positive square. When an interval is imaginary, we say that the two points have a spacelike interval between them

(region of imaginary), because the interval is more like "space than like time." On the other hand, if two objects cover the same space in a given coordinate system but it's only in time that the square of the time is positive, and the distance not zero, not the interval would be positive; this is called a pseudo-time interval. In addition to spacetime, themselves we would have a reverse "time" coordinate, such that $x^2 - t^2$ where x are two lines (position, x , time, t) and t will be "excess" called light cones) and points on these lines will be zero interval from the origin. When a light cone from a given point is always separated from it by some interval, or we can from Eq. (17-5). Incidentally, we have just proved that if light travels with speed c in a system, it travels with speed c in another. For if the interval is the same in both systems, i.e., zero at one end and zero in the other, then we see that the propagation speed of light is constant, i.e., the same as saying that the interval is zero.

17-3 Past, present, and future

The space-time regions surrounding a given spacetime point can be separated into three regions, as shown in Fig. 17-1. In one region we have causal-like intervals, and in two regions, time-like intervals. Physically, these three regions also reflect space-time around a given point is caused have an interesting physical relationship to their points: a physical object or a light cone passes a point in region I in the event of moving along at a speed less than the speed of light. Therefore events in this region can affect the point O , and have an influence on it from the past. In fact, of course, an object at O , the spacetime point is precisely in the "past" with respect to O ; it is the same spacetime point, as O , only earlier. What happened there then affects O now. Unfortunately, that is all we can say. An object object at O can get to O by moving with a certain speed less than c , so if this object were to a speed slightly exceeding it would be again the past of the same spacetime point. That is, in another coordinate system, the curve of time might go through here O and O' . So all points of O are in the "past" of O , and any thing that happens in this region can affect O . Before region II is sometimes called the "future past," or affecting past; it is the locus of all events which can affect point O in any way.

Region II, on the other hand, is a region which we can affect now O , we can "hit" things he shows my "bullets" out at speeds less than c . So O is the world whereof it can be affected by us and we can still hit the object O . Now the remarkable thing about all the rest of spacetime, i.e., region III, is that we can neither affect it now/future O , nor can it affect us now in O , because nothing can go faster than the speed of light. Of course, what happens in O can affect us later; that is, if the sun is exploding ("right now"), it takes eight minutes before we know about it and it cannot possibly affect us before it has.

Why we mean by "right now" is a mysterious thing which we cannot define and we cannot affect, but it can affect us later, or we could have affected it if we had done something to enough in the past. When we look at the Alpha Centauri, we see it as it was four years ago; we might wonder what it is like "now," "now," as is the case here from our spacetime coordinate system. We can only see Alpha Centauri by the light that has come from the past, up to four years ago, but we do not know what is today "now"; it may take four years before what is today "now" can affect us. Alpha Centauri "now" is a idea or concept of our mind; it is not something that is really thinkable physically or the otherwise, because we have to wait to observe it, we cannot exceed its light "time." Furthermore, the "now" depends on the coordinate system. If, for example, Alpha Centauri were moving to please the x would no longer with us because he would not be fixed at an angle, and his "now" would be a different time. We have already talked about the fact that simultaneity is not a unique thing.

There are certain tellers of people who believe they can know the future and there is many wonderful stories about the "I" who suddenly discover a "secret" knowledge about the future. Well, this would be a paradoxical prediction by that because "we know something is going to happen, then we can make

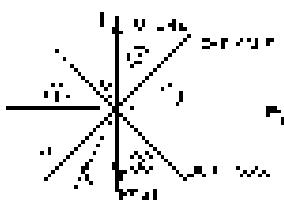

Fig. 17-1. The space-time regions surrounding a point of the origin

one we will avoid it by doing the right things. To right now, and so on. But actually there is no future tell who can even tell me if it's passed. That is to say who can tell us what is really happening right now, at any given moment. Because then is a real value. We might ask ourselves this question, which we have to the student to try to answer: Would any paradox be produced if a were suddenly to become possible to know this, that one is the spacetime coordinate system?"

17.4 More about four-vectors

Let us now return to our consideration of the analogy of the Lorentz transformation and rotations in three-space. We have been mainly to collecting up to other quantities which have the same transformation properties, as the coordinates, to both space and time, directed lines. In the case of ordinary rotations, there are many quantities in a translation, for example $\hat{x}, \hat{y}, \hat{z}$, and a linear invariant. For example, the velocity has three components, $\hat{u}_x, \hat{u}_y, \hat{u}_z$ component; when seen in a different coordinate system, none of the components is the same indeed, they will transform in this or in, say, somehow or other, however itself, has a greater variety than to any of its coordinate components, and we represent it by a directed line.

We therefore ask: Is it possible that there are quantities which transform, or which are related, in a moving system and to a non-moving system, in a way to $\hat{x}, \hat{y}, \hat{z}$ and \hat{u} ? From our acquaintance with vectors, we know that three of the quantities, like $\hat{u}_x, \hat{u}_y, \hat{u}_z$, constitute the three components of an ordinary space vector, but the fourth quantity would, "as it is," in some way be constant and three in space-time? We don't know whether there is, indeed, at least one such thing there are many of them, but that the three components of momentum and energy or the four components, therefore together to make what we call a "four-vector". In demonstrating this, since this quite accustomed to refer to \hat{u} it is everywhere, we shall use the same letter, writing in it's "the energy, the mass and the momentum, that we use in Eq. (17.1). Energy and mass, for example, differ only by a factor c^2 which is merely a question of units, so we can interchange it. In mass. Instead of trying to write it c^2 , we put $E = mc^2$, so then, of course, of this quantity it must we want to be larger amounts of also that the mass would straighten out in the last equation, but not in the intermediate ones.

This is the equation for energy and momentum are

$$\begin{aligned} E &= mc/\sqrt{1 - \hat{u}^2/c^2}, \\ p &= mv = m\hat{u}/\sqrt{1 - \hat{u}^2/c^2}. \end{aligned} \quad (17.6)$$

Again in these terms, we have

$$E^2 = p^2 + m^2c^2. \quad (17.7)$$

For example, if we measure energy in electron volts, what does a mass of an electron tell about it? If we take the mass which is energy in electron-volt, then it, we're told, is one electron volt. For example, the rest mass of an electron is 0.511×10^{-10} ev.

Now what would the momentum and energy look like in a new coordinate system? To find out, we shall have to transform Eq. (17.6) which we can do because we know how the velocity transforms. Suppose that we measure it, on this boat a velocity \hat{u} , but we look upon the same object from the point of view of a space ship which itself is moving with velocity \hat{v} , and in this system we have a point to design \hat{u}' the corresponding thing. In order to simplify things at least, we shall take the case that the velocity \hat{v} is in the direction of the \hat{x} axis, we consider the most general case. What is it, the velocity system from the space ship? It is the

component relative, the "difference" between v and v' . By the law which we worked out before,

$$v' = \frac{v - u}{1 - vu}. \quad (17.8)$$

Now let us calculate the new energy E' , the energy as it follows in the space ship would see it. He would use the same notations, of course, but he would use v' for the velocity. What we have to do is subtract u^2 , subtract it from one take the square root, and take the reciprocal:

$$\begin{aligned} v'^2 &= \frac{v^2 - 2uv + u^2}{1 - 2vu + u^2} \\ 1 - v'^2 &= 1 - 2uv + u^2 \frac{v^2 - 2uv + u^2}{1 - 2vu + u^2} \\ &= \frac{1 - v^2 - u^2 + u^2 v^2}{1 - 2vu + u^2} \\ &= \frac{(1 - u^2)(1 - v^2)}{(1 - vu)^2} \\ &= E^2/(1 - u^2). \end{aligned}$$

Therefore

$$\frac{1}{\sqrt{1 - v'^2}} = \frac{1 - vu}{\sqrt{1 - u^2}\sqrt{1 - v^2}}. \quad (17.9)$$

The energy E' is then simply m_1 , times the above expression. But we want to express the energy in terms of the original energy and momentum, and we know that

$$E = \frac{m_1 - m_1 u^2}{\sqrt{1 - u^2}\sqrt{1 - v^2}} = (m_1/\sqrt{1 - u^2}) - (m_1 u/\sqrt{1 - u^2})v,$$

or

$$E' = \frac{1 - vu}{\sqrt{1 - u^2}}, \quad (17.10)$$

which we recognize as being exactly of the same form as

$$v' = \frac{1 - vu}{\sqrt{1 - u^2}}.$$

Next we must find the new momentum p'_x . This is just the energy E' times v' , and is also simply expressed in terms of E and p_x :

$$p'_x = E'v' = \frac{m_1(1 - vu)}{\sqrt{1 - u^2}\sqrt{1 - v^2}} \frac{v - u}{(1 - vu)} = \frac{m_1(1 - vu)}{\sqrt{1 - u^2}\sqrt{1 - v^2}}.$$

Thus

$$p'_x = \frac{p_x - mE}{\sqrt{1 - u^2}}, \quad (17.11)$$

which we recognize as being of precisely the same form as

$$v' = \frac{v - u}{\sqrt{1 - u^2}}.$$

Thus the transformations for the new energy and momentum in terms of the old energy and momentum are exactly the same as the transformations for v in terms of v' , and v' in terms of v and u . All we have to do is, every time we see v in (17.4) substitute E , and every time we see v substitute p_x , and then the equations (17.4) will become the same as Eqs. (17.10) and (17.11). This would apply, if everything works right, at additional rate that $p'_x = p_x$ and that $v'_x = v_x$. To prove this would require you going back and studying the issue of motion up and down. Actually, we did study the case of rolling up and down in the last

chapter. We imagined a head-on collision and we noticed that, i.e., the components of momentum were changed when viewed from a moving system so we have already written that $\hat{p}_A' = p_A$ and $\hat{p}_B' = p_B$. The complete transformation, then, is

$$\begin{aligned} \hat{p}_A' &= p_A - \frac{vC}{\sqrt{1 - v^2}}, \\ p_A' &= p_A \\ \hat{p}_B' &= p_B \\ p_B' &= \frac{p_B + vp_A}{\sqrt{1 - v^2}}. \end{aligned} \quad (17.10)$$

In these transformations the time, v , has disappeared from p_A' which transforms like (x, t) , and which would be given by the equation $t = \gamma x$. Since the momentum is a four-vector, it can be represented on a space-time diagram as a moving vector as a "twice" four-vector, the path, as shown in Fig. 17.4. This arrow has a time component equal to the energy, and its space components represent a three-vector momentum, this arrow is more "real" than either the energy or the momentum, because there has to be a path in the diagram.

Fig. 17.4. The four-vector representation of a particle.

17.5 Four-vector algebra

The notation for four-vectors is different than that for three vectors. In the case of three-vectors, if we want to talk about the ordinary 3-vector momentum we could write it p . If we wanted to be more specific, we could say p_x , p_y , p_z , three components which are, for the case in question, p_x, p_y , and p_z , so we could simply say the general momentum p , or say that it is the 3-vector p , or that there are the three components p_x, p_y, p_z , imagine that p is any one of three directions, x, y , or z . The notation that we use for four-vectors is analogous to this. We write p , p_A , p_B , the four-vector, and p_{Ax} , p_{Ay} , p_{Az} for the four parallel directions x, y, z , or x, y, z .

We could, of course, use any notation we want; do not laugh all the time; just think, it's all possible. In fact, in other areas, we change our definition of four-vectors. The whole idea of a four-vector, in fact, is an improvement in notation so that the transformations can be completed easily. p_A , then, is a general four-vector, but for the specific case of energy, p_A , p_A is identified as the energy p_0 is the momentum in the x -direction, p_x , and it is p -vectorial, and p_1 is that in the y direction. Overall, for p_A , we add the corresponding components.

There is an equation among four vectors, when the energy is zero, for each component. For instance, the law of conservation of three-vector momentum is to be unchanged in a collision, i.e., if the sum of the momenta for a large number of interacting or colliding particles is to be a constant, and must mean that the sums of the momenta in the x -direction, in the y -direction, and in the z -direction, for all the particles must each be constant. This law alone would be impossible in relativity because c is a constant, it's like trying about only two of the components of p to be constant. I.e., it's impossible to do. If we take this case, we add the various components, so we must include all three components in our law. That is, in relativity, we must complete the law of conservation of momentum by exceeding it to include the time component. This is after all, however, to go with the other three, or that cannot be realistic importance. The conservation of energy is the fourth equation which goes with the same value of momentum to make a valid four-vector relationship in the geometry of space and time. That is the law of conservation of energy and momentum. In our discussion, condition is

$$\sum_{p \in p_A} \hat{p}_i = \sum_{p \in p_B} \hat{p}_i \quad (17.11)$$

or, in a slightly different notation

$$\sum_i p_{Ai} = \sum_j p_{Bj} \quad (17.12)$$

where $i = 1, 2, \dots$ refers to the particles going into the collision, $j = 1, 2, \dots$ refers to the particles coming out of the collision, and $\alpha = r, p, \pi$, or γ (you say "the weak ones?"). It makes no difference. The law is true for good occupation, using δ 's and ϵ 's.

In vector language we discussed one other thing, the dot product of two vectors. Let us even consider the corresponding thing in spacetime. In ordinary motion we discovered there was no invariant quantity $x^2 + y^2 - z^2$. In four dimensions, we find that the corresponding quantity is $t^2 - x^2 - y^2 - z^2$ (Eq. 17.5). How can we verify that? One way would be to represent four-dimensional things with a space-dot between, like $A_\mu \odot B_\nu$, and α^μ . In notation which is actually used is

$$\sum_i A_\mu A_\nu - \delta_{\mu\nu} = J_1^2 - J_2^2 - J_3^2. \quad (17.15)$$

The point on Σ where there is rest mass, the "time" term, is just $-c$, but the other three terms have mixed signs. This quantity then is to be the same in any coordinate system, and we may call it the square of the length of the four-vector. But how do we know what is the square of the length of the four-vector in spacetime, for a single particle? This will be equal to $p_1^2 - p_2^2 - p_3^2 = p_1^2$, or else we do $E^2 - p^2$, because we know $p_1^2 = E^2$. What is $E^2 - p^2$? It is the same long which is the same in every coordinate system. In a vacuum it must be the same for a nonrelativistic wave, which is moving right along with the particle, i.e., which is going right by standing still. If the particle is standing still, it would have no momentum. So in this coordinate system, it's particle its energy, which is zero as its rest mass. Thus $E^2 - p^2 = m^2$, so we see that the square of the length of this vector, the four-vector momentum, is equal to m^2 .

From the square of a vector, we can get in turn the "dot product," or the product which we want: " a_μ is one four-vector and b is another." Consider, for instance, the scalar product

$$\sum_i a_\mu b_\nu - \delta_{\mu\nu} = a_0 b_0 - a_1 b_1 - a_2 b_2 - a_3 b_3. \quad (17.16)$$

It is the same in all coordinate systems.

Finally, we shall mention something whose rest mass is 0, zero. A photon of light. For example, a photon is like a particle in that it has an energy and a momentum. The energy of a photon is proportional to its Planck's constant, times the frequency of the photon: $E = h\nu$. Each a photon also carries a momentum, and the momentum of a photon of some other frequency in fact is twice by the wavelength: $p = h/\lambda$. But, for a photon, there is a definite relation between the frequency and the wavelength: $\nu = c/\lambda$. The number of waves per second, times the wavelength of each, is the distance that the light goes in one second, which, of course, is c . This makes immediately that the energy of a photon, and its the momentum times c , are. If $c = 1$, the energy and momentum are equal. That is to say, the rest mass is zero. This is called in this way "zero mass." It is a particle of zero rest mass, with respect to it, it doesn't have any mass. It always goes at the speed c . The total formula for energy is $E = h\nu/c$. Now you see; $E = mc^2$, and $c = \infty$, so the energy is 0! We cannot say that it is zero, the photon really can't do any work, even though it has no mass, but the it possesses by nevertheless using the speed of light.

We also know that the momentum of any particle is equal to its total energy times its velocity if $c = 1$, $p = E$, or, in ordinary units, $p = mc^2/c$. For an electron moving at the speed of light $p = E/c = 1$. The Compton formula, etc. etc. etc. we seen from a moving system, of course given by Eq. 17.12, can tell the momentum we must subtract the energy times c (in this case $c = 1$) to keep the different energies after transmission means that there are different frequencies. This is called the Doppler effect, and one can calculate it easily from Eq. 17.12 using also $c = 1$ and $E = mc^2$.

As Minkowski said, "Space of itself, and time of itself will think and never understand, and only a live neuron between them shall survive."

Rotation in Two Dimensions

18-1 The center of mass

In the previous chapters we have been studying the mechanics of points, in small particles whose internal structure does not concern us. For the next few chapters we shall study the application of Newton's laws to more complicated things. When the word becomes more complicated, it also becomes more interesting, and we shall find that the phenomena associated with the mechanics of a more complex object than just a point are really quite striking. Of course these phenomena involve nothing but the kinematics of Newton's laws, but it is sometimes hard to believe that only *that* can be so much.

The more complicated objects we deal with can be of several kinds. Water flowing, galaxies, whirligigs, etc. The simplest "complicated" object is you, or, to start, is what we call a rigid body, a solid object that is moving as it moves again. However, even such a simple object may have a most complex motion, and we shall explore that outside the simplest aspects of such motion, in which an extended body rotates about itself. A given point on such a body then moves in a plane perpendicular to this axis. Such rotation of a body about a fixed axis is called *pure rotation*, *rotation in one dimension*. We shall later generalize the idea to three dimensions, but in doing so we shall find that, unlike the case of ordinary particle mechanics, rotations are subtle and hard to understand unless we first get a solid grounding in two dimensions.

The first interesting theorem concerning the motion of complicated objects can be observed at work if we throw an object made of a lot of blocks and gravel tied together by strings, into the air. Of course we know it goes in a parabola, because we studied that for a particle. But now our object is *not* a particle, it wobbles and it jiggles and so on. It goes up in a parabola. And, one sees now that this goes up a parabola! Certainly not the point on the corner of the brick, because that is jiggling about; rather it is the end of the wooden stick, or the middle of the wooden stick, or the middle of the block. But something goes up a parabola, there is an effective "center" which moves in a parabola. So our first theorem about complicated objects is to demonstrate that there is a mean position which is mathematically definite but not necessarily a point of the material itself, which goes in a parabola. That is called the theorem of the center of the mass, and the proof of it is as follows.

We may consider any object as being made of lots of little particles, the atoms, with various forces among them. Let i represent an index which denotes one of the particles, (there are millions of them, say 10^{23} , or something); Then the force on the i th particle is, of course, the sum since the acceleration of that particle:

$$\mathbf{F}_i = \sum_j (m_j \mathbf{a}_j) \quad (18.1)$$

In the next few chapters our moving objects will be such as which all the parts are moving at speeds very much lower than the speed of light, and we shall use the non-relativistic approximation for γ quantities. In these circumstances the mass is constant so that

$$\mathbf{F}_i = m_i \mathbf{a}_i / m_i^2 \quad (18.2)$$

Now if we add the forces on all the particles, that is, if we take the sum of all the \mathbf{F}_i 's for all the different indices, we get the total force \mathbf{F} . On the other side of the

18-2 The center of mass

18-2-1 Rotation of a rigid body

18-3 Angular momentum

18-4 Conservation of angular momentum

equation, we get the same thing as though we added before the differentiation:

$$\sum_i m_i \ddot{r}_i = \frac{d}{dt} (\sum_i m_i r_i), \quad (18.3)$$

Therefore the total force is the second derivative of the mass-times-their-position, added together.

Now the total force on all the particles is the same as the external force. Why? A. Through the air all kinds of forces act on the particles because of the strings, the wiggles, the pushing and pulling, and the elastic forces, and when it comes time to add we have to add all these together, we are reduced by Newton's Third Law. Between any two particles the elastic force tends to expand, so that when we add all the elastic forces together, if one particle has forces being exerted on it which cancel out in the sum, therefore the net result is only those forces which arise from other particles which are not included as separate objects; we should be sum. So P Eq. (18.3) is the second derivative of the center of mass, which together is called "the center of mass of the system of particles." The total object is equal to the sum of all the forces on all its constituent particles.

Now it would be nice if we could do in Eq. (18.3) as the total mass times some vector, say \vec{R} . Let us say it is the sum of all the masses, i.e., the total mass. Then \vec{R} will differ a certain amount. That is,

$$\vec{R} = \sum_i m_i \vec{r}_i / M, \quad (18.4)$$

Eq. (18.3) will be simply

$$\vec{F} = d^2(M\vec{R})/dt^2 = M(\vec{r}^2 \vec{R}/M^2), \quad (18.5)$$

since M is a constant. Thus we find that the external force is the total mass times the acceleration of an imaginary point whose position is \vec{R} . This point is called the center of mass of the body. It is a point somewhere in the "middle" of the object, a zone of average \vec{r} in which the different parts have weights or importances proportional to the masses.

We shall discuss this important theorem in greater detail in a later chapter, and we shall then see how our remarks fit two points. First, if $\vec{r}_1, \vec{r}_2, \dots, \vec{r}_N$ are the positions of the various particles in an empty space ship - right side, and wiggly and twisty, and do all kinds of things. But, if the center of mass, this is definitely located, call it \vec{R} , at a definite position, somewhere in the middle. And now what is constant about \vec{R} ? In particular, if it is initially at rest, it will stay at rest. So, if we have come out of a box, perhaps a space ship with people in it, and we calculate the location of the center of mass and find that it is still, then the center of mass is constant, so no ship will fly out of control if forces are acting on it. Of course, the space ship may move a little in space, but that is because the people are walking back and forth inside; when one walks toward the front, the ship goes toward the back since to keep the average position, all the masses *at exactly the same place*.

For rocket propulsion therefore absolutely impossible because one cannot move the center of mass. Now, but of course we find that in propelling an interesting part of the rocket, the uninteresting part must be thrown away. In other words, if we can, with a rocket of zero velocity and we spit + one plus another rocket more than 1000 miles of gas per minute, as the rocket ship goes faster, but the center of mass is still exactly where it was before. So we simply move the part that we let unaccelerated. But part we want to is accelerated.

The second point is inserting the center of mass, which is the reason we introduced it into our discussion. This time, is this if any we need separately from the "inertial" motion of the object, and may therefore be ignored in our discussion of rotation.

18-2 Translation of a rigid body

Now let us discuss rotation. Of course an ordinary object does not simply rotate, it translates, pushes one hands, or to simply rotates we shall discuss the motion of a non-existent ideal object which we call a rigid body. This means no

object, in which the forces between the atoms are so strong, and of such character, that the little forces that are needed to move it do not have to act over any extended distance; it moves almost if we wish to study the motion of each particle in the body, and ignore the motion of its center of mass, there is only one thing left for it to do, and that is to turn. We have to describe that. Now, suppose there is some line in the body which stays put (perhaps it includes the center of mass and perhaps not), and the body is rotating about this particular line as we see. How can we define this rotation? That is easy enough, for if we mark a point somewhere on the object, say P , we can always tell exactly where the object is, if we only know where this point has gone to. The only thing needed to describe the position of P at t is an angle, so rotation consists of a study of the variations of the angle with time.

In order to study rotation, we observe the angle through which a body has turned. Of course, we are not referring to any particular angle inside the object itself; it is not, but we know some angle of the object. We are talking about the angular change of the position of the whole thing, from one time to another.

First, let us study the kinematics of rotation. The angle will change with time, and just as we talked about position and velocity in the case of linear motion, so may we talk about angular position and angular velocity in the case of rotation. In fact, there is a very interesting relationship between rotation in two dimensions and three-dimensional displacement, in which almost every quantity has its analog. Thus, we take the angle θ which defines how far the body has gone around; this replaces the distance s , which defines how far it has gone along. In the same manner, we have a velocity of turning, $\omega = d\theta/dt$, which tells us how much the angle changes in a second, just as $v = ds/dt$ describes how fast a thing moves, or $a = dv/dt$ gives us its acceleration. The angle is measured in degrees, then the angular velocity ω will be ω and ω many radians per second. The greater the angular velocity, the faster the object is turning. The faster the angle changes, we can go on; we can differentiate the angular velocity with respect to time, and we can call $\alpha = d\omega/dt$ ω -rate of the angular acceleration. This would be the analog of the ordinary acceleration.

Now of course we shall have to relate the dynamics of rotation to the laws of dynamics of the particles of which the object is made, or we must find out how a particular particle moves when the angular velocity as such and such. To do this, we take a system particle which is located at a distance r from the axis and say this is at a certain location $P(x, y)$ at a given instant, on the x -axis, say, at $(r, 0)$. If it is a moment $d\theta$ later the angle $\theta + d\theta$ the whole object has turned through $d\theta$, then this particle is carried with it. It is at the same radius away from O as it was before, but is rotated by $d\theta$. The first thing we would like to know is how much the x -displacement and y -displacement y changes. It will be clear, then, that x changes by $-r\omega d\theta$, because of the way angles are defined. The change in y , then, is simply the projection of $r d\theta$ in the y -direction, i.e.

$$dy = -r d\theta \sin \theta = -r \omega d\theta \quad (18.6)$$

Similarly,

$$dx = r \omega d\theta \quad (18.7)$$

If the object is turning with a given angular velocity ω , and, by writing both Eqs. (18.6) and (18.7) by $d\theta$, the velocity of the particle is

$$v_x = -ry = -rd\theta \quad v_y = rx \omega = rd\theta \quad (18.8)$$

Of course if we want to find the magnitude of the velocity, we add since

$$v = \sqrt{v_x^2 + v_y^2} = \sqrt{(rd\theta)^2 + (rd\theta)^2} = \omega(r^2 + r^2) = \omega r \quad (18.9)$$

It should not be exaggerated that the value of the magnitude of this velocity is not ωr , it would be self evident, because by definition r moves $\omega r d\theta$ and the distance it moves per second is $\omega r d\theta$, or ωr .

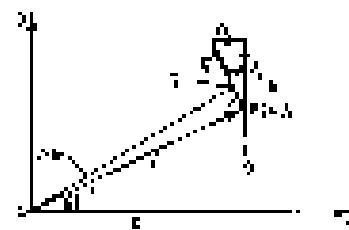

Fig. 18-1. Kinematics of two-dimensional rotation.

Let us now move on to consider the dynamics of rotation. There is one concept force must be introduced. We begin with the notion of work, which we first call the *work* (i.e., negative, re-twisted) when there is no displacement to rotate or to move due to linear movement. A force is the thing that is needed to make linear motion, and the thing that makes something rotate is a "rotary force" or a "rotating force," i.e., a torque. Quantitatively, a torque is a "force" applied to a torque about a pivot? We shall get to the theory of torque quantitatively by studying the work done in rotating an object. We can very easily way of defining a force is to say how much work it does when it acts through a given displacement. We are going to try to relate the analogy between linear and angular quantities by equating the work that we do when we turn something (i.e., in which case we have acting on it) to the torque times the angle it turns through. In other words, the definition of the torque is going to be $\tau = \text{work}/\theta$. And that the linear situation has an absolute analog: force times distance is work, and torque times angle is going to be work. That will be what torque is. Consider, for instance, a rigid body of some kind with various forces acting on it and an axis about which the body rotates. Let us at first concentrate on one force and suppose that this force is applied at a certain point (x, y). How much work would we do? This would be zero. The object through a very small angle! That is, zero. The work done is:

$$\Delta W = F_x \Delta x + F_y \Delta y \quad (13.10)$$

We do not only "resist" (see Eqs. (13.6) and (13.7)) but also add to obtain

$$\Delta W = (F_x^2 + F_y^2)^{1/2} \Delta s \quad (13.11)$$

This is, the amount of work that we have done is in fact equal to the angle through which we have turned the object, multiplied by a strange-looking combination of the force and its distance. This "strange-looking ratio" is what we call the torque. By defining the change in work as the torque times the angle, we have been the formula for torque in terms of the forces. Obviously, torque is not a completely new idea, independent of Newtonian mechanics—just now there is definite definition in terms of the forces.

When there is a vector? To do work, the work that is done is, of course, the sum of the works done by all the forces, plus the work will be a whole lot of work if added together, the sum the forces, each of which is proportional, however, to Δs . We can take the same procedure and therefore can say that the change in the work is equal to the sum of all the torques due to all the different forces that are acting, i.e., ΔW . This sum we might call the total torque, τ . Thus torque will be the moment of force of all the forces, but we shall find, see that this is only because we are working in a plane. It is the unopposed moment is, when other forces simply will affect directly, but only because they are all in the same direction. It is, then, compensated in three dimensions. Thus, for two-dimensional rotation,

$$\Delta W = \tau \Delta \theta_1 + \tau \Delta \theta_2 \quad (13.12)$$

and

$$\tau = \sum \tau_{ij} \quad (13.13)$$

It must be emphasized that the torque is the *in* a given axis. If a different axis is chosen, so that all the x_i and y_i are changed, the value of the torque is *not* by changed too.

Now we pause briefly to note that our foregoing introduction of torque, through the idea of work, gives us a much simpler result for an object in equilibrium: if all the forces on an object are in balance (i.e., if translation and rotation, not only is the net force zero, but the total of all the torques is also zero), *then* if an object is in equilibrium, it will rotate by the forces for a small displacement. Therefore, since $\Delta W = \tau \Delta \theta = 0$, the sum of all the torques must be zero. So there are two conditions for equilibrium: (1) the sum of the forces is zero, *and* then the sum of the torques is zero. Prove that it suffices to assume that the sum of torques need only one axis (in two dimensions) is zero.

Now let us consider a single force, and try to figure out exactly what this torque thing is. In Fig. 18-2 we see a force \mathbf{F} at a point P , where the object has rotated through a small angle $d\theta$. The total torque, of course, is the component of force in the direction of the displacement. In other words it is only the tangential component of the force that counts, and this must be multiplied by the distance $r \sin d\theta$. Therefore we see that the torque is also equal to the tangential component of force perpendicular to the radius times the radius. That makes sense in terms of our ordinary idea of the torque; indeed, if the force were completely radial, it would not produce any "twist" on the body; it is evident that the twisting effect should involve only the part of the force which is not pulling out from the center, and that means the tangential component. Furthermore, it is clear that a given force is more effective on a long arm than near the axis. In fact, in the case where we push right on the axle we do not twist it at all, so it makes sense that the amount of twist, or torque, is proportional both to the radial distance and to the tangential component of the force.

There is a 4.7 x 10⁻¹² coulombs for the torque which is very interesting. We have just seen that the torque is the force times the radius times the sine of the angle θ in Fig. 18-2. But if we extend the line of action of the force and draw the line OS , the perpendicular distance to the line of action of the force (the lever arm of the force) is twice that of the lever arm r shown; that is, in just the same proportion as the tangential part of the force is to the total force. Therefore the formula for the torque can also be stated as the magnitude of the force times the length of the lever arm.

The torque is also of course just the moment of the force. The origin of this word is obscure, but it may be related to the fact that "moment" is derived from the Latin *momentum*, and that the capacity of a force to move an object (using the word in its original sense) increases with the length of the lever arm. In addition, the "moment" means weighted by how far away it is from an axis.

18-3 Angular momentum

Although we have so far considered only the special case of a rigid body, the properties of torque and their mathematical relationships are interesting also even when an object is not rigid. In fact, we can prove a very remarkable theorem: just as external force is the rate of change of a quantity p , which we call the total momentum of a collection of particles, just as external torque is the rate of change of a quantity L which we call the angular momentum of the group of particles.

To prove this, we shall suppose that there is a system of particles on which there are some forces acting and find out what happens to the system as a result of the torque due to these forces. First, of course, we assume without just one particle. In Fig. 18-3 is an particle of mass m , and at axis O ; the particle is necessarily moving in a circle about O , it may be moving in an ellipse like a planet going around the sun, or in some other curve. It is moving somehow, and there are forces on it, and it accelerates according to the usual formula that the component of force is the derivative of the component of position, etc. But let us see what the torque does. The torque equals $\mathbf{r} \times \mathbf{F}_t$, and the force in the x -or y -direction is $m a_x$ times times the acceleration in the x -or y -direction:

$$\begin{aligned}\tau &= \mathbf{r} \times \mathbf{F}_t = m \mathbf{r}_t \\ &= m \omega^2 r \hat{i} \cos \theta - j m \omega^2 r \hat{i} \sin \theta\end{aligned}\quad (18.14)$$

Now, although this does not appear to be the derivative of any single quantity, it is in fact the derivative of the quantity $m \omega^2 r^2 \hat{i} = m \omega^2 \hat{i} / 2$.

$$\begin{aligned}\frac{d}{dt} \left[m \left(\frac{\partial \theta}{\partial t} \right) - i m \left(\frac{\partial x}{\partial t} \right) \right] &= m \left(\frac{d^2 \theta}{dt^2} \right) - \left(\frac{dr}{dt} \right) m \left(\frac{\partial y}{\partial t} \right) \\ &= m \omega^2 \left(\frac{\partial^2 \theta}{\partial t^2} \right) - \left(\frac{dr}{dt} \right) m \left(\frac{\partial^2 x}{\partial t^2} \right) = m \omega^2 \left(\frac{\partial^2 \theta}{\partial t^2} \right).\end{aligned}\quad (18.15)$$

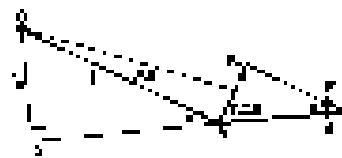

Fig. 18-2. The torque produced by a force.

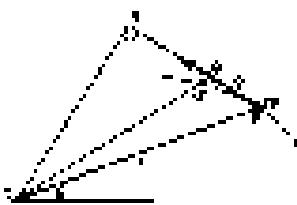

Fig. 18-3. A particle moves about an axis O .

So it is true that the torque is the rate of change of something with time! So we say again that the "something," we just gave a name, we call it L , the angular momentum.

$$L = \text{momentum} \times \text{position}/\text{mass}$$

$$\therefore \tau_{\text{ext}} = \partial L/\partial t \quad (18.16)$$

Although our present discussion is incomplete, the second form for L , given above is definitely correct. So we have found that there is also a conservation law for the angular momentum, that τ 's torque, the angular momentum, is given by an expression in terms of the components of linear momentum that is just like the formula for torque in terms of the force component! Thus, if we want to know the angular momentum of a particle about a axis, we take only the component of the moment arm that is perpendicular, and multiply it by the radius. In other words, what counts for angular momentum is not how far it is going away from the origin, i.e., how much it is going around the origin. Only the perpendicular part of the moment arm counts for angular momentum! Furthermore, the further out the line of the moment arm extends, the greater the angular momentum. And also, because the geometrical facts are the same whether the system is liberal τ or F , it is true that there is a lever arm (or the distance the lever arm of the force on the particle) which is obtained by extending the line of the moment arm, and dividing the perpendicular distance by the axis. But the angular momentum is the magnitude of the contribution times the moment arm lever arm. So we have three formulas for angular momentum, just as we have three formulas for the torque:

$$L = \tau_{\text{ext}} \times \Delta t$$

$$= \text{lever arm} \times \text{force}$$

$$= \text{lever arm} \times \text{mass} \times \text{velocity}. \quad (18.17)$$

Like torque, angular momentum depends upon the position of the axis about which it is to be calculated.

Before proceeding to a treatment of more exact and general, let us apply the above results to a planet going around the sun. In which direction is the force? The force is toward the sun. What, then, is the torque on the object? Of course, the object is not going to be at the axis, but we get a very simple result if we take it to the sun lines, for the torque is the force times the lever arm, or the component of force perpendicular to a times r . But there is an tangential force, so there is no torque about an axis other than. Therefore, the angular momentum of the planet going around the sun must remain constant. Let us see what that means. The tangential component of velocity, since the mass, m , is the same, will be constant, because that is the angular momentum, and the rate of change of angular momentum is the torque, and in this problem, the torque is zero. Of course, since the mass is also a constant, this means that the angular velocity times the radius is a constant. That is a something we already knew for the motion of a planet. Suppose we consider a small amount of time Δt . How far will the planet move when it moves from P to Q ? (Fig. 18-5) If we make Δt very small, we can sweep through the area QPF compared with the much larger area OPF , it is evidently half the base PQ times the height, OP . In other words, the area that is swept through in unit time will be equal to the velocity times the lever arm of the velocity plus one half r . Thus the rate of change of area is proportional to the angular momentum, which is constant. So Kepler's law alone, applied to equal areas in a short description of the statement of the law of conservation of angular momentum, when there is no longer granted to the laws.

18-4 Conservation of angular momentum

Now we shall give an example what happens when there is a large number of particles, such as object is made of many masses with many forces acting between them and on them from the outside. Of course, we already know that even for given τ we will have different angular particle (which is the mass or particle per its

comes from sum of $m_i \vec{r}_i \times \vec{\omega}$ due to the rate of change of the angular momentum of the particle, and that the angular momentum of the i particle is $\vec{m}_i \vec{v}_i \times \vec{r}_i$ (momentum lever arm). Now suppose we add the i particles, i.e. all the particles are still in the total torque τ . Then this will be the rate of change of the sum of the angular momenta of all the particles, and this defines a new quantity which we call the total angular momentum \vec{L} . Just as the total momentum of a object is the sum of the momenta of all the parts, so the angular momentum is the sum of the angular momenta of all the parts. Thus the rate of change of the total L is the total torque

$$\tau = \sum \tau_i, \quad \sum \frac{d\vec{L}_i}{dt} = \frac{d\vec{L}}{dt}. \quad (18.18)$$

Now it might seem that this total torque is a complicated thing. There are n of these in total, forces and n of the couplet forces to be considered. But, if we take Newton's law of action and reaction we see, not surprisingly, that the action and reaction are equal, but also that they are directed exactly oppositely along the same line. However, one of them may be zero, say $\vec{r}_i \times \vec{F}_{i\text{ext}}$, but we easily assume it. Then the two couplets in the reaction region due to other central interactions will be equal and opposite because the lever arms for any two are equal. Therefore, the external torque balance you pair by pair, and so we have: The remarkable theorem that the rate of change of the total angular momentum about any axis is equal to the external torque about that axis!

$$\tau = \sum \tau_i = \tau_{\text{ext}} = dL/dt. \quad (18.19)$$

Thus we have a very powerful theorem controlling the motion of large collections of particles, which permits us to study the overall motion without having to look at the detailed trajectory inside. The theorem is true for any collection of objects, whether they form a rigid body or not.

One extremely simple but nice case of this new theorem is the law of conservation of angular momentum: if no external couples act upon a system of particles, the angular momentum is thus constant.

A special case of great importance is that of a rigid body, that is, an object of a definite shape that is just turning around. Consider an object that is fixed to some axis of dimension, and which is rotating about a fixed axis. We can just set the object how the same body would do nothing at all. Note that it's difficult to tell what angular momentum of this object. If the mass of one of its particles is m , and its position in location is at (x_i, y_i) , then the problem is to find the angular momentum of that particle, because the total angular momentum is the sum of the angular momenta of all such particles in the body. For an object going around in a circle, the angular momentum of one is \rightarrow the mass times the velocity times the distance from the axis, and the velocity is equal to the angular velocity times the distance from the axis:

$$J_i = m v_i r_i = m \omega r_i \quad (18.20)$$

or, summing over all the particles i , we get

$$I = J_i. \quad (18.21)$$

where

$$I = \sum_i m v_i r_i. \quad (18.22)$$

This is the analog of the fact that the momentum is mass times velocity. Velocity is replaced by angular velocity, and we see that the mass is replaced by some thing which we call the moment of inertia I , which is analogous to the mass. Equations (18.21) and (18.22) mean that a body has inertia for twisting which depends not just on the mass, but on how far away they are from the axis. So, if we have two objects of the same mass, when we put the mass further away from the axis, the inertia for twisting will be higher. This is easily demonstrated by the apparatus

look in Fig. 18-4, where a weight M is kept from falling very fast because it has to turn. It being weighted now, it turns, causes us to use less by the units, and M speeds up at a constant rate. But when we change the moment of inertia by putting the two masses much farther away from the axis, then we see that M accelerates much less rapidly than it did before, because the body has much more inertia against turning. The amount of inertia is the inertia against turning, and is the sum of the contributions of all the masses, times their distance squared from the axis.

There is one important relation between mass and moment of inertia which is very dramatic. The mass of an object never changes, but its moment of inertia can be changed. If we stand on a转台 (a rotatable stand with our arms unextended, and hold some weight M in our hands) and rotate slowly, we may change our moment of inertia by drawing our arms in, but our mass does not change. When we do this, all kinds of wonderful things happen, because of the law of the conservation of angular momentum: if the net external torque is zero, then the angular momentum of the system remains constant. Initially we were rotating with a large moment of inertia I_1 at a low angular velocity ω_1 , and the angular momentum was $I_1\omega_1$. Then we changed our moment of inertia by pulling our arms in, say to a smaller value I_2 . Then the way in which has to go is the same because the total angular momentum has to stay the same, so $I_2\omega_2 = I_1\omega_1$. Using that, if we reduce the moment of inertia, we have to increase the angular velocity.

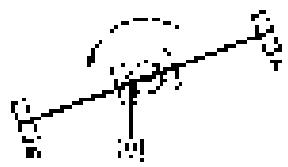

Fig. 18-4. The inertia for rotating depends upon the lever arm of the inertia.

Center of Mass; Moment of Inertia

19-1 Properties of the center of mass

In the previous chapter we found that if a great many forces are acting on a complicated mass of particles, whether the particles comprise a rigid or a nonrigid body, or a cloud of stars, or anything else, and we find the sum of all the forces (that is, of course, the external forces, because the internal forces balance out), then if we consider the body as a whole, and say it has a total mass M , there is a certain point "inside" the body, called the center of mass, such that the net resulting external force produces an acceleration of this point, just as though the whole mass were concentrated there. Let me now discuss the center of mass in a little more detail.

The location of the center of mass (abbreviated CM) is given by the equation

$$y_{CM} = \frac{\sum m_i y_i}{\sum m_i}. \quad (19.1)$$

This is, of course, a vector equation which is really three equations, one for each of the three directions. We shall consider only the x -direction, because if we can understand that, we can understand the other two. What does $X_{CM} = \sum m_i x_i / \sum m_i$ mean? Suppose for a moment that the object is divided into little pieces, all of which have the same mass m ; then the total mass is simply the number N of pieces times the mass of one piece, say one gram, or any unit. Then this equation simply says that we add all the x 's, and then divide by the number of pieces that we have added: $X_{CM} = m \sum x_i / mN = \sum x_i / N$. In other words, X_{CM} is the average of all the x 's, if the masses are equal. But suppose one of them were twice as heavy as the others. Then in the sum, that x would come in twice. This is easy to understand, for we can think of the total mass as being split into two equal parts, just like the others; then in taking the average, of course, we have to count that a twice heavier there are two masses there. Thus X is the average position, in the x -direction, of all the masses, the' mass being counted a number of times proportional to the mass, as though the object were divided into "little grams." From this it is easy to prove that X must be somewhere between the largest and the smallest x , and, therefore lies inside the envelope enclosing the entire body. It does not have to be in the material of the body, for the body could be a hoop, and the center of mass is in the center of the hoop, not in the hoop itself.

Of course, if an object is symmetrical in some way, for instance, a rectangle, so that it has a plane of symmetry, the center of mass lies somewhere on the plane of symmetry. In the case of a rectangle there are two planes, and that balances it adequately. But if it is just any symmetrical object, then the center of gravity lies somewhere on the axis of symmetry, because in those circumstances there are as many positive as negative x 's.

Another interesting proposition is the following very obvious one. Suppose that we imagine an object to be made of two pieces, A and B (Fig. 19-1). Then the center of mass of the whole object can be calculated as follows. First, find the center of mass of piece A, and then of piece B. Also, find the total mass of each piece, M_A and M_B . Then consider a new problem, in which a point mass M_A is at the center of mass of object A, and another point mass M_B is at the center of mass of object B. The center of mass of these two point masses is then the center of mass of the whole object. In other words, if the centers of mass of various parts

19-1 Properties of the center of mass

19-2 Locating the center of mass

19-3 Finding the moment of inertia

19-4 Rotational kinetic energy

Fig. 19-1. The CM of a compound body lies on the line joining the CM's of the two composite parts.

of an object have been worked out, we do not have to start all over again to find the center of mass of the whole object; we just have to put the pieces together, treating each one as a point mass situated at the center of mass of that piece. Let us see why that is. Suppose that we wanted to calculate the center of mass of a composite object, some of whose particles are considered to be members of object A and some members of object B . The total sum $\sum m_i x_i$ can then be split into two pieces—the sum $\sum_{i \in A} m_i x_i$ for the A object only, and the sum $\sum_{i \in B} m_i x_i$ for object B only. Now if we were computing the center of mass of object A alone, we would have exactly the first of these sums, and we know that this by itself is $M_A X_A$, the total mass of all the particles in A times the position of the center of mass of A , because that is the theorem of the center of mass, applied to object A . In the same manner, just by looking at object B , we get $M_B X_B$, and of course, adding the two yields $M X$:

$$M X_{\text{tot}} = \sum_i m_i x_i + \sum_n m_n x_n \\ = M_A X_A + M_B X_B. \quad (19.2)$$

Now since M is evidently the sum of M_A and M_B , we see that Eq. (19.2) can be interpreted as a special example of the center of mass formula for two point objects, one of mass M_A located at X_A and the other of mass M_B located at X_B .

The theorem concerning the motion of the center of mass is very interesting, and has played an important part in the development of our understanding of physics. Suppose we assume that Newton's law is right for the small component parts of a much larger object. Then this theorem shows that Newton's law is also correct for the larger object, even if we do not study the details of the object, but only the total force acting on it and its mass. In other words, Newton's law has the peculiar property that if it is right on a certain small scale, then it will be right on a larger scale. If we do not consider a baseball as a tremendously complex thing, made of myriads of interacting particles, but study only the motion of the center of mass and the external forces on the ball, we find $F = ma$, where F is the external force on the baseball, m is its mass, and a is the acceleration of its center of mass. So $F = ma$ is a law which reproduces itself on a larger scale. (There ought to be a good word, out of the Greek, perhaps, to describe a law which reproduces the same law on a larger scale.)

Of course, one might suspect that the first laws that would be discovered by human beings would be those that would reproduce themselves on a larger scale. Why? Because the actual scale of the fundamental gears and wheels of the universe are of cosmic dimensions, which are at much finer than our observations that we are moreover near that scale in our ordinary observations. So the first things that we would discover must be true for objects of no special size relative to all atomic scales. If the laws for small particles did not reproduce themselves on a larger scale, we would not discover these laws very easily. What about the reverse problem? Must the laws on a small scale be the same as those on a larger scale? Of course it is not necessarily so in nature, that at an atomic level the laws have to be the same as on a large scale. Suppose just the true laws of motion of atoms were given by some strange equation which does not have the property that when we go to a larger scale we reproduce the same law, but instead has the property that if we go to a larger scale, we can approximate it by a certain expression such that, if we extend that expression up and up, it keeps reproducing itself on a larger and larger scale. That is possible, and in fact that is the way it works. Newton's laws are the "last cut" of the atomic laws extrapolated to a very large size. The actual laws of motion of particles on a fine scale are very peculiar, but if we take large numbers of them and compound them, they approximate, but only approximately, Newton's laws. Newton's laws then permit us to go on to a higher and higher scale, and it still seems to be the same law. In fact, it becomes more and more accurate as the scale gets larger and larger. This self-reproducing factor of Newton's laws is thus really not a fundamental feature of nature, but is an important historical feature. We would never discover the fundamental laws of the atomic particles or first observation because the first observations are much too crude. In fact, in this

out that the fundamental atomic laws, which we call quantum mechanics, are quite different from Newton's laws, and are difficult to understand because all our direct experiences are with large-scale objects and the small-scale atoms behave like nothing we see once is so scale. So we cannot say, "An atom is just like a planet going around the sun," or anything like that. It is like nothing we are familiar with because there is nothing like it. As we apply quantum mechanics to larger and larger things, the laws about the behavior of atoms together do not reproduce themselves, but produce new laws, which are Newton's laws, which then continue to reproduce themselves from, say, micro-micromgram size, which still is billions and billions of atoms, on up to the size of the earth, and above.

Let us now return to the center of mass. The center of mass is sometimes called the center of gravity, for the reason that, in many cases, gravity may be considered uniform. Let us suppose that we have small enough dimensions that the gravitational force is not only proportional to the mass, but is everywhere parallel to some fixed line. Then consider an object in which there are gravitational forces on each of its constituent masses. Let m be the mass of one part. Then the gravitational force on that part is $m g$. Now the question is, where can we apply a single force to balance the gravitational force on the whole thing, so that the entire object, if it is a rigid body, will not turn? The answer is that the force must go through the center of mass, and we show this in the following way. In order that the body will not turn, the torque produced by all the forces must add up to zero, because if there is a torque, there is a change of angular momentum, and thus a rotation. So we want calculate the total of all the torques on all the particles, and see how much torque law is about any place and it should be zero if this axis is at the center of mass. Now, examining τ horizontally and vertically, we know that the torques are the forces in the x -direction times the lever arm x (that is to say, the lever times the lever arm around which we want to calculate the torque). Now the total torque is the sum

$$\tau = \sum m_i g x_i = g \sum m_i x_i. \quad (19.5)$$

so if the total torque is to be zero, the sum $\sum m_i x_i$ must be zero. But $\sum m_i x_i = Mx$, the total mass times the distance of the center of mass from the axis. Thus the x distance of the center of mass from the axis is zero.

Of course, we have checked the result only for the x -distance, but if we use the true center of mass the object will balance in any position, because if we turned it 90 degrees, we would have y 's instead of x 's. In other words, when an object is supported at its center of mass, there is no torque on it because of a parallel gravitational field. In case the object is so large that the nonparallelism of the gravitational forces is significant, then the center where one must apply the balancing force is not simple to describe, and is deflected slightly from the center of mass. That is why one must distinguish between the center of mass and the center of gravity. The fact that an object supported entirely at the center of mass will balance in all positions has another interesting consequence. If, instead of gravitation, we have a pseudoforce due to acceleration, we may use exactly the same mathematical procedure to find the position to support it so that there are no torques produced by the inertial force of acceleration. Suppose that the object is held in some instant inside a box, and that the box, and everything contained in it, is accelerating. We know that, from the point of view of someone at rest relative to this accelerating box, there will be an effective force due to inertia. That is, to make the object go along with the box, we have to push on it to accelerate it, and this force is "balanced" by the "force of inertia," which is a pseudoforce equal to the mass times the acceleration of the box. To the man in the box, this is the same situation as if the object were in a uniform gravitational field whose " x " value is equal to the acceleration a . Thus the inertial force due to accelerating an object has no torque about the center of mass.

This fact has a very interesting consequence. In an inertial frame that is not accelerating, the torque is always equal to the rate of change of the angular momentum. However, about an axis through the center of mass of an object which

is accelerating, it is still true that the torque is equal to the rate of change of the angular momentum. Even if the center of mass is accelerating, we may still choose one special axis, namely, one passing through the center of mass, such that it will still be true that the torque is equal to the rate of change of angular momentum around that axis. Thus the theorem that torque equals the rate of change of angular momentum is true in two general cases: (1) in fixed axis in inertial space; (2) an axis through the center of mass, even though the object may be accelerating.

19-2 Locating the center of mass

The mathematical techniques for the calculation of centers of mass are in the province of a mathematical tourist, and such problems provide good exercise in integral calculus. After you have learned calculus, however, and want to know how to locate centers of mass, it is nice to know certain tricks which can be used to do so. One such trick makes use of what is called the theorem of Pappus. It works like this: if we take any closed area in a plane and generate a solid by moving it through space such that each point is always moved perpendicular to the plane of the area, the resulting solid has a total volume equal to the area of the cross section times the distance that the center of mass moved. Certainly this is true if we move the area in a straight line perpendicular to itself; but if we move it in a circle or in some other curve, then it generates a rather peculiar volume. For a curved path, the outside goes around further, and the inside goes around less, and these effects balance out. So if we want to locate the center of mass of a plane sheet of uniform density, we can remember that the volume generated by spinning it about an axis is the distance that the center of mass goes around, times the area of the sheet.

For example, if we wish to find the center of mass of a right triangle of base B and height H (Fig. 19-2), we might solve the problem in the following way. Imagine an axis along H , and rotate the triangle about that axis through $2\pi/3$ degrees. This generates a cone. The distance that the center of mass has moved is $\pi H/3$. The area which is being moved is the area of the triangle, $\frac{1}{2}BH$. So the distance of the center of mass times the area of the triangle is the volume swept out, which is of course $\pi B^2 H/2$. Thus $(\text{area})(\frac{1}{2}\pi H)$ = $\pi B^2 H/2$, or $\pi = B/3$. In a similar manner, rotating about the other axis, or by symmetry, we find $\rho = H/3$. In fact, the center of mass of any uniform triangular area is where the three medians, the lines from the vertices through the centers of the opposite sides, all meet. That point is $1/3$ of the way along each median. Check! Since the triangle splits into 6 pieces, each parallel to a base. Note that the median line bisects every piece, and therefore the center of mass lies on this line.

Now let us try a more complicated figure. Suppose that it is desired to find the position of the center of mass of a uniform semicircular disc—a disc sliced in half. Where is the center of mass? For a full disc, it is at the center, of course, but a half-disc is more difficult. Let r be the radius and x be the distance of the center of mass from the straight edge of the disc. Spin it around this edge as axis to generate a sphere. Then the center of mass has gone around 2π , the area is $\pi r^2/2$ (because it is only half a circle). The volume generated is, of course, $4\pi r^3/3$, from which we find that

$$(2\pi r)(\frac{1}{2}\pi r^2) = 4\pi r^3/3,$$

or

$$r = 4r/3.$$

There is another theorem of Pappus, which is a special case of the above one, and therefore equally true. Suppose that instead of the solid semicircular disc, we have a semicircular piece of wire with uniform mass density along the wire, and we want to find its center of mass. In this case there is no cone in the interior, only on the wire. Then it turns out that the area which is swept by a plane curved line, when it moves as before, is the distance that the center of mass moves times the length of the line. (The line can be thought of as a very narrow area, and the previous theorem can be applied to it.)

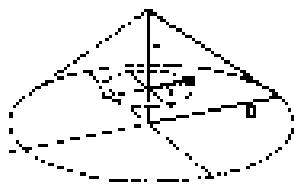

Fig. 19-2. A right triangle and a right circular cone generated by rotating the triangle.

19.3 Finding the moment of inertia

Now let us discuss the problem of finding the moments of inertia of various objects. The formula for the moment of inertia about the center of an object is

$$I = \sum m_i(x_i^2 + y_i^2)$$

or

$$I = \int (x^2 + y^2) dm = \int (x^2 + y^2) \rho dV. \quad (19.4)$$

That is, we must sum the masses, each one multiplied by the square of its distance ($x_i^2 + y_i^2$) from the axis. Note that it is not the three-dimensional distance, only the two-dimensional distance squared, even for a three-dimensional object. For the present part, we shall restrict ourselves to two-dimensional objects, but the formula for rotation about the z -axis is just the same in three dimensions.

As a simple example, consider a rod rotating about a perpendicular axis through one end (Fig. 19-3). Now we must sum all the masses times the x distances squared (the y 's being all zero in this case). What we mean by "the sum" of course, is the integral of x^2 times the little elements of mass. If we divide the rod into small elements of length dx , the corresponding elements of mass are proportional to dx , and if L were the length of the whole rod the mass would be M . Therefore

$$dm = M dx/L$$

and so

$$I = \int_0^L x^2 \frac{M dx}{L} = \frac{M}{L} \int_0^L x^2 dx = \frac{ML^2}{3}. \quad (19.5)$$

The dimensions of moment of inertia are always mass times length squared, so all we really had to work out was the factor $1/3$.

Now what is I if the rotation axis is at the center of the rod? We could just do the integral over again, letting x range from $-\frac{L}{2}$ to $\frac{L}{2}$. But let us notice a few things about the moment of inertia. We can imagine the rod as two rods, each of mass $M/2$ and length $L/2$; the moments of inertia of the two small rods are equal, and are both given by the formula (19.5). Therefore the moment of inertia is

$$I = \frac{2(M/2)(L/2)^2}{3} = \frac{ML^2}{12}. \quad (19.6)$$

Thus it is much easier to turn a rod about its center than to swing it about an end.

Of course, we could go on to compute the moments of inertia of various other bodies of interest. However, while such computations provide a valuable source of important exercise in the calculus, they are not basically of interest to us as such. There is, however, an interesting theorem which is very useful. Suppose we have an object, and we want to find its moment of inertia around some axis. This means we want the kinetic needed to carry it by rotation about that axis. Now if we support the object or pivot at the center of mass, so that the object does not turn as it rotates about the axis (because there is no torque on it, linear inertia effects, and therefore it will not turn when we start moving it), then the forces needed to swing it around act the same as though all the mass were concentrated at the center of mass, and the moment of inertia would be simply $I = MR_{CM}^2$, where R_{CM} is the distance from the axis to the center of mass. But of course that is not the right formula for the moment of inertia of an object, which is really being rotated as it revolves, because not only is the center of it moving in a circle, which would add twice an amount I_C to the moment of inertia, but also we must find I about its center of mass. So it is not unreasonable that we must add to I_C the moment of inertia I_C about the center of mass. So it is a good guess that the total moment of inertia about any axis will be

$$I = I_C + MR_{CM}^2 \quad (19.7)$$

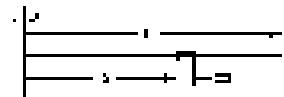

Fig. 19-3. A straight rod of length L rotating about a z -axis through one end.

This theorem is called the *parallel-axis theorem*, and may be easily proved. The moment of inertia about any axis is the same times the sum of the x_i^2 's and the y_i^2 's, each squared: $I = \sum (x_i^2 + y_i^2)m_i$. We shall concentrate on the x 's, but of course the y 's work the same way. Now x' is the distance of a particular point from the origin, but let us consider how it would look if we measured x' from the CM, instead of x from the origin. To get ready for this analysis, we write

$$x_i = x'_i + X_{CM}.$$

Then we just square this to find

$$x_i^2 = x'^2 + 2x'_iX_{CM} + X_{CM}^2.$$

So, when this is multiplied by m_i , and summed over all i , what happens? Taking the constants outside the summation sign, we get

$$I_x = \sum m_i x_i^2 + 2X_{CM} \sum m_i x'_i + X_{CM}^2 \sum m_i.$$

The third sum is easy; it's just MX_{CM}^2 . In the second sum there are two pieces, one of them is $\sum m_i x'_i$, which is the total mass times the displacement of the center of mass. But this certainly has nothing to do with the center of mass, and in these axes, the average position of all the particles, weighted by the masses, is zero. The first sum, of course, is the x part of I . Thus we arrive at Eq. (19.7), just as we guessed.

Let us check (19.7) for one example. Let us just see whether it works for the rod. For an axis through one end, the moment of inertia should be $ML^2/3$, for we calculated that. The center of mass of a rod, of course, is at the center of the rod, at a distance $L/2$. Therefore we should find that $ML^2/3 = ML^2/12 + M(L/2)^2$. Since one-quarter plus one-twelfth is one-third, we have made no fundamental error.

Incidentally, we did not really need to use an integral to find the moment of inertia (19.5). If we simply assume that it is ML^2 times γ , an unknown coefficient, and then use the argument about the two halves to go from (19.6), then from our argument about transferring the axis we could prove that $\gamma = \frac{1}{3}$. So γ must be $1/3$. There is always another way to do it!

In applying the parallel axis theorem, it is of course important to remember that the axis for I , must be parallel to the axis about which the moment of inertia is wanted.

One further property of the moment of inertia is worth mentioning because it is often helpful in finding the moment of inertia of certain kinds of objects. This property is that if one has a plane figure and a set of coordinate axes with origin in the plane and z -axis perpendicular to the plane, then the moment of inertia of this figure about the x -axis is equal to the sum of the moments of inertia about the x - and y -axes. This is easily proved by noting that

$$I_x = \sum m_i(x_i^2 + z_i^2) = \sum m_i x_i^2$$

(since $z_i = 0$). Similarly,

$$I_y = \sum m_i(x_i^2 + z_i^2) = \sum m_i y_i^2$$

but

$$\begin{aligned} I_z &= \sum m_i(x_i^2 + y_i^2) = \sum m_i x_i^2 + \sum m_i y_i^2 \\ &= I_x + I_y. \end{aligned}$$

As an example, the moment of inertia of a uniform rectangular plate of mass M , width w , and length l , about an axis perpendicular to the plate and through its center is simply

$$I = Mlw^2 + l^2w^2/12,$$

because the moment of inertia about an axis in its plane and parallel to its length is $Mw^2/12$, etc., just as for a rod of length w , and the moment of inertia about the other axis in its plane is $Ml^2/12$, just as for a rod of length l .

To summarize, the moment of inertia of an object about a given axis, which we shall call the *axis of rotation*, has the following properties:

- (a) The moment of inertia is

$$I_z = \sum m_i(r_i^2 + y_i^2) = \int (r^2 + y^2) dm.$$

- (b) If the object is made of a number of pieces, each of whose moment of inertia is known, the total moment of inertia is the sum of the moments of inertia of the pieces.
- (c) The moment of inertia about any given axis is equal to the moment of inertia about a parallel axis through the CM plus the total mass times the square of the distance from the axis to the CM.
- (d) If the object is a plane figure, its moment of inertia about any perpendicular to the plane is equal to the sum of the moments of inertia about any two mutually perpendicular axes lying in the plane and intersecting at the perpendicular axis.

The moments of inertia of a number of elements of shapes having uniform mass densities are given in Table 19-1, and the moments of inertia of some other objects, which may be deduced from Table 19-1, using the above properties, are given in Table 19-2.

Table 19-1

Object	axis	I_z
Thin rod, length L	end or center	$ML^2/12$
Thin, concentric circular ring, radii r_1 and r_2	loop at center	$M(r_1^2 + r_2^2)/2$
Sphere, radius r	through center	$2Mr^2/5$

Table 19-2

Object	axis	I_z
Rect. sheet, sides a, b	both ends	$Ma^2/12$
Rect. sheet, sides a, b	center	$M(a^2 + b^2)/12$
Thin annulus, radii r_1, r_2	any diameter	$M(r_1^2 + r_2^2)/4$
Rect. parallelepiped, sides a, b, c	c , through center	$M(a^2 + b^2)/12$
Right cyl., radius r , length L	$\perp L$, through center	$Mr^2/2$
Right cyl., radius r , length L	$\perp L$, through center	$Mr^2/4 + L^2/12$

19-4 Rotational kinetic energy

Now let us go on to discuss dynamics further. In the analogy between linear motion and rotation just on that we discussed in Chapter 18, we used the work theorem, but we did not talk about kinetic energy. What is the kinetic energy of a rigid body, rotating about a certain axis with an angular velocity ω ? We can immediately guess the correct answer by using our analogies. The moment of inertia corresponds to the mass, angular velocity corresponds to velocity, and so the kinetic energy ought to be $(1/2)\omega^2$, and indeed it is, as will now be demonstrated. Suppose the object is rotating about some axis so that each point has a velocity whose magnitude is ωr , where r is the radius from the particular point to the axis.

Then if ω is the ω of that point, the total kinetic energy of the wheel is just the sum of the kinetic energies of all of the little pieces.

$$T = \frac{1}{2} \sum m_i v_i^2 = \frac{1}{2} \sum m_i (\omega r_i)^2$$

Now v^2 is a constant, the same for all points. This

$$T = \frac{1}{2} \omega^2 \sum m_i r_i^2 = \frac{1}{2} I \omega^2. \quad (19.8)$$

At the end of Chapter 28 we put that out, but there are some interesting phenomena associated with an object which is not rigid, but which changes from one rigid condition with a definite moment of inertia to another one condition. Namely, in our example of the turntable, we had a certain moment of inertia I_{turn} with our arms stretched out, and a certain angular velocity ω_0 . When we pulled our arms in, we had a different moment of inertia I_f , and a different angular velocity ω_f . In again we were "right." The angular momentum, $I \omega$, remained constant, since there was no torque due to external forces of the turntable. This means that $I \omega_0 = I_f \omega_f$. Now what about the energy? That is an interesting question. With our arms pulled in, we turn faster, but our moment of inertia is less, and so obviously there's more energy right? But they aren't because what does decrease is $I \omega$, not ω . So the answer is, the kinetic energy before and after the kinetic energy before is $\frac{1}{2} I \omega_0^2 - \frac{1}{2} I_f \omega_f^2$, where $I = I_{\text{turn}} = I_f + I$ the angular momentum. Afterward, by the same argument, we have $\frac{1}{2} I_f \omega_f^2$, and since $\omega_f > \omega_0$, the kinetic energy of rotation is greater than it was before. So we had a certain energy when our arms were out, and when we pulled them in, we were turning faster and had more kinetic energy. What happened to the theorem of conservation law of energy? So clearly you never do any work. We did work when did we do any work? When we move a weight horizontally, we do not do any work. If we have a thing and pull it in, we do not do any work. But this is when we are not rotating! When we are rotating, there is a centrifugal force on the weights. They are trying to fly out so when we are going around we have to pull the weights in against the centrifugal force, i.e., the work we do against the centrifugal force F_c , is equal with the difference in rotational energy, and of course it does. This is where the conservation of energy comes from.

This is still another interesting fact, which we can treat only intuitively, as a matter of general knowledge. This figure is a little more abstract, but it works pointing out because it is quite curious and produces many interesting effects.

Consider first the experimental setup. Consider the body and the ring separately from the point of view of the man who is turning. After the weights are pulled in, the wheel object is spinning faster, but observe, the overall part of the body is not changing, yet it is turning faster than the ring. So, if we were to draw a circle around the inner body, and consider only ω_0 to make the circle, their angular momentum would change, they are going faster. Therefore there must be a torque exerted on the body while we spin our arms. No torque can be exerted by the centrifugal force, because that is radial. So that means that among the forces that are developed in a rotating system, centrifugal force is the business story, there is another force. The other force is called *Gyroscopic force*, and it has the very strong property that when we move something in a rotating system, it seems to be pushed sideways. Like the centrifugal force, it is an apparent force. It is the law of a reason. It is rotating, and moves something radially out, and outwards, and also push it sideways to move it radially. This is why just what we have to learn is what turned the body around.

Now let us develop a formula to show how the Coriolis force really works. Suppose Max is sitting on a carousel that is going to be stationary. But from the point of view of Joe, who is standing on the ground and who knows the right laws of mechanics, the is moving it going around. Suppose that we have drawn a radial line on the carousel, and that Max is moving some mass steadily along this line. We would like to determine what is the greatest force he is required to do this. We can do this by paying attention to the angular momentum of the mass. It is

always going around with the same tangential velocity v , so that the angular momentum is

$$L = m v_{\text{tang}} r = m v r = m v^2 r$$

so when the mass is close to the center, it has relatively little angular momentum, but if we move it to a new position farther out, if we increase r , it has more angular momentum, so a torque must be exerted in order to move it along the radius (to pull along the radius) in accordance with the conservation of angular momentum along the radius. If an object only moves on a radius, no torque is constant, so that the torque is

$$\tau = I \alpha = \frac{dI}{dt} = \frac{J_{\text{orbital}}^2}{r^3} = J_{\text{orbital}} \frac{dr}{dt},$$

where J_{orb} is the Orbital Momentum. We actually want to know is what sideways force has to be exerted by Moon in order to move its orbital speed $v = dr/dt$. This is $F_c = \tau/r = 2m\omega^2$.

Now let us have a friend for the Coriolis force let instant at the θ angle. Let's move carefully, to see whether we are understanding the origin of this force from a more elementary point of view. We note that the Coriolis force is the same in every radius, and is evidently present even at the equator. But it is especially easy to understand it at the origin, just by looking at what happens from the orbital equation of the Moon, who is standing on the ground. Figure 19-4 shows three successive views of just as it passes the origin at $t = 0$. Because of the rotation of the earth, we see that it does not move in a straight line, but in a curved path tangent to a radius of the earth at $r = 0$. In order for it to go in a curve, there must be a force to accelerate it in physical space. It is the Coriolis force.

This is not the only case in which the Coriolis force occurs. We can also show this. If an object is moving with constant speed v , and the circumference of a circle, there is also a Coriolis force. Why? Moon has a velocity say around the circle. On the other hand, he sees an object around the circle with the velocity $v = v_0 - \omega r$, because it is also carried by the rotation. Therefore we know who the force really is, namely, the total centripetal force due to the velocity v_0 , or v_0^2/r ; that is the centripetal force. Now from Moon's point of view, the centripetal force has three pieces. We may write it all out as follows:

$$F_c = \frac{v_0^2}{r} = \frac{m v_0^2}{r} = 2m\omega v_0 + m\omega^2 r.$$

Now, $m\omega$ is the force that Moon weight has. Let me try to understand it. Would she appreciate the first term? "Yes" he would say, "but if I were not rotating, there would be no centrifugal force; if I were to go around a circle with velocity v_0 ." This is simply the centripetal force that Moon would expect, having nothing to do with rotation. In addition, Moon's would notice that there is another centripetal force; but would he see on objects which are standing v_0 ? on his is moved. This is the centrifugal force. There is another term in addition to these, namely the second term which is again $2m\omega v_0$. The Coriolis force F_c is tangential when the velocity v_0 exists, and note it is radial when the velocity is tangential. i.e. v_0 , one expresses v_0 as a radius $r\omega$ relative to the other. The force is always at the same direction, relative to the velocity, no matter in which direction the velocity v_0 . The force is at right angles to the velocity, and of magnitude $2m\omega v_0$.

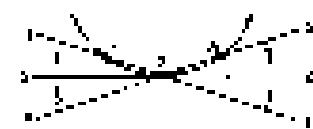

Fig. 19-4. Three successive views of a point moving rectely on a rotating turntable.

Newtonian mechanics

20-1 Torque in three dimensions

In this exercise, we shall discuss one of the most remarkable and amazing consequences of mechanics: the behavior of a rotating wheel. In order to do this we must first extend the mathematical framework of rotational motion. The principles of angular momentum, long known so far to three-dimensional space. We will see how they reduce in all cases to a very simple form. All the "cross" terms, because the word take away from us, and we must now turn to ω in subscripts. In an absolute sense we can proceed only by the fundamental laws and apply them in a very few situations of special interest.

First, we notice that if we have rotation in three dimensions, whether of a rigid body or a rigid system, what we deduced for two dimensions is still right. That is, it is still true that $\Delta E_k = \Delta E_\tau$ is the torque "in the xy-plane," or the torque "around the z-axis." That is, the net torque is still equal to the sum of the two " $\tau_{xy} = p_{xy}$, for if we go back over the derivation of Eq. (14.1a) from Newton's laws we see that we did not have to assume that the rotation was in a plane. When we differentiate $p_{xy} = p_{xy}$, we get $\Delta E_k = \Delta E_\tau$, so this theorem is still right. The quantity $p_{xy} = p_{xy}$ then, is still the angular momentum belonging to the xy-plane, or the angular momentum about the z-axis. It is being true, we can use the other part of this and get another equation. For instance, we can use the zy-plane, and it is clear from symmetry that, for just this理由 the x and z for τ we would find $\Delta E_z = \Delta E_\tau$ for the torque and $p_{zy} = p_{zy}$, would be the angular momentum associated with the zy-plane. Of course we could have another plane, the xz-plane, and for this we would find $\Delta E_x = \Delta E_\tau$, $\delta E_x^2(p_{xz}) = \Delta E_\tau$.

That these three equations can be deduced for the moment of a triple you will is quite clear. Furthermore, if we added such things as $p_{yz} = p_{yz}$, ΔE_y^2 for many variables and called it the total angular momentum we would have three terms for the three planes p_{xy} , p_{yz} and p_z , and if we did the same with the forces, we would obtain the torque in the xy, yz, xz, and z axes. Thus we would have shown that the external torque associated with any plane is equal to the rate of change of the angular momentum associated with that plane. This is just a generalization of what we wrote in two dimensions.

Let now take one step, "Ah, but there are more planes; after all, can we not take some other fixed angle, and calculate the torque in that plane from the forces?" Since we would have to write a rather lot of equations for every such plane, we would have a lot of "useless" terminology enough. It turns out that it is easier to work in the combination $\Delta E_\tau = \Delta E_\tau$. We can do this, measuring only ΔE_τ , etc., in each plane. It is useful, in a certain sense, some combination of the three existing ones for the xy, yz, xz and z-planes. There is nothing new. To this point, if we know what the forces are in the xz, xy, etc., and z-planes are, then the torque in any other plane, and vice versa, the angular momentum can also be written as a combination of these six percent of six and thirty-two percent of another, and so on. This property is called *closure* to you.

Suppose that in the system we find forces and all the torques due to angular momentum in the planes. But also ΔE_x^2 , ΔE_y^2 , ΔE_z^2 in some other dimension. To make it a little easier, we shall suppose that only the τ -terms have been listed. Most of ΔE_x^2 , etc., are zero, but this is supposed to be the case. That is, he has no planes to worry about and ΔE . He therefore has six ΔE 's and angular momentum which he would work out. For example his term in the xy-plane would be equal to $\Delta E_\tau = p_{xy}$, and ΔE for b. What we must do is to find all the relationship between the new angles and the old angles, as we will be able to make a

20-1 Torque in three dimensions

20-2 The relation between the cross products

20-3 The gyroscope

20-4 Angular momentum of a solid body

mention from Chapter 17 says "the cross product is just like vector multiplication with vectors." And indeed, that is exactly what we are looking for here. Then he may say, "Well, isn't a vector just a scalar?" A scalar cannot fail to be a vector, but we do not know that right away without making a analysis. So if the following steps we take make no analysis, We can't" because it's just a step by step, since we only want nothing but how it works. The two equations that follow are

$$\begin{aligned} \mathbf{r}_{xy} &= \mathbf{x}\mathbf{r}_y - \mathbf{y}\mathbf{r}_x \\ \mathbf{r}_{xz} &= \mathbf{x}\mathbf{r}_z - \mathbf{z}\mathbf{r}_x \\ \mathbf{r}_{yz} &= \mathbf{y}\mathbf{r}_z - \mathbf{z}\mathbf{r}_y \end{aligned} \quad (20.1)$$

We discuss the first one and it is enough to discuss among the three since the same quantity of the components is not needed in the right way. We're not calculating \mathbf{r}_{xy} , \mathbf{r}_{xz} , \mathbf{r}_{yz} . The problem depends on the fact that x can have either two values "right-handed" or "left-handed". To say clearly which hand it is right for, we say "left" the second reference to the other two quantities may cause a trouble introducing the later stage in our analysis.

This now calculates the reference in 3D system:

$$\begin{aligned} \mathbf{r}_{xy} &= \mathbf{x}'\mathbf{r}_y - \mathbf{y}'\mathbf{r}_x \\ \mathbf{r}_{xz} &= \mathbf{x}'\mathbf{r}_z - \mathbf{z}'\mathbf{r}_x \\ \mathbf{r}_{yz} &= \mathbf{y}'\mathbf{r}_z - \mathbf{z}'\mathbf{r}_y \end{aligned} \quad (20.2)$$

Now we suppose that our coordinate system is rotated by a fixed angle θ , such that the local axes are the same. (Triangle 2 has nothing to do with rotating objects or what is going on, but in the coordinate system, it is there.) The relationship between the axes and by our memory, the axes used by one other, and is supposedly constant. Thus, the coordinates of the two systems are related by

$$\begin{aligned} x' &= x \cos \theta + y \sin \theta, \\ z' &= -y \cos \theta + x \sin \theta \\ y' &= y \end{aligned} \quad (20.3)$$

Therefore, we see from y' is a vector it transforms into the new system in the same way as do x' and z' . Just as being a vector if and only if its various components is transformed linearly by x , y , and z .

$$\begin{aligned} \mathbf{r}_{xy} &= \mathbf{r}_x \cos \theta + \mathbf{r}_y \sin \theta, \\ \mathbf{r}_{xz} &= \mathbf{r}_x \sin \theta - \mathbf{r}_y \cos \theta \\ \mathbf{r}_{yz} &= \mathbf{r}_y \end{aligned} \quad (20.4)$$

Now we can find out how the x -axis transforms by merely substituting for x , y , and z the x -vectors (20.3) into (20.1). For \mathbf{r}_{xy} , \mathbf{r}_{xz} , \mathbf{r}_{yz} these given by (20.4) all make (20.4). So, we have a rather long string of terms for \mathbf{r}_{xy} , and (rather surprisingly) an additional term than it comes up in \mathbf{r}_{xz} and \mathbf{r}_{yz} , which we need to be the component of the x -plane:

$$\begin{aligned} \mathbf{r}_{xy} &= (\mathbf{x} \cos \theta + \mathbf{y} \sin \theta)(\mathbf{x} \cos \theta + \mathbf{y} \sin \theta) \\ &\quad - (\mathbf{x} \cos \theta + \mathbf{y} \sin \theta)(\mathbf{z} \cos \theta - \mathbf{z} \sin \theta) \\ &\quad + \mathbf{x}^2(\cos^2 \theta + \sin^2 \theta) - \mathbf{y}^2(\sin^2 \theta + \cos^2 \theta) \\ &\quad - \mathbf{z}(\mathbf{x} \cos \theta + \mathbf{y} \sin \theta) + \mathbf{z}^2(\cos^2 \theta) \\ &\quad + \mathbf{z}^2(\sin^2 \theta) + \mathbf{z} = \mathbf{z}(\cos^2 \theta) \\ &\Rightarrow \mathbf{r}_{xy} = \mathbf{y} \mathbf{r}_x + \mathbf{x} \mathbf{r}_y \end{aligned} \quad (20.5)$$

The result is clear, but if we only took the axes in the plane, the twist around a fixed point is insufficient; then it goes back to hexagonal in the same sense. What will be more interesting is the expression for τ_{xy} , because that is a new plane. We know the answer, the same thing with the vectorial case, but it is not so simple:

$$\begin{aligned}\tau_{xy} &= \tau_x \cos \theta - \tau_z \sin \theta \\&= \tau_x^2 \cos^2 \theta - \tau_z^2 \sin^2 \theta \\&= (\tau_x^2 - \tau_z^2) \cos^2 \theta + \tau_x \tau_z \cos \theta \\&= \tau_x \cos \theta + \tau_z \sin \theta\end{aligned}\quad (20.6)$$

Finally, we consider τ_{xz} :

$$\begin{aligned}\tau_{xz} &= 2(\tau_x \cos \theta - \tau_y \sin \theta) \\&= -(\tau_x + \tau_y + \tau_z) \sin \theta \\&= (\tau_x - \tau_z) \cos \theta - (\tau_x^2 - \tau_z^2) \sin \theta \\&= \tau_x \cos \theta - \tau_z \sin \theta\end{aligned}\quad (20.7)$$

We wanted to get a rule for finding torques in these cases in terms of torques in old sense, and now we have the rule. This can also be understood that rule. If we look carefully at (20.6), (20.7), we see that there's a close relationship between these equations and the equations (20.4), (20.5), and (20.6). Sometimes, we could call τ_x the component of summing τ_1 + τ_2 + τ_3 , component of τ_1 , then it would be all right, we would understand (20.5) is a vector transformation, once the assignment would be unchanged, as it should be. Otherwise, if we associate that the yz -plane the x -component of our study invariant vector, and with the exception, the yz -component, that these transformable expressions would not.

$$\begin{aligned}\tau_x &= \tau_1 \\&= \tau_x \cos \theta + \tau_z \sin \theta \\&= \tau_y - \tau_z \cos \theta - \tau_x \sin \theta\end{aligned}\quad (20.8)$$

where θ is just the angle for vector τ_1 .

There is a we have proved that we can identify the combination of $\tau_1 + \tau_2 + \tau_3$, with what we ordinarily call the x -component of a vector, as it is really a real vector. Although a torque is a twist of a surface, and it has no physical vector character, and most really it does not have linear character. This vector is along it angles to the axis of the twist, and its length is proportional to the strength of the twist. The dimension, probably of such a quantity like τ_1 , transforms like a real vector.

So we represent a torque by a vector; with each plane π , what the torque is supposed to be acting, we represent a point at right angles to a plane. But the "right angles" carries the sign uncancelled. To get the x -axis right, we must adopt a rule which will tell us that the torque were in clockwise sense on the z -axis. This was not required to associate with τ_1 in the "right" orientation. That is, somebody has to define "right" and "left" for us. Supposing that the coordinate system is x, y, z in a right-hand system, then the rule will be the following: if we think of the twist as if we were turning a screw having a right-hand thread, then the direction of the twist is the "new" coordinate, with that x is 1. Consideration that the screw would advance.

What is torque in reality? It is a miracle of good luck that we can associate a single axis with a plane, and therefore that we can associate a vector with the torque; it is a special property of three-dimensional space. In two dimensions, the torque is an ordinary vector, and there need be no relation associated with it. In less dimensions, it is a vector. If we had four dimensions we would be in great difficulty, because if we are using, for example, at the fourth dimension we would not only xy -plane like x, y, z, u , we would have to x, y, z, w components. There would be x, y, z, w there, and one cannot represent x, y, z, w as a vector in four dimensions.

We will be thinking in three dimensions for a long time, so it is well to realize that the triggering moment and the reaction did not depend upon the fact that a

has position and force tensor, it only depends on the transformation laws for vectors. Therefore if instead of a we had the x -component of some other vector, it is not going to make any difference. In other words, if we were to calculate $a_1 b_1 + a_2 b_2$, where a and b are vectors and call it the x -component of some new quantity c , then these two quantities form a vector c . We need a mathematical notation for the relationship of the new vector with its three components a_1, a_2 to the vectors a and b . The notation has been devised to this is $c = a \times b$. We have seen, in addition to the ordinary scalar product in the theory of vector spaces, a new kind of product called the cross product. Thus, if $c = a \times b$, this is the componentship

$$\begin{aligned} c_1 &= a_2 b_1 - a_1 b_2, \\ c_2 &= a_3 b_1 - a_1 b_3, \\ c_3 &= a_2 b_3 - a_3 b_2. \end{aligned} \quad (20.8)$$

If we reverse the order of a and b , calling a from b , a , we would have the components of c now become c_1 would be $b_2 a_1 - b_1 a_2$. The same commutative property is in like ordinary multiplication, where $ab = ba$; in the cross product, $b \times a = -a \times b$. From this, we can prove at once that if $b = 0$, the cross product is zero. Thus, $a \times a = 0$.

The cross product is very important for representing the features of rotation and it is important that we understand the geometrical realization of the three vectors a , b , and c . By means of relationships among planes is given in 17 (20.9) and 20m that one can determine what the relationship is in geometry. One knows by first that the vector c is perpendicular to both a and b . (The b vector sits in a and c if they not reduce to zero.) Second, the magnitude of c turns out to be the magnitude of a times the sine of the angle between the two. To which I continue with a point: Imagine a string from a into b through an angle less than 180° ; if you pull with a right-hand thread running in this way will produce in the direction of c . The fact that we say a right-hand screw instead of a left-hand screw is a convention, and is a geometrical consideration. If a and b are "frozen" vectors in the ordinary sense, the new kind of "vector" which we have created by $a \times b$ is not this, or slightly different to its structure from a vector, however it was made up with a special rule. If we had three ordinary vectors, we have a special name for them, which are their real vectors. Examples of such vectors are the gravitational vector \mathbf{g} , momentum \mathbf{p} , velocity \mathbf{v} , electric field \mathbf{E} , etc.; these are ordinary vector vectors. Vectors which involve just one cross product to their definition are called axial vectors or pseudovectors. Examples of pseudovectors are, of course, torque τ and the angular momentum L . It also turns out that the angular velocity ω is a pseudovector as is the magnetic field \mathbf{B} .

In order to complete the mathematical properties of vectors, we shall know all the rules for their multiplication, using the various products. In our applications to mechanics, we will use very little of this, but for the sake of completeness, we shall write down all of the rules for vector multiplication. Let us first list the results here. These are

$$\begin{aligned} (a) \quad a \times (b + c) &= a \times b + a \times c \\ (b) \quad (ab) \times b &= a(b \times b), \\ (c) \quad a \cdot (b \times c) &= (a \times b) \cdot c, \\ (d) \quad a \times (b \times c) &= (b \cdot a) c - (c \cdot a) b, \\ (e) \quad a \times a &= 0, \\ (f) \quad a \cdot (a \times b) &= 0. \end{aligned} \quad (20.10)$$

20-3 The rotation equations using cross products

Now let us ask whether any equations in physics can be solved using the cross product. The answer, of course, is that a great many equations can be written. For instance, we can immediately that the torque is equal to the position

$$\tau = \mathbf{r} \times \mathbf{F}. \quad (20.11)$$

This is a vector summary of the 1D...equations $\tau_x = r_x \dot{\theta}$, $= -r_y \dot{\theta}$, etc. By the same token, the angular momentum vector, if there is only one particle present in the system from the origin multiplied by the vector momentum.

$$\mathbf{L} = \mathbf{r} \times \mathbf{p}. \quad (20.12)$$

For three-dimensional system rotation, the dynamical law analogous to the law $\mathbf{R} = \mathbf{ap}/dt$ of Newton, is that the unique vector is the rate of change with time of the angular momentum vector:

$$\tau = d\mathbf{L}/dt. \quad (20.13)$$

Over $n=30$, 000 many particles, the average torque on a system is the rate of change of the total angular momentum:

$$\tau_{av} = d\mathbf{L}_{av}/dt. \quad (20.14)$$

Angular momentum: If the total angular momentum is zero, then the total vector angular momentum of the system is a constant. This is called the **axis of conservation of angular momentum**. If there is no torque on a given system, its angular momentum is conserved.

What about angular velocity? Is it a vector? We have already discussed turning a solid object about a fixed axis, but for a moment suppose that we are turning simultaneously the "fixed axis". It might be turning itself or it might be a box, where the box is rapidly about some other axis. The net result of such combined motions is that the object simply turns about some new axis. The **angular velocity** along this new axis is then it can be figured out this way. If the rate of turning in the xz plane is written as a vector in the xz -direction, whose length is equal to the rate of rotation in the plane, and if another vector is drawn in the yz -direction, say, where is the rate of rotating in the yz plane, then if we add these together as a vector, the magnitude of the resultant is how fast the object is turning, and the direction tells us in what plane by the rule of the parallelogram. That is to say, simply, angular velocity is a vector, whereas we drew the magnitudes of the rotations in the three planes to project them at right angles to those planes.*

An simple application of the preceding angular velocity vector, we may evaluate the power being expended by the turn of a large solid rigid body. The power, P , of course, is the rate of change of work with time; in three dimensions, the power turns out to be $P = \tau \cdot \omega$.

All the formulas that we learned for plane rotation can be generalized to 3D motion. For example, if a rigid body is turning about a certain axis with angular velocity ω , we might ask, "What is the velocity of a point of a certain *fixed* coordinate?" We can't leave it up to problem for the student to solve. Let the velocity of a particle in a rigid body be given by $\mathbf{v} = \omega \times \mathbf{r}$, where ω is the angular velocity and \mathbf{r} is the position. Also, in another example of fixed coordinates, we had a formula for Coriolis force, which can also be written using these products of \mathbf{T} , \mathbf{A} , and \mathbf{B} . That is, if a particle is moving with velocity \mathbf{v} in a coordinate system which is, in fact, rotating with angular velocity ω , and we want to find \mathbf{F} in terms of the rotating coordinate system, then we have to take the previously-formula.

20-3 The gyroscope

Let us now return to the law of conservation of angular momentum. This law may be demonstrated with a rapidly spinning wheel, or gyroscope, as follows (see Fig. 20-1). If we sit on a swivel chair and hold the spinning wheel with its axis horizontal, the wheel has an angular velocity ω . And we set it in this situation of rotating in our chair;

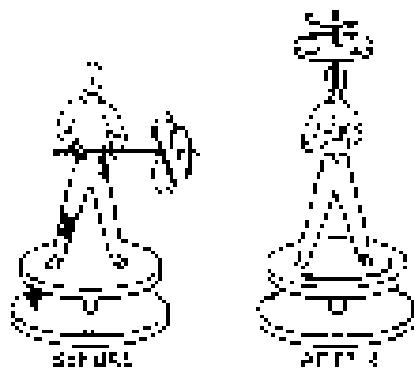

Fig. 20-1. Before and after swiveling, moment of inertia about vertical axis. (It's better to use a vertical axis, so it's easier to see what's happening.)

* That this is true can be shown by commanding the displacement of the particles of the body during an infinitesimal time Δt . If we call \mathbf{v}_i the velocity and \mathbf{r}_i the position of the i th particle, then $\mathbf{v}_i = \omega \times \mathbf{r}_i$.

Angular momentum around a vertical axis (center of the frictionless pivot of the chair) or if we turn the rest of the wheel into the vertical, the free-wheel would have angular momentum about the vertical axis, because it is now spinning about this axis. But the system (wheel, cartell, and chair) cannot have a vertical component, so we and the cartell have to turn in the direction opposite to the spin of the wheel, to balance it.

Just let us analyze it more fully the things we have just described. What is surprising and new we must understand, is the origin of the forces which can send the chair around as we are in the case of the gyroscope around the vertical. Figure 20-2 shows the wheel spinning steadily about the pivot. Therefore its angular velocity is about the axis and it is constant in angular momentum + linear motion in that direction. Now suppose that we wish to rotate the wheel about the x -axis at a small angular velocity α ; what does this do? After a short time Δt , the axis has turned to a new position, rotated an angle $\Delta\theta$ with the horizontal. Since the center part of the angular momentum is due to the spin of the wheel (that will be counteracted by the side friction), we see that the angular momentum vector has changed. What is the change in angular momentum? The x -component does not change in magnitude, but it does change its direction by an amount $\Delta\theta$. The magnitude of the vector $\Delta\theta$ is thus $\Delta\theta = \omega \Delta t$, so that the torque, which is the same rate of change of the angular momentum, is $\tau = 2I\omega\omega - I\omega^2 \Delta\theta = L\omega$. Taking the cosine law of the various vectors at the intersection, we see that

$$\tau = I\omega \times L. \quad (20.15)$$

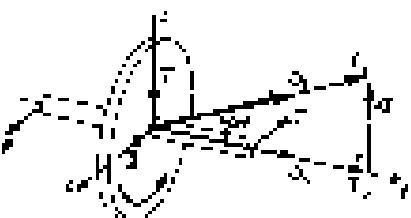

Fig. 20-2. A gyroscope.

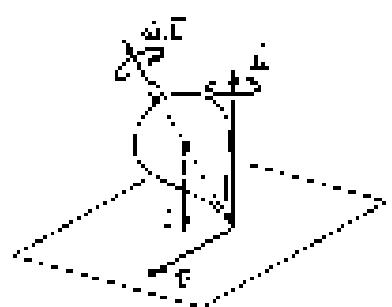

Fig. 20-3. A rapidly spinning top. Note that the direction of the torque vector is the direction of the precession.

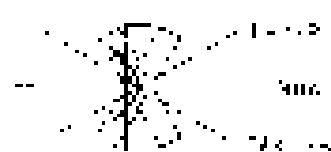

Fig. 20-4. The motion of particles in the spinning wheel of Fig. 20-2, where ω is zero, is in curved lines.

Thus, if ω and L_x are both horizontal, as shown in the figure, τ is zeroed. To produce such a torque, momenta forces F and $-F$ must be applied to the ends of the rod. How are these forces supplied? By our hands, as we turn the ends of the axis of the top off in the vertical direction. But Newton's Third Law demands that equal and opposite forces (and equal and opposite momenta) act on us. This causes us to rotate in the opposite sense around the vertical axis.

This result can be generalized to a rapidly spinning top. In the similar case of a spinning top, gravity acts on its center of mass (unless it is suspended) and points of contact with the floor (see Fig. 20-4). This torque is in the horizontal direction, and causes the top to precess with the direction of a circular path around the vertical. If Ω is the (vertical) angular velocity of rotation, we again find that

$$\tau = I\Omega\dot{\omega} = \Omega \times L.$$

Thus, when we apply a torque to a rapidly spinning top, the direction of the precessional motion is in the direction of the torque, τ , at right angles to the forces producing the torque.

We may now claim to understand the dynamics of gyroscopes, and indeed we do, rather nicely. However this is a rather "direct" way which, in a sense, appears sort of "intuitive." In real truth, we can go to more and more advanced physics, that usually comes later, can be exerted mathematically more easily than they can be really understood in a didactical or simple sense. This is a stumbling block, and as we get into more and more advanced work the more terminology will which usually will produce results we take as new but really can't be understood in any direct fashion. An example is the gyroscope, which appears in a very simple and beautiful form, but whose actual analysis is hard to understand. In our particular case, the precession is in big loops like those kind of orbits involving right angles and circles and twigs and right angles. What we should try to do is to understand it in a more physical way.

How can we explain this precession in terms of the real forces and accelerations? We note that when the wheel is precessing, the particles that are going around the wheel are not really moving in a plane because the wheel is precessing (see Fig. 20-4). As we explained previously (Fig. 19-4), the particles which are crossing through the precession axis are having a centripetal, and this requires application of a force. That is supplied by our pushing on the axis which can come up to

caused by the forces it has through its spokes. "Wait," you may say, "what about the forces that are going outside on the outer side?" It does not take long to realize that the τ must be a force in the opposite direction on that side. The net force that we have to apply is then $\tau + mg$. The forces balance out, but one of them must be applied at one side of the wheel, and the other must be applied at the other side of the wheel. We could apply τ to the left directly, but because the wheel is solid we can't just do it by pushing on the side, since forces can be applied only through the spokes.

What we learn is that if the wheel is precessing, it can balance the torque due to gravity or some other applied torque. But what we have shown is that τ is a function of an equation. That is, if the torque is given, and τ is due to gravity started right, then the wheel will precess sinusoidally and uniformly. But we have not stated that this is not true; that a uniform precession is the most general motion a spinning body can make as the result of a pure torque. The general motion involves then a "wobbling" about the mean precession. This "wobbling" is called nutation.

Some people like to say that the moment of inertia is constant, and so on and so forth, and that the torque precludes precession. It is very strong then when one suddenly lets go of a gyroscope, it does not fall under the action of gravity, but moves sideways instead. Why? Well, the component toward the axis of rotation, which we have analyzed, makes it go sideways! All the formulas in the usual like (20.9) are not going to be valid, because (20.15) is a static condition, valid only after the gyroscope is precessing steady. What really happens, in detail, is the following. If we were to let the axis accelerate down, so that it cannot precess in any manner (in the hope it's spinning there is no torque acting), and even a torque from gravity, because it is horizontal by now, but if we suddenly let go, then the axis will instantaneously be a torque from gravity. Anyone in our right mind would think that the top would fall, and that is what would occur, unless if the top is not spinning initially.

The axis actually does fall, as we would expect. But as soon as it falls, it then starts up and if this starting up were to continue, a torque would be required. In the absence of a torque in this direction, the gyroscope will fall. If the direction is again in the direction of the missing a torque. This gives the gyro a component of motion precessing around its vertical in steady precession. But because initial "over-shoots" the steady precessional velocity, and the axis actually rises again to the height from which it started. This, with followed by the end of the axis is precessing (the gyro followed by a point that is stuck in the end of an automobile tire). Call this the "gyroscopic effect". The eye follows the eye to follow, and it drops out quickly because of the friction in the optical bearings. In fact, the steady precessional drift (Fig. 20-2) - the gyro can't when spins the mass around the horizontal axis.

When the motion set in down, it's evident the gyro is pulled back to the axis of the star. Why? (They are not normal to each other, but we bring them in because we don't want the effect to affect the idea of the gyroscopic effect.) Just because it is a wonderful thing, and it is not a miracle! Two wheels rolling absolutely horizontally, and suddenly let go, then the simple precession equation would tell us that it precesses. But it was around a horizontal plane. This is impossible! Although we neglected friction, it is in the "horizontal" because it is of inertia about the rotation axis, and as it is moving about that axis, even slowly, it has a fixed angle measurement about the axis. We are difficult come round. If the gyro is precessing, then it must precess around the vertical axis. Hence then that it just continues if there is no change in the angular momentum! The answer is then the gyroscopic motion of the end of the wheel precesses to the average steady motion of the center of the equivalent rotating circle. That is, it oscillates in a vertical line. Because the law of the law of motion, it has a vertical component which is used by which is needed for the precession. As we see it has to go down a little, it needs to go up. It has to yield a little bit to the gravity; by turning its axis there a little bit it maintains the rotation about the vertical axis. Thus, the gyroscopic effect works.

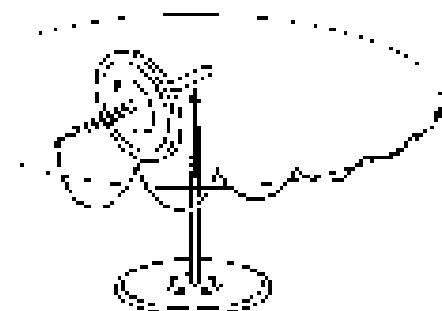

Fig. 20-5. Nutational motion of a gyroscope under gravity just after releasing and previously balanced.

20.4 Angular momentum of a solid body

Before we begin the subject of rotation in three dimensions, we shall consider, more qualitatively, a few effects that occur in two dimensions, regarding rotating rigid bodies. The main effect is that, in general, the angular momentum of a rigid body is not necessarily in the same direction as the center-of-mass velocity. Consider a wheel that is free to rotate about its shaft in a horizontal direction, so that the axis through the center of gravity, to be given \vec{v}_c (Fig. 20.6). When we spin the wheel around the axis, anybody knows that there will be shaking at the bearings because of the so-called τ_{fr} we have learned of. Qualitatively, we know that in the rotating system there is one tangential force acting on the wheel, trying to draw all mass toward the center. This tends to bring up the wheel and the wheel axis is perpendicular to the shaft. To resist this tendency, a torque is exerted by the bearings. This is a torque exerted by the bearings, causing a rate of change of angular momentum. How can there be a rate of change of angular momentum when we are simply turning the wheel about the shaft? Suppose we bring the angular velocity or ABC components ω_x , ω_y , ω_z perpendicular and parallel to the axis of the wheel. What is the angular momentum? The moment of inertia about these two axes are different, so the angular momentum components, which in this particular case of course only is equal to the moments of inertia times the corresponding angular velocity components, are at a different rate than are the angular velocity components. The effect of the angular momentum vector is at a distance from the center of the shaft. When we sum the effects, we have to sum the tangential momentum vectors in space, so we can result compute on the shaft.

Although it is much too complicated to prove here, there is a very important, and interesting property of the moments of inertia which is very descriptive and important, and which is the focus of our above analysis. This property is the following: Any rigid body, even an irregular one like a potato, possesses three mutually perpendicular axes through its C.G., such that the moment of inertia about one of these axes has the greatest possible value for any axis through the C.G. of the body; another of the axes has the minimum possible value, and the moment of inertia about the third axis is intermediate between these two (or equal to one of them). These axes are called the principal axes of the body, and they have the important property that if the body is rotated about one of them, its angular momentum is in the same direction as the angular velocity. If a body having axes of symmetry, the principal axes are along the symmetry axes.

If we take the x , y , and z axes along the principal axes, and call the corresponding principal moments of inertia I_x , I_y , and I_z , we may easily compute the angular momentum and the kinetic energy of rotation of the body by any angular velocity ω . If we resolve ω into components ω_x , ω_y , and ω_z , we find the components of the unit vectors \hat{i} , \hat{j} , \hat{k} , and along with ω we may readily calculate the components of

$$\vec{L} = I_x \omega_x \hat{i} + I_y \omega_y \hat{j} + I_z \omega_z \hat{k} \quad (20.16)$$

The kinetic energy of rotation is

$$K_E = \frac{1}{2}(I_x \dot{\omega}_x^2 + I_y \dot{\omega}_y^2 + I_z \dot{\omega}_z^2) \quad (20.17)$$

The Harmonic Oscillator

21-1 Linear differential equations

In the study of physics, usually the course is divided into a series of subjects such as mechanics, elasticity, optics, etc., and one subject after the other. For example, this course has so far dealt mainly with mechanics. But a strange thing occurs again and again: The same laws often appear in different fields of science, and even in other sciences, are often almost exactly the same, so that many phenomena have analogs in these different fields. This is the simplest example, the propagation of sound waves, in many ways analogous to the propagation of light waves. If we study something in great detail we discover that in a lot of our work it is no time so it would be if we were studying up in great detail. So the study of a science, even in one field may permit an extension of its knowledge. In fact, it is hard to realize from the first that such extensions are possible, for otherwise one might not understand the reason for spending a great deal of time and energy on what appears to be only a small part of mechanics.

The harmonic oscillator, which we are about to study, has close analogs in many other fields; although we start with a mechanical example of a weight on a spring, or a pendulum with a small swing, or certain other mechanical vibrations, we are really studying a certain differential equation. This equation appears again and again in physics and in all sciences, and in fact it is a sort of so many phenomena that its close study is well worth our while. Some of the phenomena involving this equation are the oscillations of a mass on a spring; the oscillations of charges flowing, laws and teeth in an electric circuit; the vibrations of a tuning fork which is generating sound waves; the analogous vibrations of the electrons in an atom, which generate light waves. The equation for the vibration of a system, such as a thermometer trying to adjust a temperature, complicated in reactions in chemical reactions, the growth and decay of bacteria in interaction with the food supply and the parasites the bacteria produce; losses eating rotting fruits, apples, and so on; there are phenomena follow equations which are very similar to one another, and this is the reason why we study this important oscillation in such detail. The equation is one called linear differential equations with constant coefficients. A linear differential equation with constant coefficients is a differential equation containing at most of terms, each term being a derivative of the dependent variable with respect to the independent variable, and multiplied by some constant. Thus

$$a_n y^{(n)} + a_{n-1} y^{(n-1)} + \cdots + a_1 y' + a_0 y = f(t) \quad (2-1)$$

is called a linear differential equation of order n with constant coefficients (with a_i is constant).

21-2 The harmonic oscillator

Perhaps the simplest mechanical system whose motion follows a linear differential equation with constant coefficients is a mass on a spring. First the spring is stretched to balance the gravity; once it's balanced, we then displace the vertical displacement of the mass from its equilibrium position (Fig. 21-1). We will call the upward displacement y , and we also suppose that the spring is perfectly linear, that is, when we displace pulling back when the spring is stretched is precisely proportional to the amount of stretch. That is, the force is $-kx$ (with a

21-4 Initial conditions

21-5 Forced oscillations

Fig. 21-1. A mass on a spring: a simple example of a harmonic oscillator.

in. (21.2) is named as the "differential". Thus the mass takes the acceleration measured earlier:

$$m \frac{d^2x/dt^2}{dt} = -kx. \quad (21.3)$$

For simplicity, suppose it bounces (so we change our unit of time measurement) that the ratio $x_0/m = 1$. We shall then study the equation

$$\frac{dx/dt}{dt} = -\omega. \quad (21.4)$$

In other words come back to Eq. (21.2) with the x and m explicitly given.

We have already analyzed Eq. (21.3) in detail numerically when we first introduced the subject of mechanics; see section 10. Equations like Eq. (21.3) in fact oscillate. By numerical integration we found a curve (Fig. 9-4) which showed that if x was initially displaced, but $v=0$, it would bounce down and go through zero; we do not then follow it any further, but of course we know that x will keep going up and down—forever. When we calculated the motion numerically, we found that it went through the equilibrium point at $x = 1.5708$. The length of the whole cycle is four times the long, or $T = 0.2\pi/\omega = \pi$. This was found numerically, before we knew much calculus. We assume that in the meantime the Mathematics Department has brought for us a function, which, when differentiated twice, is equal to itself with a negative sign. (There are, of course, many ways of getting at this function in a direct fashion, but there are many ways of doing it, already knowing what the answer is.) The function is $\cos t$. If we differentiate this we find $d^2x/dt^2 = -\sin x$ and $d^2x/dt^2 = -\cos t = -x$. The function $x = \cos t$ starts at $t = 0$ with $x = 1$, and no initial velocity, that is, $v = 0$, exactly where which we started when we did our numerical work. Now that we know that $x = \cos t$, we can calculate a general value for the time at which it should zero, $x = 0$. The answer is $t = \pi/2$, or 1.5708. We were wrong in the last figure because of the errors of numerical analysis, but it was very close!

Now let us finish with the original problem. We reduce the time units to real seconds. What is the solution then? First of all, we might think that we can get the constant A involved by multiplying each by m (canceling). We let us do the equation, $x = A \cos t$; then we find $dx/dt = -A \sin t$, and $d^2x/dt^2 = -A \cos t = -x$. This we expect to occur because (as we did not succeed in solving Eq. (21.3)) now we get Eq. (21.3) again! That is, the \cos function one of the most important properties of the differential equations if we multiply a variable of the equation by any constant, it is still a solution. The mathematical reason for this is clear. If you substitute a constant multiple of the equation, say by A , we see that all derivatives cancel—multiplied by A , and therefore Ax is just a solution of the original equation as x was. The physics is this. In the following, if we have a weight on a spring, and pull it down a certain far, the force is twice as much; the resulting acceleration is twice as great; the velocity it acquires in a given time is twice as great; the distance covered in a given time is twice as great; and it has to cover twice as great a distance in order to get back to the origin because it is pulled down twice as far. So it takes the same time to get back to the origin irrespective of the initial displacement. To start with with a linear equation, the motion has to have some power, no matter how "strong" it is.

That was the wrong thing to do—but only taught us that we can multiply the solution by anything and it satisfies the same equation, but with different amplitude. After multiplying and dividing by m , we replace x with a constant multiple of x , we find that we must take the scale of time. In other words, Eq. (21.3) has a solution of the form

$$x = A \cos \omega t. \quad (21.5)$$

It is important to realize that ω is positive, since ω is the angular velocity of a spinning body, but we can only take it if we are not allowed to use our same letters for more than one thing! (because we put a subscript "0" on $x_0 > 0$, we are going to have more omega before long; i.e., we remember the ω_0 refers to the initial motion of this oscillator. Now why is (21.5) just? Just because we are more successful, because $d^2x/dt^2 = -A \omega^2 \cos \omega t$ and $d^2x/dt^2 = -\omega^2 x$.

So, if we have solved the equation that we really wanted to solve. The equation $\ddot{x} + \omega_0^2 x = -\sqrt{A} \cos(\omega t + \phi)$ reduces to Eq. (21.2) if $\omega_0^2 = \omega^2$.

The next thing we must investigate is the physical significance of ω_0 . By now, you know that the spring force is proportional to the angle it makes with \vec{x} , so if we neglect air resistance, it will go through a complete cycle, when the "angle" changes by 2π . The quantity ω_0 is often called the phase of the motion. In order to change ω_0 by 2π , the time must change by an amount τ_0 , called the period of one complete oscillation, of course τ_0 must be such that $\omega \tau_0 = 2\pi$. That is, ω_0 must account for one cycle of the angle, and that's why τ_0 will repeat itself—if we increase t by τ_0 , we add 2π to the phase. That is,

$$\omega_0 = 2\pi/\tau_0, \quad \lambda = \sqrt{\omega_0^2}, \quad (21.5)$$

Thus if we had a heavier mass, it would take longer to oscillate back and forth on a spring. That is because there are more inertia, and so, although forces are the same, it takes longer to get the mass moving. Or, if the spring is stiffer, it will move more quickly, and that is right because it less of the energy is stored.

Note that the period of oscillation of a mass on a spring does not depend in any way on whether it has started, how far from $x=0$ it is. The period is determined, but the amplitude of the oscillation is determined by the amount of energy $E(1/2)$. The amplitude is determined, in fact, by how we let go of the initial position, or starting conditions.

Actually, we have not quite found the most general solution of Eq. (21.2). There are other solutions. It should be clear why: because \ddot{x} is the force exerted by $x = \omega_0 \sin(\omega t + \phi)$ with an initial displacement and initial velocity. But it is possible, for instance, for the mass to start at $x = 0$ and $\dot{x} = 0$ and yet still give $\ddot{x} = 0$ impulse kick, so that it has some speed at $t = 0$. Such a motion is not represented by a sine—it is represented by a sine. To put it another way, if $x = 0$ is not a solution, then is it not obvious that if we want to happen to walk into the room at exactly x which we want (say, $x = 0^\circ$) and see the mass at $t = 0$ passing, $\dot{x} = 0^\circ$, we will keep on going past the same? Therefore, $x = 0$ is not just the most general solution, it must be possible to shift the beginning of time, or to speak, to an example where if we write the solution this way, $x = A \cos(\omega_0 t + \phi_0)$, where ϕ_0 is some constant. This also corresponds to shifting the origin of time to some new time t_0 . For this reason we may expand

$$x(t) = A \cos(\omega_0 t + \phi) = A \cos(\omega_0 t_0 + \phi_0) \cos(\omega_0(t - t_0))$$

and write

$$x = A \cos(\omega_0 t_0 + \phi_0) \cos(\omega_0 t),$$

where $A = \text{const}$ and $\phi_0 = -\omega_0 t_0$. Any one of these terms is a possible way to write the harmonic general solution of (21.2), that is, every solution of the differential equation $\ddot{x} + \omega_0^2 x = 0$, the solution in the world can be written as

$$(a) \quad x = A \cos(\omega_0 t + \phi), \quad (21.6)$$

or

$$(b) \quad x = A \cos(\omega_0 t + \phi_0), \quad (21.6)$$

or

$$(c) \quad x = A \cos(\omega_0 t_0 + \phi) \cos(\omega_0 t).$$

Some of the quantities in (21.6) have names: ω_0 is called the angular frequency, λ is the number of times by which the phase changes in a second. This is determined by the differential equation. The other constants are not determined by the equation, but by how the motion is started. Of these constants, A means the maximum displacement attained by the mass, and is called the amplitude of oscillation, ϕ is constant ϕ_0 is sometimes called the phase of the oscillation, but can be confusing, because ϕ_0 is people call it — a true phase, and not the phase change — with time. We might say that ϕ_0 is a phase shift from some definite zero. Let me put it differently. Different ϕ_0 is a constant of motion at different phases. That is to say, the value for ϕ_0 we want to start the phase at ϕ_0 , is completely specific.

21-3 Harmonic motion and circular motion

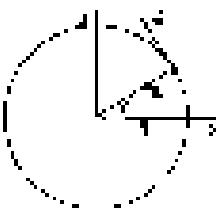

Fig. 21-2. A particle moving in a circular path at constant speed.

The last two sections are involved in the solution of Eq. (21.2) except for one, there might be some relationship to circles. This is artificial, of course, because there's no circle explicitly involved in the linear motion—it just goes up and down. We may point out that we have, in fact, already solved that differential equation when we were studying the mechanics of circular motion. If a particle moves in a circle with a constant speed v , the radius vector from the center of the circle to the particle turns through an angle whose size is proportional to the time. That we call the angle $\theta = \omega t$ (Fig. 21-2), for which $\omega = v/R$. We know that there is an angle between x and θ : $\alpha = \theta - x$ (Fig. 21-2). Now we also know that the position x , y is given by $x = R \cos \theta$, $y = R \sin \theta$.

$$x = R \cos \theta, \quad y = R \sin \theta.$$

Now what about the acceleration? What is the x -component of acceleration, $a_x = d^2x/dt^2$? We have already worked that out previously; it's the magnitude of the acceleration times the cosine of the projection angle, with a minus sign because it's toward the center. Now we also know that

$$a_x = -R \cos \theta = -\omega^2 R \cos \theta = -\omega^2 x. \quad (21.7)$$

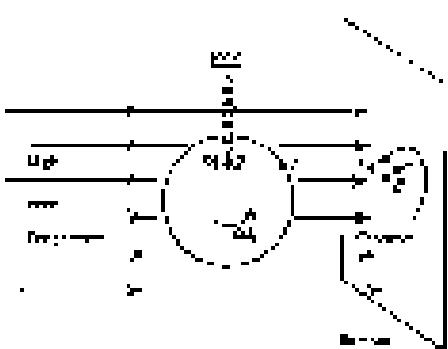

Fig. 21-3 Demonstration of the equivalence between simple harmonic motion and uniform circular motion.

In other words, when a particle is moving in a circle, the horizontal component of its velocity is an acceleration which is proportional to the horizontal displacement from the center. Of course we can have the solution for motion in a circle: $x = R \cos \omega t$. Equation (21.7) does not depend upon the radius of the circle, so for a circle of any radius, one has the same equation for a given ω . Thus for several reasons, we expect that the displacement of a mass in a ring will turn out to be proportional to the x and will, in fact, be exactly the same function as we would expect if we looked at the x -component of the position of an object rotating in a circle with angular velocity ω . And that is this: one can do this an experiment to show that the up-and-down motion of a mass on a spring is the same as that of a point going around in a circle. In Fig. 21-3 one light is projected on a screen, casts a shadow of a small sphere at x_0 and of a vertically oscillating mass, side-by-side. If we let go of the mass at the eight o'clock position from the right place, and if the stair speed is carefully adjusted so that the sphere is just, each should follow the other exactly. One can then check the numerical solution we obtained earlier with the engine function, and see whether that agrees very well.

Here we may point out that because uniform motion in a circle is so closely related mathematically to oscillatory, periodic motion, we can analyze most of our motion in a simpler way if we imagine it to be a projection of something going in a circle. In other words, although the distance y —from nothing to the oscillating problem, we may still artificially supplement Eq. (21.2) with another equation using y , and put the two together. If we do this, we will be able to analyze the one-dimensional oscillations with circular motions, which is a lot easier than having to solve a difference equation. The trick in doing this is to use complex numbers, a procedure we shall introduce in the next chapter.

21-4 Initial conditions

Now let us consider who determines the constants A and B , or α and β . Of course these are determined by how we start the motion. If we start the motion with just a small displacement, that is one type of way to do it; if we start with the initial displacement zero, then push up when we let go, we get still a different motion. The constants A and B , or α and β , or any other way of getting it, are determined, of course, by the way we initially started, not by any other degrees of the system. These are called the initial conditions. We would like to say that the initial conditions will be constants. Although this can be done using any one of the forms (21.6), it turns out to be easiest if we use Eq. (21.3c). Suppose that at $t = 0$ we have started with an initial displacement x_0 , and a zero velocity. At

This is the most general way we can start the motion. (We cannot specify the initial time t_0 at which it started, because that is determined by the spring, once we specify v_0 .) Now, we have two initial values A and B . We start with the equation for x :

$$x = A \cos(\omega_0 t) + B \sin(\omega_0 t).$$

Since we shall later need the velocity v_0 , we differentiate x and obtain

$$v = -\omega_0 A \sin(\omega_0 t) + \omega_0 B \cos(\omega_0 t).$$

These are again two initial conditions, but we have *zero* knowledge about A and B , and $v_0 = 0$. So if we put $v_0 = 0$ in these equations, on the left we get A_0 and B_0 . Because that is what A and B did when $v_0 = 0$; also, we know that the cosine of zero is unity, and anything of zero is zero. Therefore we get

$$A_0 = 0 \cdot 1 = 0 \cdot 0 = 0,$$

and

$$B_0 = -\omega_0 A_0 \cdot 0 + \omega_0 \cdot 0 \cdot 1 = \omega_0 \cdot 0.$$

So for simple harmonic motion we find that

$$A = A_0, \quad B = v_0/\omega_0.$$

From these values of A and B , we can now work x if we wish.

That is *too bad* for our purpose, but there is one physically interesting thing to check, and that is the conservation of energy. Since there was no friction present, energy ought to be conserved. Let us see. We know that

$$x = A \cos(\omega_0 t) + B \sin(\omega_0 t)$$

then

$$v = -\omega_0 A \sin(\omega_0 t) + \omega_0 B \cos(\omega_0 t).$$

Now let us look at what the kinetic energy, T , and what the potential energy are. The potential energy at any moment is $(1/2)kx^2$, where x is the displacement and k is the constant of the spring. If we substitute for x , using our expression above, we get

$$E = \frac{1}{2}kx^2 = \frac{1}{2}k(A \cos(\omega_0 t) + B \sin(\omega_0 t))^2.$$

Of course the potential energy is *not* constant; the potential never becomes negative, because x always has energy in the spring, but the amount of energy fluctuates with x . The kinetic energy, on the other hand, is $(1/2)m v^2$ and by a similar argument we get

$$T = \frac{1}{2}mv^2 = \frac{1}{2}m\omega_0^2(A \cos(\omega_0 t) + B \sin(\omega_0 t))^2.$$

Now the kinetic energy is zero when x is at its maximum, because then v is zero (velocity); on the other hand, it is maximal when x is passing through zero, because then v is moving fastest. This variation of the kinetic energy is just the opposite of that of the potential energy. If we let the total energy E equal to be a constant, if we note that $E = m\dot{x}^2$, we see that

$$\dot{x} + 0 = \sqrt{m\omega_0^2}[(A \cos(\omega_0 t) + B \sin(\omega_0 t)) - \sin(\omega_0 t)] = \sqrt{m\omega_0^2}x'$$

The energy is dependent on the sign of the amplitude. If we lower twice the amplitude, we get an oscillation which has four times the energy. The average potential energy is $(1/2)A^2$. The maximum and, therefore, half the total, and the average kinetic energy is likewise $(1/2)$ the total energy.

21-5 Forced oscillations

Next we shall discuss the forced harmonic oscillation, *i.e.*, one in which there is an external driving force on top. The equation then is the following:

$$m\ddot{x} + \omega_0^2 x = -Av + F(t). \quad (21.8)$$

We would like to find out what happens in these circumstances. The external driving force can have various kinds of functional dependences on the time; the first one that we shall analyze is very simple—*i.e.*, suppose that the force is oscillating:

$$F(t) = F_0 \cos \omega t. \quad (21.5)$$

We find, however, that this ω is not necessarily ω_0 , we have to make some assumptions; the forcing may be done at different frequencies. So we try to solve Eq. (21.4) with the special force (21.5). What is the solution of (21.4)? One special solution, we shall discuss the more general cases later), is

$$x = C \cos \omega t, \quad (21.6)$$

where the constant is to be determined. In other words, we might suppose that if we kept pushing back and forth the mass would *oscillate* back and forth in step with the force. We could try it anyway. So let's put (21.6) into (21.4), and get

$$m\omega^2 C \cos \omega t = -m \omega^2 C \cos \omega t + M \ddot{x} \cos \omega t. \quad (21.7)$$

We have also put in $k = m\omega_0^2$, so that we will understand the equation better at the end. Now because the cosine object is zero, we can divide it out, and that shows that (21.7) is, in fact, a solution, provided we pick C just right. The answer is that $C = M/m$:

$$C = M/m(\omega_0^2 - \omega^2). \quad (21.8)$$

That is, an oscillates at the same frequency as the force, but with an amplitude which depends on the frequency of the force, and so upon the frequency of the mass vibration of the oscillator. It means, then, that if ω is very much compared with ω_0 , then the displacement and the force are in the same direction. On the other hand, if we shake it back and forth very fast, then (21.8) tells us that C is negative. If ω is above the natural frequency ω_0 , the harmonic oscillator ω . (We will call ω the *natural frequency* of the harmonic oscillator, and ω the applied frequency.) At very high frequencies the displacement may become very large and there is then *resonance* and *amplification*.

Of course the solution we have found is not sufficient only in things described just right, for otherwise there is a part which usually does not enter at all. The other part is called the *transient response* to $F(t)$, while (21.6) and (21.8) are called the *steady-state response*.

According to our form, ω (21.8), a very remarkable thing should also occur: if ω is almost exactly the same as ω_0 , then C could approach infinity. So we require the frequency of the force to be "in exact" with the natural frequency. Then we should get an enormous displacement. This is well known, especially when we pushed a child on a swing. It does not work very well unless our eyes and just our seat stay at a column. If we happen to get the right timing, then the swing goes very high, but if we lose the swing timing, the swing is over, may be pushing after we should be pulling, and so on, and it makes her work.

If we make ω exactly equal to ω_0 , we find that it should oscillate at us infinite amplitude, which is, of course, impossible. Therefore it follows that something goes wrong with the equation. There are some other external forces, and other forces, which are not in (21.8) but which occur in the real world. So the amplitude does not necessarily do some reason, it may be that the spring has got

Algebra

22-1 Addition and multiplication

In our study of oscillating systems we shall have occasion to use one of the most remarkable, or most remarkable formulas in all of mathematics. From the physicist's point of view we could bring up the Pythagorean theorem in two minutes or so, and be done with it. But, as you know, much fun intellectual enjoyment is to be had in multiplying our instead of just spending a few minutes on this amazing result, we shall pursue the issue by its proper setting, in the grand design of that branch of mathematics which is called elementary algebra.

Now you may ask, "What is mathematics doing in a physics book?" We have several possible answers. And, at some level, mathematics is an important tool. In fact, we did only now begin giving the formula in two minutes. On the other hand, in theoretical physics we discover that all the laws can be written in mathematical form, and that this has a certain simplicity and beauty about it. So, it is only, in order to understand nature, it may be necessary to have a deeper understanding of mathematical relationships. But the real reason is that the subject is enjoyable, and it is enough to turn six and seven up in different ways, and we have a dozen courses in different departments. Since compartmentalization is really artificial, and we should take our intellectual pleasures where we find them.

Another reason for treating them carefully is algebra now, even though most of the actual algebra in high school is that part was the first time we studied it. The equations were therefore, and it was the work, not as physicists now. Every so often it is a good pleasure to look back to see what territory has been covered, and who has gone map or not of the whole thing is. Perhaps we can contribute to the Mathematics Department will present this as one mechanics in such a way as to give when I say we were trying to work on the physics course.

The subject of algebra will not be developed from the point of view of symmetry, condition, exactly, because the mathematicians are mainly interested in how various properties and facts are demonstrated, and new assumptions are obviously required, and what is not required. They are not interested in the how of why they prove. For example, we may find the Pythagorean theorem quite interesting, that the sum of the squares of the sides of a right triangle is equal to the square of the hypotenuse; this is an extremely fine, a very simple thing which may be appreciated without discussing the question of how to prove it, or what axioms are required. So, in the same spirit, we will describe qualitatively. This may put in that way, the system of elementary algebra. We say elementary algebra, because there is a branch of mathematics called modern algebra, in which some of the ideas such as $a^b = ab$, are abandoned, and it is not called algebra, but we shall not discuss that.

To continue the subject we start in the middle. We suppose that we already know what integers are, what zero is and what it means to increase a number by one unit. You may say, "That is not in the middle!" But it is considerable from a mathematical standpoint, because we could go even further back and describe the theory of sets in order to derive some of these properties of integers. But we are not going in that direction, the discussion of mathematical philosophy and mathematical logic, but rather in the other direction, from the assumption that we know what integers are and we know how to count.

Consider n a certain number of an integer, and we count successively n a number of times, the number we call $n+1$. And that defines addition of integers.

22-1 Addition and multiplication

22-2 The inverse operations

22-3 Abstraction and generalization

22-4 Approximation, irrational numbers

22-5 Complex numbers

22-6 Imaginary numbers

Once we have defined addition, then we can consider this: if we start with nothing and add a to it, a times in succession, we call the result multiplication of integers, we call it a times a .

Now we can also have a succession of multiplications: if we start with 1 and multiply by a, b times in succession, we call that relative to a power of.

Now as a consequence of these definitions it can be easily shown that all of the following relationships are true:

$$\begin{array}{ll}
 \text{(a)} \quad a + b = b + a & \text{(b)} \quad a + (b + c) = (a + b) + c \\
 \text{(c)} \quad ab = ba & \text{(d)} \quad a(b - c) = ab - ac \\
 \text{(e)} \quad (ab)c = a(bc) & \text{(f)} \quad (ab)^n = a^n b^n \\
 \text{(g)} \quad a^m \cdot a^n = a^{m+n} & \text{(h)} \quad (a^m)^n = a^{mn} \\
 \text{(i)} \quad a^{-1} \cdot a = 1 & \text{(j)} \quad a^0 = 1 \\
 \text{(k)} \quad a^{-1} = a^{-1} &
 \end{array} \tag{2.1}$$

These results are well known and we shall not belabor the point, we merely list them. Of course, 1 and 0 have special properties; for example, $a + 0 = a$, $a \cdot 1 = a$, and $0 \cdot 0 = 0$ is the first proof of 0.

In this chapter we will also look at a few other properties like continuity and ordering, which are very hard to define; we will let the reader carry on it. Furthermore, it is definitely true that we have written down too many "definitions"; some of them may be redundant from the others but we shall not worry about such details.

23-3. The inverse operations

In addition to the conventional four of addition, multiplication, and raising to a power, we have also two inverse operations which are defined as follows. Let us assume that a and b are given, and that we wish to find other values of b satisfying such equations as $a + b = c$, or $ab = c$. If $a + b = c$, b is defined as $c - a$, which is called subtraction. The operation called division is also clear: if $ab = c$, then $b = c/a$ defines division. A solution of the equation $ab = c$ "backwardly" shows if we have a power $b^m = c$ and we ask ourselves, "What is b ?" it is called the *mth root of c* : $b = \sqrt[m]{c}$. For instance, if we are considering the following question, "What integer, raised to the third power, equals 8?" the one answer is called the *cubic root of 8*: $\sqrt[3]{8} = 2$. These are direct and inverse equalities, these are the inverse problems associated with powers, and the other inverse problem would be, "To what power must we raise 2 to get 8?" This is called taking the logarithm. If $2^x = 8$, we write $x = \log_2 8$. The fact that it has a unique solution relative to the value x does not mean that it is any less elementary, it just applies to integers, like the other processes. Although logarithms are a little in an algebra class, in practice they are, of course, just as simple as roots; they are just a different kind of solution of a algebraic equation. The direct and inverse operations are summarized as follows:

(a) addition	(b) subtraction
$a + b = c$	$b = c - a$
(c) multiplication	(d) division
$ab = c$	$b = c/a$
(e) power	(f) root
$b^m = c$	$b = \sqrt[m]{c}$
(g) power	(h) logarithm
$b^x = c$	$x = \log_b c$

Now here is the idea. These relationships are rules one cannot break, since they follow from the definitions of addition, multiplication, and raising to a power. We are going to discuss whether or not we can broaden the class of systems

which a , b , and c represent so that they will obey those same rules, although the processes for $a = b - c$, and $bc = 0$, will not be deductible in terms of the operation of adding 1. For instance, an associative multiplication by induction.

21-3 Abstraction and generalization

When we try to solve simple algebraic equations, taking all these definitions, we soon discover some insoluble problems, such as the following: Suppose that we try to solve the equation $a = b - c$. That means, according to our definition of subtraction, that we must find a number which, when added to c , gives b . And of course there is no such number, because we consider only positive integers; this is an insoluble problem. However, the plan, the great idea, is that: abstraction and generalization. From the whole structure of algebra, rules plus integers, we restrict the original definitions of addition and multiplication, but we leave cases like (22.1) and (22.2), and assume these to be true in general on a wider class of numbers, even though they are originally defined on a smaller class. Thus, in characterizing integers systematically by definition of rules, we use the rules as the definition of the symbols, which then represent a more general kind of number. As an example, by working with fractions alone we can show that $3 - 5 = 0 - 2$. So that we can see that one can make all subtractions, provided we define a whose set of non members is $0, -1, 0, -2, 0, -3, 0, -4$, and so on, called the negative integers—but we may use $+$ —the other rules, like $a + b = ab$ —are not enough to find what the rules are for multiplying negative numbers, and we will discover, in fact, that “ $+$ ” of the rules can be associated with negative as well as positive integers.

So we have increased the range of objects over which the rules work, but the meaning of the symbols is different.

One cannot say, for instance, that -2 times 3 really means to add 3 together successively -2 times. That means nothing. But nevertheless everything will work out all right according to the rules.

An interesting problem comes up in taking powers. Suppose that we wish to discover what $a^{1/2}$ means. We know already that $a^{1/2}$ is a solution of the problem, $a = x^2 + y^2$, i.e., knowing that, we know that $a^{1/2} = \sqrt{a}$. Therefore $a^{1/2} \cdot a^{1/2} = a^{1/2}a^{1/2}$, by the definition of division. With a little more work, this can be reduced to a . So we find that the negative powers are the reciprocals of the positive powers, but $a^{1/2}$ is a meaningless symbol, because if a is a positive or negative integer, the square of it is greater than 1 , and we do not yet know what we mean by “divided by a number greater than 1 ”.

Onward! The great plan is to continue the process of generalization; whenever we find another problem that we cannot solve we extend our realm of numbers. Consider division: we cannot find a number which is an integer when a large integer, which is equal to the result of dividing 3 by 5 . But if we suppose that all fractional numbers satisfy the rules, then we can talk about multiplication and adding fractions, and everything works as well as it did before.

Take another one step of progress: what is $a^{3/2}$? We know only that $(1/a)^2 = 1$, since this is the definition of $1/a$. So we know also that $(a^{1/2} \cdot a)^2 = a^{1/2} \cdot a^{1/2} = a^2$, because this is one of the rules. Then by the definition of roots we find that $a^{3/2} = \sqrt[3]{a^2}$.

In this way, then, we can refine what we mean by putting fractions in the number system, by using the rules themselves to help us determine the meaning—it is not arbitrary. It is a new rule, but that all the “old” work for positive and negative integers, as well as for fractions.

We go on in the process of generalization. Are there any other equations we cannot solve? Yes, for example, it is impossible to solve this equation, $x = 2^{-x} = \sqrt{x}$. It is impossible to find a number which is natural (a fraction) whose square is equal to 2 . It is very easy for us in modern days to answer this question. We knew the decimal system, and as we have no difficulty in specifying the meaning of an ordinary decimal as a type of expression relative to the expansion of 2 . Historically, this idea presented great difficulty to the Greeks. To say

define $\sqrt[n]{x}$, which is meant by it requires that we add some substance of continuity and ordering, and it is, in fact, what we have done at this point. It was done formally and rigorously, by Dedekind. However, without worrying about the mathematical rigor of the thing, it is quite easy to understand that what we mean is that we are going to find a whole sequence of approximating fractions, perfect fractions (from now on they'll be called), which stop at somewhere, is of course rational, which goes on going, getting closer and closer to the desired result. That is good enough for what we wish to discuss, and it permits us to make ourselves in numerical numbers and to calculate things like the square root of 2 to any accuracy that we desire, with enough work.

23.4 Approximating irrational numbers

The next problem comes with what happens with the irrational powers. Suppose that we want to extract, for instance, $10^{1/3}$. In principle, the answer is simple enough. If we express this as the sum of 10 to a certain number of decimal places, then the power is a fixed, and we can then the approximation, just using the above method, and get an answer which is to $10^{1/3}$. Then we may just repeat a few more decimal places (it is again rational), to be as approximate as we like. This time it's much higher now because there is a much bigger denominator in the fraction, and get a better approximation. Of course we are going to get some extremely high numbers involved here, and the work is quite difficult. How can we cope with this problem?

In the computations of square roots, cube roots, and other small roots, there is some arithmetical process available to which we can go one decimal place at a time. But the situation of higher powers is rather different, irrational powers and the logarithms that go with them, the inverse relation. The reason that there is no simple arithmetical procedure with these. The first tables were built up which permit us to calculate these powers, and these are called the tables of logarithms. At the tables of powers, depending on which way the table is set up. It is only a question of looking up; if we take our same number to an irrational power, we can look it up easier than having to compute it. Of course, with computation, it is just a technical problem, but it is an interesting one, and a most historical study. In the first place, not only do we have the problem of extracting $x = 10^{1/3}$, but we also have the problem of solving $10^x = 2$ or $x = \log_{10} 2$. This is not a number where we have to define a new kind of number for the root, it is merely a nonreal number. The answer is simply an irrational number, or, writing decimal, will be a new kind of a number.

Let us now discuss the problem of calculating solutions of such equations, the power idea is really very simple. If we could calculate 10^1 , and $10^{1/10}$, and $10^{1/100}$, and $10^{1/1000}$, and so on, and multiply the n all together, we would get $10 \cdot 10^{1/10} \cdot 10^{1/100} \cdots 10^{1/10^n}$, and then is the general answer which things were. Our instead of calculating $10^{1/10}$ and so on, we shall calculate $10^{1/2}$, $10^{1/4}$, and so on. Before we start, we should explain why we make so much work with 10, instead of some other number. Of course we realize that logarithm tables are of great practical utility, quite aside from the mathematical problem of taking roots, since with any base at all.

$$\log_b(x^n) = \log_b x + \log_b n. \quad (23.1)$$

We are all aware that the fact that one can use this is that is a practical way to calculate numbers if we have a table of logarithms. There's quite less is with a two, which we compute? It makes no difference what base is used; we can use the same although b , the time, and if we are using long division, or any particular base, even if it's not large division or any other way, namely by a change in scale, a multiplying factor. If we multiply $10 \cdot (23.1)$ by 61, it is just as true, and if we had a table of \log_6 with a base 6, and similarly eliminating all of our entries by 61, then we'd have no essential difference. A priori then we know the logarithms of all the numbers to the base 6. In other words, we can solve the equation $6^x = 61$ for x by a table of \log_6 .

we have a table. The problem is to find the logarithm of the state number, or to some other base, for every number x . We would like a table of $\log_b x$. It is easy to do, because we can always write $x = b^y$, which means $\log_b x = y$. As a matter of fact, $b = \exp x$. Then, if we put $x = 1$ and take $\log_b 1$, we see that $\log_b 1 = \log_b b^0 = 0$. In other words, 0 is the base column in base b . Thus $\log_b x = \log_b b^y = y$, which is a constant, times the entry in the base b . Therefore any log table is equivalent to any other log table if we multiply by a constant and then, for convenience, if $y < 0$. This permits us to choose a particular base, and for convenience we take the base ten. (The question may arise as to whether there is any normal base, one base in which things are still simpler, and we shall try to find an answer to that after we, by means, shall introduce the base 10.)

Table 22-1

Square Root of Ten

Number x	$10\log x$	10^x	$10^{10\log x} = x$
1	0.00	1.000000	1.00
1.12	0.12	3.14278	3.14

* This is a definite arithmetic procedure, but the easiest way to find the square root of any number N is to choose some fairly close, but not too large, starting value $a_0 = g_0 + (\delta/2)$, and now the average of a_0 and N/a_0 . The next choice is $a_1 = \frac{1}{2}(a_0 + N/a_0)$. Convergence is very rapid— π numbers, for example, double each time.

10¹⁰th power of 10¹⁰⁻⁰⁰³ to get back to 10, so we had better not start with too big a number; it has to be close to 1. What we notice is that the small numbers that we started in 1 begin to look as though we are merely dividing by 2 each time: we see: 16 it becomes 8, then 16, 223; so it is clear that our result is approximately. If we take another look, we shall see 1000 is something, and rather than actually take all the steps to 1000, we guess at the ultimate limit. When we take a step of fraction 5 of 1000 as a quotient we ask what will the answer be? Of course it will be some number close to 1000¹⁰⁻⁰⁰³; but exactly 100022311.3, however—we can get a better answer by the following trick. We subtract the 1, and then divide by the power 5. This ought to convert all the numbers to the same value. We see that they are very closely spaced. At the top of the table they are not equal, but as they come down, they get closer and closer to a constant value. What is the value? Again we look to see how the last is changing, and it has changed next to 1000 divided by 211, by 24, by 51 by 10. These changes are obviously half of each other, very closely, as we have seen. Therefore, if we kept going, the changes would be 13, 7, 3, 2 and 1, minus or less, or a total of 26. Thus we have only 26 more to go, and so we find that the final number is 1.33023. Actually, we shall have to add the error, which should be 1.33023, but to keep it realistic, we shall not alter anything in the arithmetic.) From this table we can now calculate any power of 10 by multiplying the power, call it 100404.

i.e. we have easily calculated logarithms, because the process we shall use is where logarithmic values actually come from. The procedure is shown in Table 22-2, and the numerical values are shown in Table 22-3 (columns 2 and 3).

Table 22-2

Calculation of a logarithm $\log_{10} 2$

$$\begin{aligned} 1 &= 1.00000 \quad 1.124682 \\ 1.124682 &= 1.00461 \dots 1.000000, \text{ etc.} \\ \dots 2 &= (1.124682)(1.00461) \dots 1.000000(1.000000) \\ &= 10^{\left[\frac{1}{1024} (223 - 12 - \ln + 7 + 0.25) \right]} = 10^{\left[\frac{18.754}{1024} \right]} \\ &= 1.000000 \quad \left(\frac{18754}{1024} = 0.25 \right) \\ 10^{\frac{1}{1024}} &= 1.000201 \end{aligned}$$

Suppose we want the logarithm of 2. That is, we want to know to what power we must raise 10 to get 2. Can we raise 10 to the 1/2 power? No; that is too big. In other words, we can see that the answer is going to be bigger than 1/2, and less than 1/2. So we take the factor 10^{1/2} out; we divide 2 by 1.333 . . . and get 1.333 . . . , and so on, and now we know that we have taken away 0.22000001 from the logarithm. Then, number 1.124 . . . is zero the number which log₁₀ we have. When we are finished we shall add back the 1/4, or 25% there. Now we look at the table for the next number just below 1.124 . . . and that is 1.004603. We therefore divide by 1.004603 and get 1.000201. From that we observe the 2 can be made up of a product of numbers that are in Table 22-1, as follows:

$$2 = (1.124682)(1.004603)(1.000000)(1.000000)$$

The 1.000000 factor (1.000000) fell over naturally, which is beyond the range of our table. To get the logarithm of this factor, we see in the result that $10^{1/2} = 1 = 1.33023$ or 1/1024. We find $1 = 0.25 \times 1$. Therefore our answer is 10 to the following power: 1/26 = 12 - 12 - 1/4 - 0.25/1/1024. Adding these together we get .08251/1024. Dividing we get 0.00001, so we know that the $\log_{10} 2 = 0.30103$, which I happen to be right to 5 digits!

This is how logarithms were originally computed by Mr. Briggs of Hullux, in 1623. He said, "I computed approximately 10 square roots of 20.7. We know he was

we've computed only the first 27, because the rest of them can be obtained by this trick with $a = 2$. It's worth noticing that square root of 10 means seven digits, which is no more than twice the six digits we did; however, it was more work because he calculated to sixteen decimal places, and then reduced his answer to fourteen digits by putting off the point. And there were corresponding errors. He used tables of 'logarithms' to fourteen decimal places by John Napier, which is quite curious. But all logarithmic tables for common logarithms were calculated from Mr. Briggs' tables by reducing the number of decimal places. Only in modern times with the BPPA and computing machines have new tables been independently computed. There are such 'one-liner' methods for computing logarithms today, using certain series expansions.

In the above process, we discovered something not so interesting: one thing that you've heard before is we can calculate \log_e easily; we have discovered that $10^x = 1 + 2.30258 \dots$ by sheer numerical analysis. Of course this also means that $\log_{10} x = 1 + \text{something}$ where $x > 1$. Now log₁₀ is to any other base a merely a multiple of log₁₀ from the result that $\log_a x = \log_{10} x / \log_{10} a$. So 10 was used only because we have 10 fingers, and the arithmetic is nice, but 2 is also really not a bad base, one that has nothing to do with the number of fingers on human beings. We might say it's a change of base of logarithms is quite convenient and useful because any the method which people have chosen is to calculate the logarithms by multiplying all the logarithms in the base 10 by "1.397...". This then can't be able to using some other base, and this is called the natural base or base e. Note that $\log_e(1 + x) \approx x$, or $e^x \approx 1 + x$ as $x \rightarrow 0$.

It is easy enough to find out who x is: $y = 0.101025 \dots$ or $10^{0.101025} \dots$ an irrational power of 10. Both of the successive square roots of 10 can be used to compute, not just logarithms, but also 10 to any power, so let me start to calculate this natural base e. For convenience we transform $0.101025 \dots$ into $441.73/4096$. Now 441.73 is $2^6 + 120 + 32 + 16 + 2 = 0.73$. Therefore x , since it is an exponent of a sum, will be a product of the numbers

$$0.73428(0.33853)(0.674402)(0.28774)(0.15153)(0.08085)(0.001642) = 2.3184$$

(The only problem is the last one, which is 0.001642, which is not in the table, but we know that it is small enough, the answer is $1 + 2.30258 \dots$). When we multiply all the \log_e 's together, we get 2.3184 (it should be 2.3183, but it is good enough). The use of such tables, then, is the way in which irrational powers and the logarithms of irrational numbers can actually be computed bases other than the binomials.

20-5 Complex numbers

Now it turns out that after all that work we cannot solve every equation! For example, what's the square root of -1 ? Suppose we have to find $x^2 = -1$. The equation $x^2 = -1$ is forced to be irrational, otherwise that we have discussed, so x^2 , is equal to -1 . So we again have to go outside our numbers to a new number. I.e., as suggested, there's specific solution to $x^2 = -1$ is called *imagination*, we shall call it i ; it has the property, by definition, that its square is -1 . That is about all we can say; to say anything else, there is more than one root of the equation $x^2 = -1$. Surprised? Well, our teacher could say, "No, I'm the -1 , why is minus your i ?" Let just go ahead and say that by definition that i does it, $i^2 = -1$, now let's try another very equation we can write a basically form of the equation $x^2 = -1$ is changed everywhere. This is called taking the complex conjugate. Now we are going to make up numbers by adding a complex part, and multiplying it by numbers and adding other numbers, and so on, according to all of our rules. In this way we find that numbers $x + yi$ can be written in the form $p + qi$, where p and q are what we call real numbers, i.e., the numbers we were talking about in the beginning. The number i is called the unit imaginary number. Any real multiple of i is called pure imaginary. The most general number, as it is at the bottom of the line, is called a complex number. Things may get very worse if, for instance, we multiply two such numbers, let us say $(x + yi)(u + vi)$. Then

Using the rules, we get

$$\begin{aligned} (r - s)(r + s) &= r^2 - s^2 + 2rs - 2rs \\ &= r^2 - s^2 + 2rs - 2rs \\ &= r^2 - s^2 = rs - rs, \end{aligned} \quad (32.4)$$

since $r^2 - s^2 = 1$. Therefore all the numbers that now belong to the ring (32.3) have this most convenient form.

"Now you say, "This can go no further. We have defined powers of logarithms and all the rest, and when we are finished, somebody else will come along with another equation, which can not be solved, like $x^2 + 1x^2 = -x$." Then we have to generalize all over again." But it turns out that one has one more or less, not the square root of -1, every algebraic equation can be solved! This is a far more fine. What we must leave to the Mathematics Department to prove. The proofs are very long, it is, and very necessarily, but certainly not difficult. In fact, the most obvious supposition is that we are going to have to invent again and again one again. But the easiest method of all is that we do not. This is the last situation. After this invention of complex numbers, we find that the rules still work with computers, and we are finished inventing new things. When we find the same idea general for any complex number, we can solve any equation and do it algebraically, in terms of a finite number of these symbols. We do not find any new symbols. The logarithm of a, for example, has a definite result, it is not curved in, nor is it something. We will discuss that now.

We have already discussed multiplication, and addition is easy; if we have two complex numbers, $(x - iy) + (j - iz)$, we simply $\rightarrow (j - i) + (y - z)$. Now we can add and multiply complex numbers. But the real problem, however, is to compute complex powers of complex numbers. It turns out that the problem is actually no more difficult than computing complex powers of real numbers. So let us concentrate now on the problem of calculating 10^a to a complex power, not just at integral powers, but $10^{0.1}$ etc. Of course, we may also times use our rule (32.1) and (32.2). Thus

$$10^{x+iy} = (10^x)^i e^{iy}. \quad (32.5)$$

But if we already know how to compute 10^x we can always multiply anything by anything else; therefore the problem is to determine $i10^x$. Let us call some complex number, $r = iy$. To obtain, however, look at y . Now if

$$10^y = x + iy,$$

then the complex conjugate of this equation must also be true, so that

$$10^{-y} = x - iy.$$

(This we see that we can, sketchily, a number of things without actually computing anything, by using our rules.) The deduction which is resulting using by multiplying these together:

$$10^y 10^{-y} = (x + iy)(x - iy) = x^2 + y^2. \quad (32.6)$$

Thus if we find x , we have y .

Now the problem is how to compute 10^x to an imaginary power. What grade is i in $i10^x$? We may work out our ratio until we can go no further, but here is a reasonable grade. If we can compute it for any particular x , we can get it for the rest. If we know 10^x for arguments x and $x + \Delta$, we want x for twice that x , we can double the number, and so on. But how can we find 10^x for even the special value of $\pi/2$? To do so we shall make one additional assumption, which is not specific to the economy of all the other rules, but which leads to reasonable results and permits us to make progress. When the power is small, we shall suppose that the "true" $10^x = 1 + 2.3025x$ is right, as a generalization of the only "true" a , for complex numbers. Therefore, we begin, with the assumption that this a is true in general, and this tells us that $10^x = 1 + 2.3025 \cdot x$, for $x \ll 1$. So we assume that if x is very small, any part in 10^x , we have a rather good approximation to 10^x .

Now we make a table by which we can compute all the imaginary powers of 10, that is, complex $e^{i\theta}$. It is shown as follows. The first power we want is the 1/1000 power, which as you know is very nearly $1 - i \cdot 0.0001000$. Thus we start with

$$10^{-0.001} = 1.0000 + 0.0003489i, \quad (22.3)$$

and if we keep on multiplying by itself, we can get to a higher imaginary power. In fact, we just reverse the procedure we used in making our logarithmic and exponential law square, 4th power, 8th power, etc., of (22.7), and thus build up the values shown in Table 22-3. We notice an interesting thing, that the numbers are positive at first, but then owing to $i^2 = -1$, they become negative. We shall look it up. That is how we get to a moment. For first, we may be curious to find for what number θ the real part of 10^θ is zero. The θ -value should be i , and we would have $10^i = e^{i\theta} = \cos \theta + i \sin \theta$. As an example, if we want to be able just as we calculated before, let us now use Table 22-3 to find $\log_{10} i$.

What is i ? The number i is Table 22-3 does we have to multiply together to get a pure imaginary result? After a little trial and error, we discover that to recover a 10 times, it is best to multiply "312" by "123." This gives 0.12056 + 0.993486. Then we discover that we should multiply this by a number whose imaginary part is about equal to the size of the real part we are trying to remove. Thus we choose "74" since 74^2 is 0.14848, since that is closest to 0.12056. This then gives $-0.01163 + 0.98907$. Now we have $e^{i\theta} = 1$, and must divide by $0.98907 - 0.01163i$. How do we do this? By inverting the sign of i and multiplying by $0.98907 + 0.01163i$, which leaves $i^2 = -1$. Continuing in this way, we find that the extra power to which 10 must be raised to give i is 0.512 + 138 = 64 = $2 + 6(20) + 100$, or 693,200/1000. If we take 100 in that power, we come up with $e^{i\theta} = 0.98907$.

22-4 Imaginary exponents

To further investigate the subject of taking complex imaginary powers, let us look at the powers of 10 taking various exponents, not doubling the power each time, in order to follow Table 22-3 better and to see what happens to those minus signs. This is shown in Table 22-4, in which we take $10^{i\theta}$, and just keep multiplying. We see that a decrease passes through zero, owing to $\theta = 0$ if we could just lie between $\theta = 10$ and $\theta = 11$ it would obviously swing to -10 and swing back. The value is going back and forth.

In Fig. 22-1 the dots represent the numbers cast up in Table 22-1, and the lines are just drawn to help you visually. You see that the numbers are not oscillating; 10^{iθ} represents itself, it is a periodic thing, and so even i is very analogous to ω , because if a certain power is k then the fourth power of that would be i^4 squared. It would be plus one, and therefore, since $i^4 = 1$ is equal to by taking the fourth power we discover that $10^{i4\theta}$ is equal to $+1$. Therefore, if we wanted $10^{i20\theta}$, for instance, we could write $+1 \cdot 10^{i2\theta} \cdot 10^{i18\theta}$. In other words, it has a period, it repeats. Of course we recognize what a sine wave looks like. They look like the sine and cosine, and we shall see them, but while the algebraic sine and also basic cosine. However, instead of using the base 10, we shall put them into our natural base, which only changes the horizontal scale; so we denote $e^{i\theta}$ by c , and write $10^{i\theta} = c^{\theta}$, where c is a real number. Now $c^0 = 1$, up and down, with this as the general course of c plus i times, along the circumference of c . Thus

$$c^{\theta} = \cos \theta + i \sin \theta. \quad (22.6)$$

What are the properties of $\cos \theta$ and $\sin \theta$? First, we know, for instance, that $x^2 + y^2 = 1$, but it is also proved that $\cos^2 \theta + \sin^2 \theta = 1$ just as for the base 10. Therefore $\cos^2 \theta + \sin^2 \theta = 1$. We also know that $\cos \theta \sin \theta = \sin \theta \cos \theta = 0$ and the sine and cosine are nearly 1, and $\sin \theta$ is nearly θ and $\cos \theta$ is $1 - \theta$. But all of our previous properties of these trigonometric functions, when carried from being imaginary numbers, are the same as the new ones of this situation.

Table 22-3

Successive Powers of

$$10^{-0.001} = 1 - 0.0003489i$$

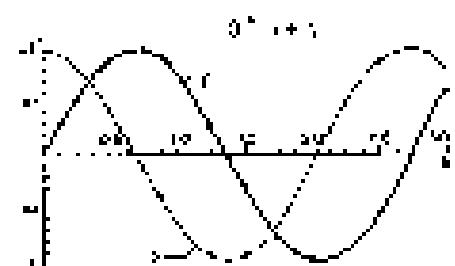

Figure 22-1

Is this good enough? Let us find out to what power we need to e . What \rightarrow the logarithm of the base e ? We stacked it, as before. In the case 10 it was 2.3026, but when we change our logarithm's base to e , we have to multiply by 2.3026, and if we divided it comes out 1.3863. So this will be called "algebraic π ." But we see, π differs from the regular π ' by only one place at the last point, and that, of course, \rightarrow the result of others at the arithmetic. So we have created two new functions in a purely algebraic manner, trigonine and the one which refers to algebra and only to circles. We wake up at the end to discover the very identities that are natural to geometry. So there is a connection, you might say between algebra and geometry.

We summarize with this, the sine and cosine formula in mathematics:

$$e^{it} = \cos t + i \sin t \quad (2.9)$$

This is our new:

We now close the geometry to the algebra by representing complex numbers as points; the horizontal position of a point x is the vertical position of a point $i y$ (Fig. 22-2). We represent every complex number, $x + iy$, then if the radial distance to the point of origin x and the angle is called t , the algebraic law is that $x + iy$ is written in the form e^{it} , where the geometrical relationship between x , y , r , and t are as shown. This, then, is the unification of algebra and geometry.

When we begin this chapter, we did only with the basic notion of integers and counting, we had little idea of the power of the processes of the method and generalization. Using the art of algebraic "tricks," or properties of numbers, Eq. (2.8), and the definitions of inverse operations (2.6), we can handle here, otherwise, to our absolute not only numbers but also all things like ratios of lengths, powers, and trigonometric functions (for these are with the simple powers of the numbers (2.6) all unity by connecting to successive higher roots or root).

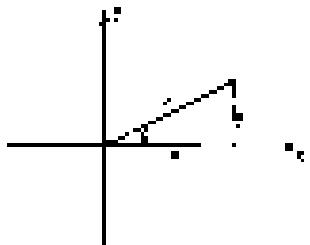

Fig. 22-2 $x + iy = re^{it}$.

Harmonics

13-1 Complex numbers and harmonic motion

In the present chapter we shall continue our discussion of the harmonic oscillator and, in particular, of forced harmonic oscillation, using a new technique called analysis. In the preceding chapter we introduced the idea of complex numbers, which have real and imaginary parts and which can be represented on a diagram in which the horizontal axis is the imaginary part and the vertical axis represents the real part. If a is a complex number, we may write it as $a = a_r + ia_i$, with the subscript r telling us the real part of a and the subscript i telling the imaginary part of a . Referring to Fig. 27, we see that we may also write a complex number $a = x + iy$ in the form $x + iy = re^{i\theta}$, where $r^2 = x^2 + y^2$ ($r = |a|$) and $\theta = \arg(a)$. (The complex conjugate of a , written a^* , is obtained by reversing the sign of $i\theta$.) So we shall represent a complex number a by two figures: a real axis (the imaginary part), a magnitude r and a phase angle θ , described. Here x and y and r are clearly *real* and $\sin \theta$ and $\cos \theta$ give a complex number $x + iy$, i.e. $\sqrt{r^2} = j\sin \theta$ and $a = jy/r$, the ratio of the imaginary to the real part.

We are going to apply complex numbers to the analysis of physical phenomena by the following rule. We have complex to change the basis set; the real values may have a driving force which is a certain constant times cos ωt . Now note it since, $F = F_r$, we can write the solution as the real part of a complex number $F = F_r e^{i\omega t}$ because $e^{i\omega t} = \cos \omega t + j \sin \omega t$. The reason we do this is that it is easier to work with exponential functions than with a cosine. So the whole trick is to represent all oscillatory functions as the real part of certain complex functions. The complex number F that we have so defined is not a real physical force, because it is in physics, in reality, complex, i.e. it has both its imaginary part, only a real part. We shall, however, speak of the "force" F , just, for convenience, the actual force is the *real part* of that expression.

To take another example, suppose we want to represent a force which is a cosine wave that is out of phase with a delayed phase ϕ . This, after all, would be the real part of $F_r e^{i(\omega t - \phi)}$, but exponents being what they are, we can write $F_r e^{i(\omega t - \phi)} = F_r e^{i\omega t} e^{-i\phi}$. Thus we see that the only law of causality is that ϕ is the sum of sines and cosines; this is the reason we choose to use complex numbers. We shall often write

$$F = F_r e^{i(\omega t - \phi)} = F_r e^{i\omega t}. \quad (13.1)$$

We write a little $e^{i(\omega t - \phi)}$ over the F to remind ourselves that this quantity is a complex number; here the number is

$$e^{i\omega t} = \rho e^{i\omega t}$$

Now let us solve an equation, using complex numbers, to see whether we can work out a problem for some real case. For example, let us try to solve

$$\frac{d^2x}{dt^2} + kx = F_r \cos \omega t, \quad (13.2)$$

where F is the force which drives the oscillator and x is the displacement. Now, about the right way seems to suggest that x and F are actually complex numbers, for a mathematical purpose only. That is to say, x has a real part and an imaginary part, and F has a real part and an imaginary part, too!

13-1 Complex numbers and harmonic motion

13-2 The forced oscillator with damping

13-3 Electrical resonance

13-4 Resonance in nature

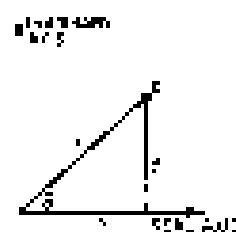

Fig. 27. A complex number may be represented by a point in the "complex plane".

Now if we had a solution of (21.2) with complex numbers, and substituted the complex numbers in the equation, we would get

$$\frac{d^2x_1}{dt^2} + \frac{k(x_1 - x_2)}{m} = \frac{\alpha_r + i\omega}{m}$$

or

$$\frac{d^2x_1}{dt^2} + \frac{kx_1}{m} + \left(\frac{d^2x_2}{dt^2} + \frac{kx_2}{m} \right) = \frac{\alpha_r + i\omega}{m}$$

Now, since if two complex numbers are equal, their real parts must be equal and their complex parts must be equal, we deduce that the real part of x_1 satisfies the equation with the real part of the force. We may emphasize, however, that this assumption introduces real x_1 and its imaginary part is not zero in general, but is only zero for equations which are linear, that is, for equations in which ω appears in every term only in the last power or the tenth power. For instance, if there were in the equation a term kx^2 then when we substitute $x_1 = A_r e^{i\omega t}$, we can't get $x_1 = kx^2$, but when separated into real and imaginary parts this would yield $kA_r^2 - \omega^2$ as the real part and $2kA_r \omega$ as the imaginary part. So we see that the real part of the equation which does involve just ω^2 , but ω not ω^2 . In this case we get a different result so that the two we will be able to solve, with x_1 , the complex x_2 being the independent variable that the two we will be able to solve, with x_2 , the complex x_1 being the independent variable.

Let us now try our new method for the problem of the damped mass-spring, that we already know how to solve. We want to solve Eq. (21.2) now, but we say that we are going to do it in a new way.

$$\frac{d^2x}{dt^2} + \frac{kx}{m} = \frac{F_0 e^{i\omega t}}{m} \quad (21.3)$$

where $F_0 e^{i\omega t}$ is complex number. Of course x will also be complex, but remember the rule: take the real part to find x_1 , what is really going to be easy to solve (21.3) is the forced solution; we shall discuss other solutions later. The function x then has the same frequency as the applied force, and has same amplitude of oscillation and same phase, and so it can be represented also by some complex number A whose magnitude represents the ratio of x to x_1 whose phase represents the difference in the same way as for the force. Now a wonderful feature of an exponential function is that $d(e^{i\omega t})/dt = i\omega e^{i\omega t}$. When we differentiate an exponential function, we bring down the exponent as a simple multiple. The second derivative does the same thing, if (dx/dt) is multiplied by $i\omega$, then it is very simple to prove immediately, by inspection, that the equation is true if every time we see a differentiation we simply multiply by $i\omega$. Differentiation is now as easy as multiplication. The idea of using exponentials in such a Tertius' logarithms is almost as great as the invention of logarithms, in which multiplication is replaced by addition. Non-differentiation is replaced by multiplication. This we inquire here:

$$(d^2x/dt^2) = (d^2x_1/dt^2) - i\omega \dot{x}_1 \quad (21.4)$$

We have introduced the common factor $e^{i\omega t}$. See how simple it is! Differential equations are immediately converted, by sight, into more algebraic eq's where you only have the solution by sight, that,

$$x = \frac{F_0/m}{(k/m) - \omega^2} e^{i\omega t}$$

since $(i\omega)^2 = -\omega^2$. This may be slightly simplified by substituting $k/m = \omega_0^2$ which gives

$$x = F_0/m \cdot \frac{1}{\omega_0^2 - \omega^2} e^{i\omega t} \quad (21.5)$$

This, of course, is the situation which before for since $m(\ddot{x} - \omega^2 x) = 0$ is a real number, the phase angles of \dot{x} and of x are the same (as we have seen $\omega^2 > \omega_0^2$ as mentioned previously). The angle $\angle(\dot{x})$, which requires how fast x oscillates, is related to the angle of the F by the factor $\angle(F_0 e^{i\omega t}) = \omega^2 t$, and this factor becomes $\omega_0^2 t$.

encounters which ω is nearly equal to ω_0 . So we get a very strong resonance effect. At such the right frequency ω_0 if we add a pendulum at the end of a string and shake it at just the right frequency, we can make it swing very high!

23.3 The forced oscillator with damping

Now, let's look at how we analyze oscillatory motion with the more elegant mathematical technique. But the elegance of the technique is not at all exhibited in such a problem that can be solved easily by other methods. In our problem, often one appears to be more difficult problems. Let us consider some another, more difficult problem, which is common and a relatively realistic situation. In the previous unit (Equation 23.9), we saw that if the frequency ω were exactly equal to ω_0 , we would have no damped response. Actually, of course, no such infinite response occurs because some other damping-like friction, which we have set for ignored, limits the response. So we therefore set in Eq. 23.9 a friction term.

Obviously such a problem is very difficult because of the oscillator and complexity of the frictional term. That is... however, every circumstance in which the frictional force is proportional to the speed with which an object moves, an example of such friction is the friction for slow motion of an object in oil or a thick liquid. There is no force when it is not moving $v < 0$, but the faster it moves, the harder the oil tries to go past the object, and the greater is the resistance. So we will assume that the F_f is in addition to the term in (23.2), we have some proportional proportionality to the velocity: $F_f = -\gamma v$, it may be convenient, in our mathematical analysis, to write the constant γ from Eq. 23.2 to simplify the equation a little. This is just the same trick we use with ϵ when we replace it by $m\ddot{x}$ to simplify the physics. This circumstance will be

$$m(d^2x/dt^2) + \gamma dx/dt + kx = F \quad (23.6)$$

or, setting $\omega_0^2 = k/m$ and $\gamma = m\beta/\omega_0$ and canceling out the mass m ,

$$(d^2x/dt^2) + \gamma dx/dt + \omega_0^2 x = F/m. \quad (23.6a)$$

Now we're at the equation in the most convenient form possible. If γ is very small, and represents very little friction; if γ is very large, there is a tremendous amount of friction. How does $x(t)$ in this linear differential equation? Suppose that the driving force is constant in time ($F = A$; we could pick this from (23.2) and try to solve it, but we want instead solve it by our new method). Thus we write F as $F = A e^{i\omega t}$, A is F and ω is the real part of ω , and substitute this into (23.6a). It is not even necessary to do the actual substituting, for we can see at a glance that the equation would become

$$(i\omega)^2 x + i\gamma \omega x - \omega_0^2 x = (F/m)e^{i\omega t}. \quad (23.7)$$

As a matter of fact, if we tried to solve Eq. 23.6a by our old straightforward way, we would really complicate the analysis of the "complex" method. If we divide by $e^{i\omega t}$ on both sides, then we can obtain the necessary function, given force F ; it is

$$x = (F/m)(\phi - \omega^2 - i\gamma\omega) \quad (23.8)$$

This result x is given by F times a certain factor. There is no additional factor for the factor, we've already taken care of it, b . We may call B for "resonant process":

$$B = \frac{m\omega_0^2}{m\omega_0^2 - \omega^2 - i\gamma\omega}$$

and

$$\phi = F/m \quad (23.9)$$

(Although the letters ϕ and ω_0 are in very common use, this B has no particular meaning.) This factor B can either be written as $B = \phi$, or as a certain \rightarrow quantity \times times ω^2 . If it is written as a certain magnitude times ω^2 , let us see what it means

Now $\hat{F} = F_0 e^{i\omega t}$, and the real part of F is the real part of $F_0 e^{i\omega t}$. That is, $F_0 \cos(\omega t - \phi)$. Now, Eq. (23.9) tells us that ϕ is equal to $\pi/2 - \theta$, making $R = \rho^2$ as another name for R , we get

$$R = \rho^2 = \omega^2 F_0^2 / (\omega^2 + \gamma^2).$$

Finally, going even further back, we see that the phasor \vec{x} , which is the real part of the complex \vec{x} , is equal to the real part of $\vec{F}_0 e^{i\omega t}$. But ρ and θ are real, and the real part of $e^{i\omega t}$ is simply $\cos(\omega t + \theta)$. Thus,

$$\vec{x} = \rho \vec{F}_0 \cos(\omega t + \theta) = R \vec{F}_0. \quad (23.10)$$

This tells us that the amplitude of the response is the magnitude of the force F multiplied by a certain magnification factor, ρ . This gives us the "resonance" of oscillation. It also tells us, however, that \vec{x} is not oscillating in phase with the force, which has the phase θ , but is shifted by $\pi/2$ extra current θ . Therefore ρ and θ represent ratios of the response and the phase shift of the response.

Now let's work out what ρ is. If we have a complex number, the square of the magnitude is equal to the number times its complex conjugate; thus,

$$\begin{aligned} \rho^2 &= \frac{1}{m^2(\omega^2 - \omega^2 - 2\omega i\omega\gamma) + \omega^2 + \gamma^2} \\ &= \frac{1}{m^2((\omega^2 - \omega^2)^2 + \gamma^2\omega^2)}. \end{aligned} \quad (23.11)$$

In addition, the phase-angle θ is easily found, for if we write

$$1/\rho = 1/\rho e^{i\theta} = (1/\rho) e^{-i\theta} = m\omega i(-\omega^2 + \gamma^2\omega),$$

we see that

$$\tan \theta = -m\omega(\omega^2 - \gamma^2). \quad (23.12)$$

If ω equals ω_0 , then $\tan \theta = -\infty$. A negative value for θ results for all ω , and this corresponds to the displacement x lagging the force F .

Figure 23.2 shows how ρ^2 varies as a function of frequency (ω^2) is physically more interesting than ρ , because it is proportional to the square of the amplitude. Of course, this is the curve that is developed in the oscillator by the forces. We see that if ω^2 is very small, then $1/\rho(\omega^2 - \omega^2)^2$ is the most important term, and the response lies high up toward infinity when ω equals ω_0 . Now, the "infinity" is not actually infinite because if $\omega = \omega_0$, then $1/\rho^2\omega^2$ is still there. The shape of ρ^2 is shown in Fig. 23.1.

In certain circumstances we get a slightly different form to curve (23.12), also called a "resonance" formula, and one in ρ^2 linking ω and ω_0 . Representing a different phenomenon, but it does not. The reason is that if ω is very small, the most important part of the curve is $1/\rho(\omega^2 - \omega_0^2)$, and we may replace $(\omega^2 - \omega_0^2)$ by an approximate formula which is very accurate if ω is small and very near ω_0 . Since $\omega_0^2 = \omega_0^2(\omega_0 - \omega_0 + \omega)$, this is nearly the same as $1/\omega_0(\omega_0 - \omega)$ and the two terms are nearly the same as each other. Using these in (23.12), we see that $1/\rho^2 = \omega^2 - \omega_0^2/(\omega_0^2 - \omega^2)$, or that

$$\rho = \sqrt{2\omega_0/(\omega_0^2 - \omega^2 - 2\omega_0^2)} \quad \text{if } \omega \ll \omega_0 \quad \text{and} \quad \omega \neq \omega_0. \quad (23.13)$$

It is easy to find the corresponding form θ for ρ^2 . It is

$$\theta^2 = 1/(2\omega_0^2)(\omega_0^2 - \omega^2 + \gamma^2/2).$$

We shall leave it as an exercise to show the following: if we call the maximum height of the curve of ρ^2 as ω_0 units, and we ask for the width $\Delta\omega$ of the curve, at one-half the maximum height, i.e., at half the maximum height of the curve is $\Delta\omega = \gamma$, supposing that γ is small. The resonance is sharper and sharper as the friction factors are made smaller and smaller.

As another measure of the width, some people use a quantity Ω which is defined as $\Omega = \omega_0/\omega$. The higher is the resonance, the higher the Ω ; $\Omega = 100$ means a resonance whose width is only 10% of the frequency scale. The Ω of the capacitor shown in Fig. 29-2 is 1.

The importance of the resonance phenomenon is that it occurs in many other circumstances, and on the rest of this chapter will describe some of these other circumstances.

29-3 Electrical resonance

The simplest and most widespread application of resonance is inductively. In the electrical work there are a number of objects which can be connected in simple electric circuits. These parts are circuit elements, as they are often called, and of three main types, although each one has a little bit of the other two mixed in. Before discussing them in greater detail, let us note that the weight of an inductor usually depends mainly on the end of a spring, only an approximation. All the mass is not necessarily at the "mass"; some of the mass is in the helical coil spring. Similarly, all of the spring is not at the "spring"; the mass itself has a little elasticity, and so though it may appear as if it is not absolutely rigid, and as it goes up and down, it never goes so slightly under the action of the spring pullings. The same thing is true in electricity. There is an experimental, though we can't jump things into "circuit elements" which are assumed to have particular characteristics. To set the proper time to discuss the experimental part, we shall simply assume that it is true in the circuit elements.

The three main kinds of circuit elements are the following. The first is called a capacitor (Fig. 29-4); an example is two plane metallic plates spaced a way or d , distance apart, by an insulating material. When the plates are charged there is a certain voltage difference between them; a certain difference in potential between them. The same difference of potential appears between the terminals alone, because if there were any difference along the connecting wire, electricity would flow right away. So there is a certain voltage difference V between the plates. If there is a certain electric charge q and $-q$ on them, respectively. Between the plates there will be a certain electric field; which we can find a formula. In it (Chap. 13 and 14):

$$V = qd/\epsilon_0 A, \quad (29-1)$$

where d is the spacing and A is the area of the plates. Note that the potential difference is a linear function of the charge. If we do not have insulated wires, but insulated electrons which are of any sort of use, the difference in potential is still directly proportional to the charge, but the constant of proportionality may not be so easy to compute. However, all we need to know is that the potential difference per unit capacity is proportional to the charge. If $C = q/V$, the proportionality constant is $1/C$, where C is the capacity of the object.

The second kind of circuit element is called a resistor; it offers resistance to the flow of electrical current. It turns out that metallic wires and many other substances resist the flow of electricity in this manner; a resistor is a voltage difference across a piece of something where there exists an electric current. And this is proportional to the electric voltage difference:

$$V = IR = R \text{ (current).} \quad (29-2)$$

The proportionality constant is called the resistance R . This relationship is already familiar to you; it is Ohm's law.

If we think of the charge and a capacitor as being analogous to the displacement x of a harmonic system, we see that the current, $I = dq/dt$, is analogous to velocity, (dx/dt) is analogous to a spring constant k , and R is analogous to the resistive coefficient γ . Now it is very interesting that there exists another circuit element which is the analog of m . This is the coil which builds up a magnetic field W in association to a direct current i . A changing magnetic field builds up the voltage V which is proportional to di/dt (this is how a transformer works).

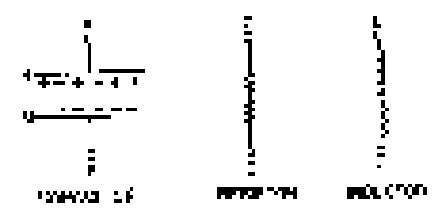

Fig. 29-4. The three passive circuit elements.

(21) The magnetic field is proportional to current, and the induced voltage (so-called inductance) is proportional to the rate of change of current:

$$V = L \frac{di/dt}{dt} = L \frac{di}{dt} \quad (21.16)$$

Let us return to the ω -circuit, and let's always assume a sinusoidal voltage input:

Fig. 21-5 An oscillatory electrical circuit with resistance, inductance, and capacitance.

Suppose we have a circuit in which we have connected the three circuit elements in series (Fig. 21-5); then the voltage across the whole thing (from 1 to 2) is the work done in carrying charge through, and it consists of the sum of several pieces: across the inductor, $V_L = L \frac{di^2/dt^2}{dt}$; across the resistance, $V_R = R \frac{di}{dt}$; across the capacitor, $V_C = q/C$. Let our initial guess be the apedical equation:

$$L \frac{di^2/dt^2}{dt} + R \frac{di}{dt} - q/C = P(t) \quad (21.17)$$

Now we see that this equation is exactly the same as the second real equation (21.6), and it must also be solved in exactly the same manner. We suppose that $P(t)$ is oscillatory; we are dealing, then, with a generator with a pure sine wave oscillation. Then we can write our Eq. (21.7) as a complex \tilde{P} with the understanding that it must be ultimately multiplied by $e^{i\omega t}$, and the real part taken, in order to get the true P . Likewise, the charge q must be rearranged, and then integrated over the same amount of time T as in Eq. (21.8); we write the corresponding equation, integrated over the time of ωT (that is, T divided by ω). Thus Eq. (21.17) translates to

$$\left[L(\omega)^2 + R\omega \right] + \frac{1}{C} \tilde{q} = \tilde{P}$$

or

$$\tilde{q} = \frac{\tilde{P}}{L(\omega)^2 + R\omega \pm \frac{1}{C}}$$

which we can write in the form

$$q = P(t)(\omega^2 - x^2 + i\omega x) \quad (21.18)$$

where $x^2 = 1/C$ and $x = \omega/\sqrt{L}$ is exactly the same denominator as we had in the ω -circuit, now with exactly the same "constant product" $1/C$ corresponding cross between the ω -circuit and node \tilde{q} , the next entries in Table 21-1.

Table 21-1

General nomenclature	Mechanical analog	Electrical property
independent variable	time (t)	time (t)
dependent variable	position (x)	charge (q)
force	mass m	inductance (L)
displacement	displacement (x)	resistance ($R = \Omega$)
stress	surface (σ)	capacitance ($C = \text{farad}$)
constant frequency	$\omega = 2\pi f$	$\omega^2 = L/C$
period	$T = 2\pi\sqrt{m/L}$	$T = 2\pi\sqrt{C/R}$
degree of merit	$R = \text{const}$	$G = \text{const}$

We must use ω in small harmonic motion. In the electrical circuit, a different notation is used. (From one field to another, the analysis is not really very different, but the way of writing the equations is often different.) For d , it is customarily used instead of ω in electrical engineering, in rad/sec (rps). (After all, ω must be the angular f .) Also, the engineer would rather have a relationship between P and \dot{q} (the integral of \tilde{q} over time), just because they are more used to it that way. Thus, since $f = \omega/2\pi = \omega/2\pi$, we can just substitute f for ω and \dot{q} :

$$V = Q\omega^2 - R\dot{q} + 1/2\omega C\dot{q}^2 = 2f. \quad (21.19)$$

Another way is to modify Eq. (23.17), so that it accommodates one other sees it in this way:

$$A \sin(\omega t + \phi) = (1/\rho) \int J dt = 100 \quad (23.20)$$

At this rate, we have an alternating 100 ohm resistance if and current J which is just the same as (23.12) except divided by ρ , and that satisfies Eq. (23.14). The quantity $\omega + \phi = \psi$ is a complex number, and is used in quantum mechanical calculations that it has a name, was called the complex propagation ψ . Thus we can write $\psi = \phi$. The reason that engineers like to do this is that they learned something when they were young: "as far as business when they only have direct resistance and not. But they have become more educated and know no circuits, so they want them to be in book the same". Thus this writing $\psi = \phi$, the only difference being that the resistance is now given by a more complicated thing, imaginary, or $i\omega$. So that says that they cannot use what everyone else in the world uses for imaginary numbers, they have to use $i\omega$! But Cut, the ammeter said they did not invent so that rule long ago when ψ was ϕ ? (they may get into trouble when they talk about the real resistance for which they also use). The difficulties of science are so large exactly the different ways of doing the same, and all the other difficulties we shall have are due to man, not by nature.)

23-4 Resonance in nature

Although we have imagined the electrical case, in detail, we could also bring up some other cases in safety texts, and such exactly how the resonance argument is important. There are many of consequences in nature in which something is "resonantly" excited in which the resonance phenomenon occurs. We will look, in an earlier chapter, let us say demonstrate it. If we walk around our store, putting books off the shelves and simply shaking them up, there is an example of a grave consequence to us (Fig. 23-1) and comes from the same argument, what does. Only first we demonstrate, however, organized in taking the easiest possible example, it takes only five or six books arranged quite a series of shelves, and which are oscillating.

The first we can do from mechanics, the first one a large effect the atmosphere or the whole earth. In the atmosphere, which we suppose surrounds the earth evenly in all directions, is pulled to one side by the wind or, rather, squared pressure from a trouble here and there, and then if you let it go, it would probably go up and down; this is an oscillator. This oscillator is driven by the moon, which is a basically rotating galaxy in the earth, and the component of the force, say to every direction, has a cosine component, and as the response of the atmosphere to the tidal pull of the moon is that of an oscillator. The expected response of the atmosphere is shown in Fig. 23-6. A second feature is another, theoretical curve under discussion, is the peak from which rises take out of center. Now one might think, if we only have one point of this resonance curve, since we only have the one frequency, corresponding to the rotation of the earth under the moon, which occurs at a period of 12.42 hours = 12 hours for the earth, then the two don't fit together, plus a little, and to take the moon's lagging behind. But from the rest of the atmospheric tides, just from the papers themselves of today we can get ω_1 , ω_2 , and ω_3 . From these we can get ψ_1 , ψ_2 , and ψ_3 thus draw the entire curve! This is an example of very good science. From two nodes we obtain two numbers, and from these two numbers we draw a curve that agrees with ψ measured year. I made the very point that determines the curve. It is of the use unless we can measure everything else, and in the case of geostrophic, that is, Chen et al., result. But in this particular case there is another thing which we can give, however, namely that in the same tides as the tidal frequency ω_1 ; that is, if someone described the atmosphere as it would oscillate with the frequency ω_1 . Now there was just a large disturbance in 1851; the Krakatoa volcano exploded and had the island blown off, and it made such a large explosion, in fact so large that the period of oscillation of the atmosphere could be measured. It came out to $16\frac{1}{2}$ years. These obtained from

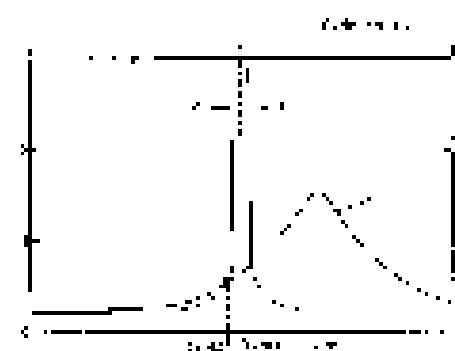

Fig. 23-6. Response of the atmosphere to a steady Earth-shaker. a is the required response of the atmospheric tide; a of gravitational origin: peak amplitude 130x1. It is derived from measured data (Hansen and others of Met Office, Work and MacDowell, "Rotation of the Earth," Cambridge University Press, 1940).

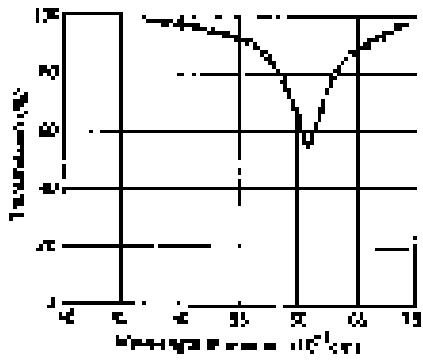

Fig. 23-7. Transmission of infrared radiation through a thin (0.17μ) sodium chloride film. [After R. S. Becker, J. Phys. B, 23, 723 (1922); Kittel, Introduction to Solid State Physics, Wiley, 1956.]

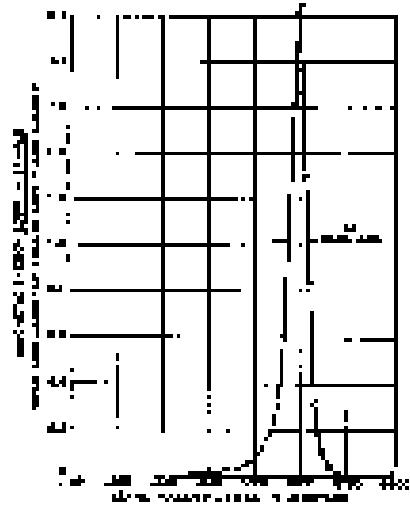

Fig. 23-8. Magnetic energy loss in para-xylylene organic compound as a function of applied magnetic field frequency. [Holden et al., Phys. Rev. 75, 161 (1949).]

Fig. 23-6 shows us 20 terms; and 20 minutes, so there we have at least one check on the validity of our understanding of the atmospheric waves.

Now we go to the next scale of mechanical oscillation. The time we make a sodium chloride crystal which has sodium ions and chlorine ions next to each other, as we described in an early chapter. These ions are constantly changing, alternately plus & minus. Now there is an interesting oscillation possible. Suppose the + would drift all the way to the right and all the negative charges to the left, and then go; they would then oscillate back and forth. As sodium, since against the calcium lattice. How can we now do such a thing? That is easy, for if we apply an electric field to the crystal, it will steal the plus sign one way and the minus charge the other way. So by using an external electric field we can produce net lattice oscillations. The frequency of the electric field needed is so high, however, that it corresponds to infrared radiation. So we try to find a resonance curve by measuring the absorption of infrared light by sodium chloride. Such a curve is shown in Fig. 23-7. The abscissa is not frequency, but is given in terms of wavelength, but that is just a technical matter, of course, since for a wave there is a definite relation between frequency and wavelength; or it is really a frequency scale, and a certain frequency corresponds to the length of a wave.

But what about the width? What determines the width? There are many cases in which the width, that is, how wide the curve is not really associated with ω_0 , that one would have thermally. There are two reasons why there can be a wider curve than the theoretical curve. If the atoms do not all have the same frequency, as might happen if the crystal were strained in certain regions, so that in these regions the oscillation frequency were slightly different than in other regions, then when we tune it many resonance curves may appear here as we apparently get a wider curve. The... for this of water is a very easy problem we cannot measure the frequency precisely enough. If we open the slit of the spectrometer fairly wide, so actually we don't see just one frequency, we actually had a certain range of frequencies, we may not have the resolving power needed to see a narrow curve. Otherwise, we cannot say whether the width in Fig. 23-7 is natural, or whether it is due to inhomogeneities in the crystal or to some width of the slit of the spectrometer.

Now we turn to a more esoteric example, and that is the swinging of a \leftrightarrow pendulum. If we take a magnet, with two south + north poles, in a constant magnetic field, the magnet will be pulled one way and the S end the other way, and this will in general be a torque on it, so it will vibrate about its equilibrium position, like a compass needle. However, the magnet is usually single-layered wires. These atoms here are in your memory, but the torque does not produce a simple motion in the direction of the field, but instead it has a, a precession. Now, look at it from the side, and one component is swinging, and we can detect or drive that swinging and measure the frequency. The curve in Fig. 23-8 represents a typical such resonance curve. What has been done here is slightly different, however. The frequency of the initial tick, that is used to drive this swinging, is always kept the same, while we would have expected that the increasing ω_0 would vary the amplitude of the curve. They could, as done, that way, but technically it was easier for them to keep the frequency ω_0 fixed and change the strength of the constant magnetic field, which corresponds to changing ω_0 in our example. They have plotted the resonance curve against ω_0 . Anyway, he is a typical resonance with a certain ω_0 and γ .

Now we go still further. Our next example has to do with a rotating atom. The motions of electrons and neutrons in nuclei are really in certain ways, and we can demonstrate this by the following experiment. We bombard a lithium atom with protons, and we discover that a certain rate for producing protons, occurring the at very low energy, has a sharp resonance. We note in Fig. 23-9, however, the following: from one reason, the horizontal scale is not a frequency, it is an energy. The reason is that in quantum mechanics, what we think of classically as the energy will turn out to be really related to a frequency of a wave on a string. When we calculate something which is simple, classical mechanics has to do with a frequency, we find that when we do quantum mechanics experiments with atomic

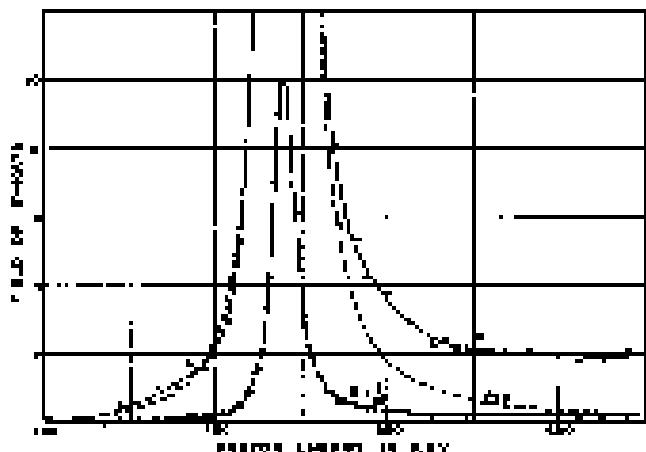

Fig. 23-9. The intensity of gamma radiation from lithium, in units of 10^{-3} , vs. energy of the bombarding proton. The dashed curve is a theoretical one calculated for a proton with no angular momentum $J = 0$. (Bonner and Evans, Phys. Rev. 73, 953 (1948))

more, we get the corresponding curve as a reaction scheme. In fact, this curve is a demonstration of this relationship, in a sense. It shows that if you plot and count how many days it costs to count, which of course they do.

Now we turn to another example which also involves a nuclear energy level, but with a much higher level here. The π^+ in Fig. 21-1 has a range of approximately $10,000$ cm when cold, while the π^+ $\rightarrow \pi^+ + \pi^-$ is approximately 10^{-2} cm, very cold; in other words, this has a β of 10^{11} . When the curve was measured it was the largest β of any reaction that had ever been measured. It was measured by Dr. M. W. Macmillan and G. C. Rieke of this subject group. The behavior of the curve is peculiar, because the technique for obtaining the slightly different intensities was to use the Doppler effect, by moving the source relative to the detector. One can see how delicate the experiment is when we realize that the speed involved is 10^8 centimeters per second! On the usual scale of the spectrum in frequency would correspond to a point about 10^{15} cm to the left—slightly off the paper!

Finally, if we look in an issue of the *Physical Review*, say that of January 1, 1962, will we find a resonance curve? Every book has a resonance curve, and Fig. 24-1 is the resonance curve for the one I am interested in now, which is very interesting. It is the resonance found in a certain reaction among strange particles, a reaction in which a K^- and a neutron interact. The reaction is denoted by saying how many of some kinds of particle is emitted, and depending on whether one how many come out, one gets different curves, but of the same shape and with the peak at the same energy. We thus believe that there is a resonance for a certain energy for each K^- meson. And presumably means that there is some kind of a cold, a condition corresponding to the resonance which can be obtained by scattering like a K^- and a proton. This is a new particle interaction. Today we do not know whether to call it a bump like this a "resonance" or simply a resonance. What there is is a very narrow resonance, which occurs at a very definite energy, just as though there were a particle of that energy present in nature. When the resonance is this, then we do not know whether to say there is a particle which does not live very long, or simply a condition of the reaction probability. In the second chapter, one point in particular the reader has when we start chapter two whether this resonance **was** not **absent**. So our next should now come still another particle in it!

Fig. 23-11. Measurement representation of the cross section for the reaction (a) $K^- + p \rightarrow K^- + \pi^+ + \pi^-$ and (b) $K^- + p \rightarrow K^- + \pi^0 + \pi^0$. The lower curves (a) and (b) represent the measured resonance background, while the upper curves contain in addition the expected resonance. (Macmillan et al., Phys. Rev., Lett. 4, 28 (1962))

Transients

24-1 The energy of an oscillator

Although this chapter is entitled "transients," certain parts of it are, in a way, sort of the last chapter on forced oscillation. One of the features of forced oscillation which we have not yet discussed is the energy of the oscillation. Let us now consider total energy.

In a mechanical oscillator, how much kinetic energy is there? It is proportional to the square of the velocity. Now what about an important point? Consider an arbitrary quantity A , which may be the velocity or something else that we want to discuss. When we write $A = A_0 e^{i\omega t}$, A is complex - unless, the real and imaginary, A , the imaginary work is only the $\sin(\omega t)$ part; therefore if, for some reason, we want to take the square of A , it is not right to square the complex number and then take the real part because the real part of the square of a complex number is not just the square of the real part, but also involves the imaginary part. So when we write in that the energy we have to get away from the complex notation for A so it's better with the inner workings are:

Show this true physical A is the real part of $A_0 e^{i\omega t + \phi}$, that is, $A = A_0 \cos(\omega t + \phi)$, where A_0 , the complex number, is written as $A_0 e^{i\phi}$. Now the square of this real physical quantity is $A^2 = A_0^2 \cos^2(\omega t + \phi)$. The square of the quantity, then, goes up and down from a maximum to zero, like the square of the cosine. The square of the cosine has a maximum of 1 and a minimum of 0, and its average value is $1/2$.

In many circumstances we are not interested in the energy at any specific instant during the oscillation; for a single number of oscillations we usually want the average of A^2 , the mean of the square total over a period of time compared with the period of oscillation. In these circumstances, the average of the cosine signal may be real, so we have the following theorem: if A is represented by a complex number, then the mean of A^2 is equal to $|A|^2$. Now $|A|^2$ is the square of the magnitude of the complex A . (This can be written in many ways - some people like to write $|A|^2$ as $A \bar{A}$ with \bar{A} being A 's complex conjugate.) We shall prove this in several stages.

Now let us consider the energy in a forced oscillator. The equation for the forced oscillator is

$$m d^2x/dt^2 + 2m\alpha dx/dt + m\omega_0^2 x = F(t). \quad (24.1)$$

Now, provided, of course, $F(t)$ is a certain function of t . Now let us consider the situation: how much work is done by the outside force F ? The work done by the force per second, i.e., the power, is the force times the velocity. (We know that the differential work is $-F dx$ or $F dx$, and the power is dW/dt .) Thus

$$P = F \frac{dx}{dt} = m \left[\left(\frac{dx}{dt} \right) \left(\frac{d^2x}{dt^2} \right) + \omega_0^2 \left(\frac{dx}{dt} \right)^2 \right] = m \left(\frac{dx}{dt} \right)^2. \quad (24.2)$$

But the first two terms on the right can then be written as $m(d^2x/dt^2)(dx/dt)^2$; $m(dx/dt)^2$ is immediately verified by differentiating. That is to say, the term in brackets is a pure derivative of two terms that are easy to understand: one is the kinetic energy of motion, and the other is the potential energy of the spring. Let us call this quantity the stored energy; that is, the energy stored in the oscillator. Suppose that we want the average power over many cycles when the oscillator is being forced and has been running for a long time. In the long run, the stored

24-1 The energy of an oscillator

24-2 Damped oscillations

24-3 Mechanical transients

energy does not change—the derivative gives no average effect. In other words, if we average the power in the long run, all the energy disappears and ends up in the resistor as $\text{heat} = \text{power}^2/\text{resistance}^2$. There is some energy stored in the oscillation, but this does not change with time, if we average over many cycles. Therefore, the mean power ($\langle P \rangle$) is

$$\langle P \rangle = \langle \text{power} \rangle = \langle \dot{E} \rangle^2 \quad (24.1)$$

Using our method of writing complex numbers, and our choice, $\dot{E}_0 = (\text{A}^2)/\text{j}\omega L$, we see that this mean power, $\langle \cos(\omega t) \rangle = \text{j}\omega L$, then $d\dot{E}/dt = -\text{j}\omega^2 L^2$. Therefore, in these circumstances, the average power can also be written as

$$\langle P \rangle = \frac{1}{2} \text{Im}(\dot{E}^2) \quad (24.2)$$

In the notation for damped circuits, $\text{j}\omega L$ is replaced by the constant γ (if it is real), where γ corresponds to \dot{E}_0 , and ω corresponds to the resistance R . Thus the rate of the energy loss—the power divided by the damping function—is the resistance at the d.c. unit times the average square of the current:

$$\langle P \rangle = R \langle I^2 \rangle = R \cdot \langle \dot{E}^2 \rangle \quad (24.3)$$

This energy, of course, goes into heating the resistor; it is sometimes called the heating loss or the hunk heating.

Another interesting feature to observe is how much energy is stored. That is not the same as the power, however, although power was at first used to define it since energy, after all, has no sense excepting power, though it costs the only heating (radiative) losses. At any instant there is a certain amount of stored energy, so we would like to calculate the mean stored energy ($\langle E \rangle$) also. This we already calculated with the average of $(\dot{E} \cdot \dot{E})^2$, so we find

$$\begin{aligned} \langle E \rangle &= \text{Im}(\dot{E} \dot{E}^*) = \frac{1}{2} \text{Im}(\dot{E}^2) \\ &= \frac{1}{2} \text{Im}(\omega^2 - \omega_0^2) \text{Im} \dot{E}. \end{aligned} \quad (24.4)$$

Now, when an oscillator is very efficient, and if ω is near ω_0 , so that γ is large, the stored energy is very big. We can get a large stored energy from a relatively small force. But it requires a great deal of work in setting the oscillator going, but then to keep it steady, all it has to do is to fight the friction. The oscillator can have a great deal of energy if the friction is very low, and even though it is oscillating strongly, not much energy is being lost. The efficiency of an oscillator can be measured by how much energy is stored, compared with how much work the source does per oscillation.

How does the stored energy compare with the amount of work that is done in one cycle? This is called the Q of the system, and Q is defined as 2 π times the mean stored energy, divided by the work done per cycle. (If we were to say the work done per cycle instead of per cycle, then the 2 π disappears.)

$$Q = 2\pi \frac{\text{Im}(\dot{E}^2)}{\text{Im}(\dot{E}^2) \cdot \text{Im}(\dot{E}^*)} = \frac{\omega^2 + \omega_0^2}{2\gamma\omega} \quad (24.5)$$

Q is not a very useful number unless it is very large. When γ is relatively large, it gives a measure of how good the oscillator is. People have tried to define Q in the simplest and most useful way: various definitions came up from one another, but it is very large; all definitions are in agreement. The most generally accepted definition is Eq. (24.5), which depends on γ . For a good oscillator, close to resonance, we can simplify (24.5) a little by setting $\omega = \omega_0$, and we then have $Q = \omega_0/\gamma$, which is the definition of Q that we used before.

What is Q for an electrical circuit? To find out, we merely have to integrate \dot{E} over t , $\dot{E} = \text{A} \cos(\omega t)$, and $1/2$ for $\text{Im}(\dot{E}^2)$ (see Table 21-1). The Q of a resistor is $L\omega/R$, where ω is the resonant frequency. If we consider a circuit with a high Q , the reason is that the amount of energy stored in the oscillation is much larger compared with the amount of work done per cycle by the machinery that drives the oscillation.

24-3 Damped oscillations

We now turn to our main topic of discussion, transients. By "transient" is meant a solution of the differential equation when there is no force present, but when the system is not simple at rest. Of course, if x is standing still at the origin w.l.o.g. the force acting on it is zero (position "at rest" here!) suppose the spring has been stretched; say it was stretched by a distance a , while, and then released off the forces. What happens then? Let us first get a rough view of what will happen for a very high Ω system. As long as forces is acting, the stored energy stays the same, and there is a certain amount of work that is being done. Now suppose we turn off the force, and no more work is being done. Then the forces which are taking up the energy of the spring are no longer doing up its energy. There is no more driver. The losses ω_0^2 have to consume, so to speak, the energy that is stored. Let us suppose that $\Omega/\omega_0 = 1000$. Then the work done per cycle is $1/1000$ of the stored energy. Is it too reasonable that it is oscillating with no driving force, that in one cycle the system will still lose a tremendous of its energy? & which means it would have been supplied from the outside, and that is the constant condition, always losing $1/1000$ of its energy per cycle? So, in a sense, does a relatively high Ω system, we would expect that the following would be roughly right (we will later do it exactly, and it will turn out that it was right!)

$$dE/dt = -\omega E/\Omega. \quad (24.8)$$

This is rough because it is mainly for large Ω . In each cycle the system loses a fraction $1/\Omega$ of the stored energy E . Thus in a given amount of time all the energy will change by an amount $\omega E/\Omega$, since due to lack of inertia we can add with the time of $1/\omega$. What is the frequency? Let us suppose that the system moves as nicely, w/o losing any force, that it will go ω_0 will oscillate essentially the same freq. every all by itself. So we will guess that ω is the *resonant frequency* ω_0 . Then we deduce from Eq. (A) that the stored energy will vary as

$$E = E_0 e^{-\omega t/\Omega} = E_0 e^{-\omega t}. \quad (24.9)$$

This would be the minimum of the wave function, incident. What would the form be for amplitude of the oscillation x as a function of the time? The answer? No. The amount of energy in a spring, say, goes to the square of the displacement; the kinetic energy goes to the square of the velocity, so the total energy goes to the square of the displacement. Thus the displacement, the amplitude of oscillation, will decrease half as fast because of the square. In other words, we guess that the solution for the damped transient motion will be an oscillation of frequency close to the natural frequency ω_0 , in which the amplitude of the sine-wave motion will diminish as $e^{-\omega t}$:

$$x = A_0 e^{-\Omega t/\Omega} \cos(\omega_0 t). \quad (24.10)$$

This equation and Eq. 24-1 give us an idea of what we should expect: now let us try to understand the motion precisely by solving the differential equation of the motion i.e.:

so, starting with Eq. (24.1), with no outside force, how do we solve it? Doing physics, we didn't have to worry about the initial conditions w/o the slope when the solution is. And all with our previous experience, let us try an oscillation an exponential curve, $x = A e^{i\omega t}$ (Why do we say this? It is the easiest thing to differentiate!) We put this into Eq. (24.1) (with $m = 0$), using the rule that each time we differentiate x w.r.t. t we get $-i\omega x$ instead of $i\omega x$. So we really quite similar to substitution. This is no surprise looks like this.

$$(-\omega^2 + i\omega \cdot -i\omega^2) A e^{i\omega t} = 0. \quad (24.11)$$

The last factor must be zero for all t , which is impossible unless $(i)^2 = -1$ & A is not solution at all. It stands off, or (2)

$$\omega^2 + \alpha^2 = \omega_0^2 = 0 \quad (24.12)$$

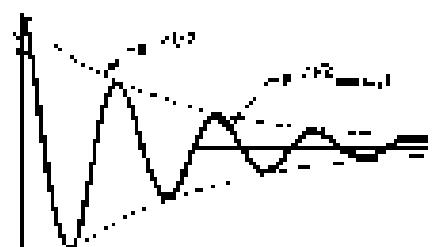

Fig. 24-1. A damped cosine oscillation.

If we can take this root and an m , then we will have a solution in which x need not be zero:

$$x = \text{Re}(2 - \sqrt{\omega_0^2 - \omega^2})e^{i\theta} \quad (24.15)$$

For a while we shall assume that ω is fairly small compared with ω_0 , so that $\omega_0^2 - \omega^2$ is definitely positive, and the i is entering the numerator to bring the square root. This only holds some time so that we get two solutions! Thus

$$\omega_1 = 2\sqrt{2} + \sqrt{\omega_0^2 - \omega^2}e^{i\theta} = \text{Re}(2 + \omega_0) \quad (24.16)$$

and

$$\omega_2 = 2\sqrt{2} - \sqrt{\omega_0^2 - \omega^2}e^{i\theta} = \text{Re}(2 - \omega_0) \quad (24.17)$$

Let us consider the first one, supposing that we had not the issue that the square root has two possible values. (But we know that a solution like $x = A e^{i\theta}$ is, when A is any constant of course.) Now, if we substitute ω_1 , because i is going to come up many times and it takes longer to write, we get all $x_1 = \sqrt{\omega_1^2 - \omega^2} e^{i\theta} = \omega_1 \cos(\theta) - i\omega_1 \sin(\theta) = -i\omega_1 = -\omega_0$, and the $x_2 = A e^{-i\theta} \omega_0 e^{i\theta} = \omega_0$, or what is the same, because of the wonderful properties of an exponential,

$$x_1 = \omega_0 e^{-i\theta} \omega_0 e^{i\theta} \quad (24.18)$$

First, we recognize ω_0 as an oscillation, an oscillation at frequency ω_0 , which is NOT exactly the frequency ω_0 , but is rather close to it if it is a good system... Second, the amplitude of the oscillation is increasing exponentially. If we take, for instance, the real part of (24.16), we get

$$x_1 = A e^{-i\theta} \omega_0 e^{i\theta} \cos \theta \quad (24.19)$$

This is very much like our general solution (24.14) except that the frequency really is ω_0 . This is the very exact result, the same thing—we have the right idea. But everything is not all right. When is x_1 right? Let's see what we have.

The other solution is ω_2 , and we see that the difference is only that the sign of ω_2 is reversed:

$$x_2 = A e^{i\theta} \omega_0 e^{-i\theta} \quad (24.20)$$

What does this mean? We shall soon prove that if x_1 and x_2 are each a possible solution of Eq. (24.3) with $P = 0$, then $x_1 + x_2$ is also a solution of the same equation. So the general solution x is of the undetermined form:

$$x = e^{-i\theta} (A_1 e^{i\theta} + A_2 e^{-i\theta}) \quad (24.21)$$

Now you may wonder why we bother to give this other solution, since we were only happy with the ω_1 in x all by itself. What is the extra use for this? Of course we know we should only take the real part! We know that we must take the real part but how do we mathematical know that we only wanted the real part? When we had a concrete driving force $F(t)$, we put in an x without force to go with it, and the imaginary part of the equation, as we speak, was driven in a definite way. But when we put $F(t) = 0$, our convention that x should be only the real part of whatever we write down is purely our own, and the mathematical equations do not know it yet. The physical world does not care, but the answer that we want or happy with x is not just its complex. The engineer does not know that we are definitely going to take the real part, so it has to present us, so to speak, with a complex conjugate type of solution, so that by putting them together we can always get a real solution; that is what x_2 is doing. That is, in order for x to be real, the x_1 will have to be the complex conjugate of x_2 , so that the imaginary parts disappear. So it turns out that A is the complex conjugate of A_1 , not our real solution is

$$A = e^{-i\theta} (A_1 e^{i\theta} + A_2 e^{-i\theta}). \quad (24.22)$$

So our real solution is an oscillation with a phase shift and a damping—just as advertised.

24-3 Damped oscillations

Now let us see if the above really works. We construct the electrical circuit shown in Fig. 24-2, in which we apply to an inductor the voltage across it is reduced & after an oscillatory form it vanishes by damped oscillations. It is an oscillatory circuit, and it generates a transient of some kind. It corresponds to a circumstance in which we suddenly apply a function to a system that is initially at 0. It is the electrical analog of a charged capacitor, oscillator, and we watch the oscillation on an oscilloscope where we can see the curves that we were talking to anyone. (The horizontal "motion" of the oscilloscope is driven at a uniform speed, while the vertical motion is the voltage across the inductor. The rest of the circuit is only a technical detail.) We would like to repeat the experiment many times, since the persistence of vision is not good enough to see only one trace on the screen. So we do the experiment over and over by closing the switch 60 times a second; each time we close the switch, we can start the oscilloscope triggered sweep, and it draws one curve, over and over, in Figs. 24-3 to 24-6 we see examples of damped oscillations normally photographed on an oscilloscope screen. Figure 24-3 shows a damped oscillation in a circuit which has a high Ω , a small r . In fact, r is so very low, it oscillates many times on the way down.

But let us say what happens if we increase Ω so that the oscillation dies out more rapidly. We can decrease Ω by increasing the resistance R in the circuit. When we increase the resistance in the circuit, it looks like this (Fig. 24-4). Then if we increase the resistance in the circuit still more, it dies out faster yet (Fig. 24-5). But when we just increase the resistance in the circuit, we cannot see any oscillation at all. The question is, is it because our eyes are not good enough? If we increase the resistance yet more, we get a curve like that of Fig. 24-6, which does not appear to have any oscillations, but it persists. Now, how can we explain that by the hand?

The resistance is, of course, proportional to the current in the inductor; therefore, specifically, $r \propto R/L$. Now if we increase the r in the solution (24-14) and (24-15) that we were so happy with earlier, it's + sign in when ω_0^2 cancels out; we must write it a different way, as

$$\omega_0^2 = \omega_0^2/4 - \omega_0^2 \quad \text{and} \quad \omega/2 = \sqrt{\omega_0^2/4 - \omega_0^2}.$$

These are now two real terms and, following the same line of the hand and reasoning as previously, we again find two solutions: $e^{i\omega t}$ and $e^{-i\omega t}$. If we now substitute for x_0 , we get

$$x = A e^{i\omega t} e^{i\omega_0 t} - B e^{-i\omega t} e^{-i\omega_0 t},$$

a non-exponential decay with no oscillations. Likewise, the other solution is

$$x = A e^{i\omega t} e^{-i\omega_0 t} - B e^{-i\omega t} e^{i\omega_0 t}.$$

Note that the square root cannot exceed $\omega_0/2$, because even if $\omega_0 = 0$, one term just equals the other. But ω_0^2 is like $\omega_0^2/4$ but $\omega_0^2/4$ is less than $\omega_0^2/2$, and the term in parentheses is therefore always a positive number. Good goodness! Why? Because if it were negative, we would find a ratio to a positive number, which would mean it was exploding! Increasing more and more resistance into the circuit we know it is not going to go back—quite the contrary. So now we have two solutions, each one by itself a damped exponential... but one is in a minus times plus, plus times minus the other. The general solution is of course a combination of the two, the constant is the combination depending upon how long the motion starts—what the initial conditions of the problem are. In Fig. 24-6, why this circuit appears to be starting, the A is negative and the B is positive, so we get the difference of two exponential curves.

Now let us discuss how we can find the two oscillations, A and B (A , A' and B'), if we know how the motion is started.

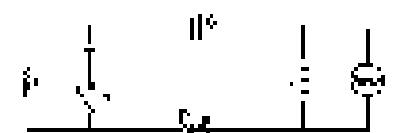

Fig. 24-2. An electrical circuit for damped oscillations.

Figure 24-3

Figure 24-4

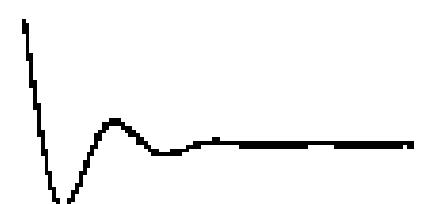

Figure 24-5

Figure 24-6

Suppose that $\dot{x}(t) = 0$ implying that $x = x_0$, and $d\dot{x}/dt = \dot{x}_0$. If we put $t = 0$, $x = x_0$, and $d\dot{x}/dt = \dot{x}_0$ in the equations

$$\begin{aligned} x &= e^{-\alpha t} (x_0 e^{\alpha t} + A e^{-\alpha t}), \\ \dot{x} &= e^{-\alpha t} (-\alpha x_0 + A\alpha e^{-\alpha t}) + (-\alpha/2 + \omega_0^2) A^2 e^{-2\alpha t}, \end{aligned}$$

we find, since $e^{2\alpha t} = e^{2\alpha t} - 1$,

$$\begin{aligned} x_0 &= A + A^2 = 2A, \\ \dot{x}_0 &= (-\alpha/2)(A - A^2) + (\omega_0^2 A - A^2) \\ &= 1A_0/2 - 3A_0(2/A), \end{aligned}$$

where $A = x_0 - M_0$, and $A^2 = A_B - M_0$. Thus we find

$$A_0 = x_0/2$$

and

$$G = \omega_0 + \omega_0 e^{2\alpha t}/2. \quad (24.21)$$

This completely determines A and A^2 , and therefore the complex curve of the Lissajous oscillation in terms of how it begins. Essentially, we can write the solution in either way if we note that

$$e^A + e^{-A} = 2\cos A \quad \text{and} \quad e^{2A} = e^{2\alpha t} = 2\sin A.$$

We may then write the complete solution as

$$x = e^{-\alpha t} \left[x_0 \cos \omega_0 t + \frac{\omega_0 + 2\omega_0^2/2}{\alpha} \sin \omega_0 t \right], \quad (24.22)$$

where $\omega_0 = +\sqrt{\omega_0^2 - \alpha^2}/4$. This is the mathematical expression for the very familiar damped cosine. We shan't make much use of it, but there are a number of points we should like to emphasize that are true in a more general sense.

First of all the "shape" of such a system as $\ddot{x} = -\omega^2 x$ (external force is expressed by zero) in representation of pure exponentials is *pure* (that is we write as e^{At}). This is a good solution to try in such circumstances. The values of α may be complex in general, the imaginary parts representing damping. Finally the extreme mathematical solution of the sinusoidal and exponential function discussed in Chapter 10 which appears physically as a change from oscillatory to exponential because *either* some physical parameter (in this case resistance, α) exceeds some critical value

Linear Systems and Review

25-1 Linear Differential Equations

In this chapter we shall discuss certain aspects of oscillating systems that are more generally true than the particular systems we have been discussing. For our particular system, the "harmonic" equation that we have been solving is

$$m \frac{d^2y}{dt^2} + c m \frac{dy}{dt} + my = f(t). \quad (25.1)$$

Now this particular combination of "operations" on the variable x has the interesting property that if we substitute $(x_1 + x_2)$ for x , then we get the sum of the outputs of x_1 and x_2 ; or, if we multiply x by a, then we get just a times the value combination. This is easy to prove. Just as a "function" function, because we are tired of writing $\text{Comb}(x)$ there is $(^2\text{C}_1)$, we shall use the symbol $L(x)$ instead. When we do this it means the left-hand side of (25.1), with x substituted in. Then the system of equations $\underline{x}(x_1 + x_2)$ would mean the following:

$$\underline{x}(x_1 + x_2) = m \frac{d^2(x_1 + x_2)}{dt^2} + c m \frac{d(x_1 + x_2)}{dt} + m(x_1 + x_2) \quad (25.2)$$

(We underline the \underline{x} since it is a linear composite and it is not an ordinary function.) It is sometimes true that an operator is linear but it makes no "sense" when we call it a function."

Our first statement was that

$$\underline{x}(x + y) = L(x) + L(y), \quad (25.3)$$

which follows from the fact that $y(x+y) = xy + yx$; $d(xy)/dx = dy/dx + x dy/dx$.

Our second statement was to statements,

$$\underline{x}(ax) = a\underline{x}(x). \quad (25.4)$$

[An $\underline{x}(y)$, $(^2\text{C}_1)$ and (25.4) are very closely related, because if we let $x = ax$ into (25.1), this is the same as setting $a = 1$ in (25.4), and so on.]

If there are linear problems, there may be more difficulties, and more terms in \underline{x} ; the question of interest is whether the two equations (25.3) and (25.4) are maintained or not. If they are, we call such a problem a linear problem. In this chapter we shall discuss some of the properties that exist because the system is linear. To appreciate the generality of some of the results, let us first return to our specific analysis of a special equation.

Now let's recall some of the properties of linear differential equations, having illustrated them already with the specific equation (25.1) that we have studied in detail. The first property of interest is this: suppose that we want to solve the differential equation for a transient, the free oscillation, with no driving term. That is, we want to solve

$$\underline{x}(x) = 0. \quad (25.5)$$

Suppose that, by some hook or crook, we have found a particular solution, which we shall call x_p . That is, we have $x = x_p$ for which $\underline{x}(x_p) = 0$. Now we notice that $x_p(t) = e^{rt}$ is a solution to the static equation, we can multiply this special solution by any constant whatever, and get a new solution. In other words, if we had a

- 25-3 Oscillations in linear systems
- 25-4 Analogy in physics
- 25-5 Series and parallel impediment

motion of a certain "rigid" thin rod when one "end" is again a solution. Since $\underline{L}(x_1) = \underline{L}(x_2) = 0$, $\underline{L}(x_1 + x_2) = 0$.

Now, suppose that, by hand or by stock, we have already found several given x_1 , x_2 also \underline{x}_1 , \underline{x}_2 . (Remember this when we substituted $x = e^{\alpha t}$.) So, finding the function $\underline{x} = \underline{x}_1 + \underline{x}_2$ are values for x , that is, two solutions, x_1 and x_2 . Now let us show that the combination $(x_1 + x_2)$ is also a solution. In other words, if $\underline{L}(x_1) = x_1 - \underline{x}_1 = 0$, $\underline{L}(x_2) = x_2 - \underline{x}_2 = 0$, then $\underline{L}(x_1 + x_2) = \underline{L}(x_1) + \underline{L}(x_2) = 0$. So, if we have found a number of solutions for the motion of a linear system we can add them together.

Combining both two ideas, we see, of course, that we can also add this one and two of the other, if x_1 is a solution, x_2 is not. Thus, for any sum of these two solutions such as $x_1 + x_2$ is also a solution. If we happen to be able to find three solutions, then we find each any combination of the three will always be also a solution, and so on. It turns out that the number of ways we call **linearly independent solutions**⁴ but we have obtained for our oscillating problem is only one. The number of independent solutions that one finds in the general case depends upon what is called the number of degrees of freedom. We shall not discuss this in detail now, but if we have a second-order differential equation there may be many linearly independent solutions, and we have found some of them; so we have the most general solution.

Now let us go on to another proposition which applies to the situation in which the system is subjected to an external force. Suppose the equation is

$$\underline{L}(x) = F(t), \quad (25.5)$$

and suppose that we have found a specific, *particular* solution of it. Let us say that this solution is x_1 , and that $\underline{L}(x_1) = F(t)$. Suppose we want to find yet another solution; suppose we add x_1 to x_2 in one of the ways x_2 is a solution of the free equation (25.4), say x_2 . Then we see by (25.5) that

$$\underline{L}(x_1 + x_2) = \underline{L}(x_1) + \underline{L}(x_2) = F(t) + 0 = F(t). \quad (25.6)$$

Therefore for the "forced" equation we can add any "free" solution, and we get another solution. The free solution is called a **complementary solution**.

When we have no forces acting, and suddenly a new one on, we can not immediately get the steady motion that we solved for with the one *free* solution, but for a while there is a transient. While, since x_1 is free, then, if we wait long enough, the "forced" solution has a limit, and once it keeps on being caused by the force. Ultimately, for any purposes of time, the solution is unique, but initially the motions are distributed with interesting areas, depending on how the object was started.

14-2 Superposition of solutions

Now we come to another interesting proposition. Suppose that we have a certain particular driving force F_1 (let us say an oscillatory one with a certain $\omega_1 = \omega_1$, but any conclusion will be true for any form known form of F_1) and we have solved for the forced motion (with or without the transient; it makes no difference). Now suppose some other forces is acting, let us say F_2 , and we solve the same problem, but for a different force. Then another transient comes along and says, "I leave this problem for you to solve. I give the force $F_1 + F_2$." Can we do it? Of course we can do it, because the solution is the sum of the two solutions x_1 and x_2 for the forces taken separately—a most remarkable claim it is indeed. If we use (25.6), we see that

$$\underline{L}(x_1 + x_2) = \underline{L}(x_1) + \underline{L}(x_2) = F_1(t) + F_2(t) \quad (25.7)$$

⁴ Solutions which cannot be expressed as linear combinations of each other are called **independent**.

This is an example of what is called the principle of superposition for linear systems, and it is very important. It means the following: if we have a complicated function which can be broken up in any convenient manner into a sum of separate pieces, each of which is in some way simple, or else so that it can't easily give rise to which we have worked out how we can solve it separately, then "whatever is available for the whole must, however, we may simply add the pieces of the solution together, in the same manner as the total force is a mechanical sum of pieces." (Fig. 25-1).

I shall give another example of the principle of superposition. In Chapter 13 we saw that it was one of the basic facts of the laws of electricity that if we have a certain distribution of charges, and calculate the electric field E_1 arising from these charges in a certain place, and at the other hand, we have another set of charges, and we calculate the field E_2 due to this, at the same point in space; then if both charge distributions are present at the same time, the field E at that is the sum of E_1 due to one set plus E_2 due to the other. In other words, if we know the field due to a certain charge, then the field due to many charges is merely the vector sum of the fields of the charges taken individually. This is exactly analogous to the above proposition that if we know the result of two given forces taken at the same time, even if the forces are considered separately, then just again the sum of the corresponding individual responses.

The reason why this is true of electricity is that the most basic law of electricity, Maxwell's equations, which determine the electric field, turn out to be differential equations which are linear, i.e., which have the property (25.3). What corresponds to the force is the charge density, the electric field, and the equation which determines the electric field in terms of the charge density.

As another interesting example of the proposition, let us see how it is possible to "select" in a particular radio station at the same time as all the other stations are broadcasting. The radio station transmits, independently, an oscillating electric field of very high frequency which goes out over radio waves. Let's say that the amplitude of the oscillation of the field is unchanged, independent of the speed of the wave, v , which is very slow, and we are not going to worry about it. When one hears this station is broadcasting at a frequency of 780 kilocycles,⁷ this indicates that 780,000 oscillations per second is the frequency of the continuous flow of the driven antenna, and this drives the electrons up and down at that frequency in the antenna. Now at the same time we may have another radio station, in the same town, broadcasting at a different frequency, say 785 kilocycles per second, even the electrons in one antenna are also being driven by that frequency. Now the question is, how is it that we can separate the signal coming up into the antenna at 785 kilocycles from "the driving in at 780 kilocycles"? We certainly do not hear both stations at the same time.

By the principle of superposition, the response of the electric circuit is, in radio, the sum of ψ_1 which is a linear circuit in accordance with setting A to the electric field $E_1 = E_0 \cos(\omega_1 t + \phi)$, and ψ_2 which we will never drive, having been, in fact, every proposition of superposition, because in fact the two cannot exist having both of them in one system. But remember, for a resistive circuit, the response ψ_2 to the amplitude of ψ_1 per unit F , is a "frac-tion of the frequency," looks like Fig. 25-2. If it were a very high Q circuit, the response would have a very sharp maximum. Now suppose that the two stations are comparable in strength, that is, the two forces have the same amplitude. Then we note that we get the sum of ψ_1 and ψ_2 . But, in Fig. 25-2, ψ_2 remembers, while ψ_1 is small. So, in spite of the fact that the two signals are equal in strength, when they go through the radio circuit, a circuit of the form shown for ψ_2 , the frequency of the transmission of one station, then the response to this station is much greater than to the other. Therefore the complete response, with both signals acting, is almost all ψ_2 at ω_2 , and we have selected the station we want.

Now what about the tuning? How do we tune it? We change ω by changing the C or the L of the circuit, because the frequency of the circuit has to do with the combination of L and C . In particular, most radios are built so that one can change the capacitance. When we reverse the switch, we can make a new setting of

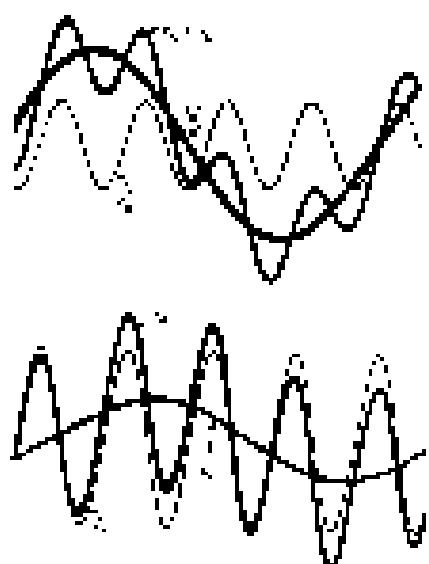

Fig. 25-1. An example of the principle of superposition for linear systems.

Fig. 25-2. The principle of superposition in electrodynamics.

Fig. 25-3. A sharply tuned resonance curve.

the coil, so that the natural frequency of the circuit is shifted, say, to ω_1 . In this circumstance we hear neither one station nor the other; we get silence, provided there is no other station at frequency ω_2 . If we keep on changing the capacitance until the resonant curve is at ω_2 , then of course we hear the other station. That is how tuning works. It is again the principle of superposition, now combined with a resonant response.*

To conclude this discussion, let us describe qualitatively what happens if we proceed further. It is always a linear problem with a given force, where the force is quite complicated. Out of the many possible procedures, there are two especially useful general ways that we can solve the problem. One is this: suppose that we can solve it for specific known forces, such as sine waves of different frequencies. We know it is child's play to solve it for sine waves. So we have the simplest "child's play" cases. Now the question is whether any very complicated force can be represented as the sum of two or more "child's play" forces. In Fig. 25-3 we already have a fairly complicated curve, and of course we can make it more complicated still if we add in more waves. So it is certainly possible to obtain very complicated curves. And, in fact, the reverse is also true: practically every curve can be obtained by adding together enough numbers of sine waves of different wavelengths (or frequencies) for each one of which we know the answer. We just have to know *how* each sine wave belongs to just to make the given F , and then our answer, x , is the sum (superposition sum) of the sine waves, each multiplied by its coefficient of A to F . This method of solution is called the *method of Fourier analysis* or *Fourier synthesis*. We are not going to actually carry out such an analysis just now; we only wish to indicate what is involved.

Another way in which our complicated problem can be solved is the following very interesting one. Suppose that, by some fortuitous mechanical effort, it were possible to solve our problem for a special force, namely an impulse. The force is quickly turned on, and then off. It is all over. Actually we need only care for an impulse of some unit strength; any other strength can be gotten by multiplication by an appropriate factor. We know that the response to an impulse is damped oscillation. Now what can we say about some other force, for instance a force like that of Fig. 25-4?

Such a force can be likened to a succession of blows with a hammer. First there is no force, and all of a sudden there is a steady force—impulse, impulse, impulse, impulse . . . and then it stops. In other words we imagine the external force to be a series of impulses, very close together. Now, we know the result for an impulse, so the result for a whole series of impulses will be a whole series of damped oscillations: it will be the curve for the first impulse, and then slightly later the curve for the second impulse, and the curve for the third impulse, and so on. Thus we can represent, mathematically, the complete situation for arbitrary functions if we know the answer for all impulses. We get the answer for any other force simply by integration. This method is called the *Gren's function method*. A Gran's function is a response to an impulse, and the method of calculating any force by putting together the response of impulses is called the *Gren's function method*.

The physical principles involved in both of these schemes are no simple, involving just one linear equation, that they can be readily understood, but the mathematical problems are, as indeed, the most subtle in science and so on, and so it is best advised for us to attack right now. For we most likely return to this some day when you have had more practice in mechanics. But the idea is very simple indeed.

Finally, we make some remarks on this linear solution that are important. The answer is simple, because we're in Euler form! So most of the time we can linear

* Of modern superheterodyne receivers the local oscillator is more complex. The amplitude is adjusted to a fixed frequency (called the *locoscene*); and an oscillator of variable variable frequency is combined with the input signal in a nonlinear circuit to produce a new frequency (the difference of signal and oscillator frequency), equal to the *IF frequency*, which is then amplified. This will be discussed in Chapter 32.

problems. But just think: it's important in physics that the fundamental laws of physics are often linear. The Maxwell equations for the laws of electricity and magnetism, for example. The general laws of quantum mechanics aren't, as far as we know, to be linear equations. That is why we spend so much time on linear oscillators: because if we understand linear oscillators, we are, really, in principle, in understand a lot of things.

We mention another situation where linear equations are found. When displacement is small, many functions can be approximated linearly. For example, if we have a simple pendulum, the second equation for its motion is

$$\frac{d^2\theta}{dt^2} = -g/l \sin \theta \quad (25.9)$$

This equation can be solved by direct integration, but the easier way to solve it is numerically, as was shown in Chapter 9 on Newton's Laws of Motion. A non-linear equation cannot be solved, numerically, any other way than numerically. Now for small θ , $\sin \theta$ is practically equal to θ , and we have, from eq. (25.9), after division by l , that these are many circumstances where small effects are linear! For the example here the swing of a pendulum through small angles. As another example, if we pull a table cloth, or a spring, the force is proportional to the extension. If we pull hard, we break the spring, and the force is a completely different function of the distance! Linear equations are important. In fact they are so important that perhaps 90 percent of the time we are solving linear equations in physics and in engineering.

25-3 Oscillations in Linear systems

Let us now review the things we have been talking about. In the past few chapters, it is very easy for the physics of oscillations to become obscured by the mathematics. The physics is actually very simple, and if we may forget the mathematics for a moment we will see that we can understand almost everything that happens in an oscillating system. First, if we have only the spring and the weight, it is easy to understand why the system oscillates: it is a consequence of friction. We pull the mass down and the force pulls it back up; it is zero when which is the place it likes to be. It cannot just stop entirely because of its momentum it keeps on going and swinging to the other side and back and forth. See, if there were no friction, we would simply continue an oscillatory motion, and indeed we get one. But if there is even a little bit of friction, then on the return cycle, the swing will not be quite as high as it was the first time.

Now what happens, cycle by cycle? That depends on the kind and amount of friction. Suppose that we could exert a kind of friction force that always remains in the same proportion to the other forces, of gravity and of the spring, as the amplitude of oscillation does. In other words, for smaller oscillations the friction would be weaker than for big oscillations. And in fact friction does not have this property, so a general law of friction must be carefully imagined for the easy purpose of creating a friction that is exactly proportional to the velocity, so that for big oscillations it is stronger and for small oscillations it is weaker. If we happen to have such a kind of friction, then all the end of each successive cycle the system is in the same position as it was at the start except a little bit smaller. All the forces are smaller in the same proportion: the spring force is reduced, the inertial effects are lower because the accelerations are now weaker, and the friction is less too, by our careful design. When we actually have that kind of friction, we find that each oscillation is in exactly the same place as the first one, except reduced in amplitude. If the first cycle dropped 10 percent, e.g., to 90 percent of what it was at the start, the next will drop it to 90 percent of 90 percent, and so on: the ends of the oscillations are reduced by the same factor of themselves in every cycle. An exponential function is a curve which does just that. It changes by the same factor in each equal interval of time. That is, every time the amplitude of one cycle ends, i.e. in the passing from one cycle to the next, the amplitude of the next is a^2 , and of the next, a^3 . So the amplitude is some constant raised to a power equal to the number of cycles times a :

$$A = A_0 a^n \quad (25.10)$$

But of course $\dot{\theta} \sim \omega$, so it is perfectly clear that the general solution will be some kind of oscillation, decaying toward time, in amplitude which goes with $e^{-\alpha t}$, or less. That can be written as $\theta = \theta_0 e^{-\alpha t}$, if α is positive and not less than 1. So this is not the solution itself like $\theta = A \sin(\omega t)$. It is very simple.

What happens if the friction is non-linear? Well, for example, consider a rubber band, so that the friction force is a certain constant amount, and is independent of the size of the oscillation that receives its direction each half-cycle. Then the equation is no longer linear, it becomes hard to solve, and must be solved by the numerical method given in Chapter 3, or by considering each half-cycle separately. The numerical method is the most powerful method of all, and can solve any situation. It is only when we have a simple problem that we can use mathematical analysis.

We have had analysis up to the point where it solves only the simplest possible equations. As soon as the equations get a little more complicated just a little, they can not be solved analytically. But the numerical method, which was advertised at the beginning of the course, can take care of any equation of physical interest.

Now, what about the resonance curve? Why is there a resonance? Just imagine for a moment that there is no friction, and we have one spring, which oscillates by $\theta_0 \cos(\omega t)$. If we let go, the pendulum just sits there, since it went by, of course we could make it go like mad. But if we close our eyes and do not touch it, and let it sit there, what happens, what is going on? Imagine! Since it has no friction, it continues, applying what is it trying to do wrong way. When we happen to have the tuning just right, of course, each tap is given at just the right time, and so it goes higher and higher and higher. So without friction we get a curve which looks like the solid curve in Fig. 22-7 for different frequencies. Our desire, to understand the resonance curve, in order to get the exact shape of the curve it is probably just as well to do the mathematics. The curve goes toward infinity as $\omega \rightarrow \omega_0$, where ω_0 is the natural frequency of the oscillator.

Now suppose there is a little bit of friction; then when the displacement of the oscillator is small, the friction does not stop it much. The resonance curve is the same, except when we are near resonance. The cost of having, infinite near resonance, is not only going to get us into trouble when we do by bumping each time is enough to compensate for the loss of energy by friction during the cycle. So the top of the curve remains off—it does not go to infinity. If there is more friction, the top of the curve is reduced off still more. Now someone might say, "I thought the width of the curve depended on the friction." This is because the curve is usually plotted so that the top of the curve is constant anyway. However, the mathematical expression is even simpler to understand. If we just plot on the curves on Fig. 22-7, we see that frequency is just the friction as it slows the top. If there is less friction, we can go farther up into that little bump before the friction cuts it off, so it's relatively narrow. Then the higher the peak of the curve, the narrower the width of the resonance region.

Finally, we take the case where $\omega > \omega_0$, which is called over-damped. It turns out that if there is too much friction, the system does not oscillate at all. The energy in the spring is barely able to move it against the frictional force, and so it slowly comes down to the equilibrium point.

22-4 Analogy in physics

The first lesson of this review is to note that masses and springs are not the only linear systems that there are others. In particular, there are electrical systems called linear circuits in which we find a complete analog to mechanical systems. We did not learn exactly how one of the objects in an electrical circuit works in the way that one or two in mechanics does in mechanics; we may assert, from an experimentally verifiable fact that they behave as stated.

For example, let us take the simplest possible circuit—just one. We have a piece of wire which is just a resistor, and we connect it to a difference in potential. If "difference" means that there are voltages along through the wire, then the current

another terminal. The work done is qV . The higher the voltage difference, the more work was done when we charge, or worse, "to be" from the high potential end of the terminal to the low-potential one. So charge release energy is going from one end to the other. Now the charges do nothing but fly from one end straight to the other end; the resistance being effectively negligible to the current, and the resistance unless the following are far almost all ordinary substances if there is a current I , that is, on the to many charges per second moving down, the number per second that comes available through the wire is proportional to the total current and there will be a linear proportionality to the total voltage there:

$$I = qE = R(q/dm) \quad (25.11)$$

The coefficient R is called the resistance, and the equation is called Ohm's law. The unit of resistance, because it is equal to one volt per ampere. In magnetized situations, to get such a frictional force in proportion to the voltage is difficult; in an electrical system, it is very easy, and this is why it is extremely convenient to meet resistors.

When often interested to know much work is done per second, the power loss of the energy liberated by the charges as they move over the wire. When we carry a charge (or voltage) V , the work required to move charge per second would be qV/qdm , which is the same as $W = qV = q^2R$. This is called the heating loss. This is how much heat is generated in the resistance per second, by the conversion of energy. It is in fact the resistive energy dissipation lost by a work.

Of course, there are other interesting properties of mechanical systems, such as the mass (potential), and it turns out that there is an electrical analog to inertia also. It is possible to make something to act as inductor, having a roughly called inductance, such that a current once started through the inductor, does not want to stop. It requires a voltage in order to change the current! If the current is constant, there is no voltage across an inductor. We already do not know anything about inductance, it is only that we always the current, but the effects of inductance show up. The equation is

$$V = L(dI/dt) = Ld^2q/dt^2, \quad (25.12)$$

and the unit of inductance, called the Henry, is just the one you applied to the inductance so we have here produced a change of charge per second in the current. Equation (25.12) is the law of Newton's law for electricity, if we will: $F = ma$ corresponds to $V = Ld^2q/dt^2$, and L corresponds to inertia. All of the consequent equations for the two kinds of systems will have the same calculations because, if we do the integrations, we can change any letter in the equations, changing letter and we get the same equation, the value variables will have a correspondence in the two systems.

Now what electrical thing corresponds to the mechanical spring, in which there was a force proportional to the stretch? If we start with $F = -kx$, and replace $F = E$ and $x = q$, we get $E = -qV$. It turns out that there is such a thing, in fact, it is the only one of the three circuit elements we can really realize and, because we did study a pair of parallel plates, and we found that if there were a charge of certain equal, opposite amounts on each plate, the field between them would be proportional to the size of these caps. So the work there in moving a test charge across the gap from one plate to the other is precisely proportional to the charge. The work is the product of the voltage difference, which is the time integral of the electric field from one place to another. It turns out for historical reasons, that the constant of proportionality is not called C , but $1/C$. We could have been called C , but it was not. So we have

$$V = q/C. \quad (25.13)$$

The unit of capacitance, C , is the factor a charge of one coulomb on each plate of capacitor upon a given a voltage difference of one volt.

There are two analogies, and the right one corresponding to the oscillating circuit becomes the following, by direct substitution of & 25.14 for α , etc.

$$v(t)/x_0(t) = v_0(x_0(0)) + \omega t - K, \quad (25.14)$$

$$2\omega^2 q(t)^2 + R^2 x_0(t)^2 + \omega^2 C = K. \quad (25.15)$$

Now everything we learned about (25.14) can be transformed to apply to (25.15). This is because it is linear, & much the same that this is a similar thing we learned.

Suppose we have a mechanical system which is quite complicated, but just consists of a spring, but several masses on several springs. i.e. think again for why do we do? Now it's. Perhaps, for best, we can make an equivalent circuit which will have the same equations as the thing we are trying to analyze. For instance, if we wanted to analyze a mass on a spring, why can we not make an equivalent circuit in which we see an inductance proportional to the mass, a resistance proportional to the constricting force, R^2 is proportional to K , all in the same way? Then, of course, this one final circuit will be the exact analog of our mechanical case, in the sense that whatever it does, in response to V (V also is more or less equivalent to the forces that are being), so the x would do in response to the V signal. So if we have a complicated thing with a whole lot of interconnected elements, we can incorporate a whole lot of resistances, inductances, & capacitors, etc to make the most wholly analogous system. What is the advantage here? One problem is just as hard (or as easy) as the other, because they are exactly equivalent. The advantage is not that it is any easier to solve the mathematical equations, but we discuss. That we have an electrical circuit, although this is the method used by electrical engineers!, but instead, the real reason for looking at the analog is that it is easier to make the electrical circuit out of charge + anything in the system.

Suppose we have designed an automobile, and want to know how much it is going to shake when it goes over a certain kind of bumpy road. We build an electrical circuit with inductances to represent the inertia of the wheels, spring constants as resistances to represent the springs of the wheels, and resistors to represent the shock absorbers, and we do for all other parts of the automobile. Then we see a bumpy road. All right, we apply it, where there's a generator, which represents wheels and such, a kind of source, and then look at how the left wheel rotates by measuring the charge on some capacitor. Having measured it (it is easy to do, we don't need to be applying too much). Do we need a shock absorber, or less shock absorber? With a computerized thing like this, we make the car actually change the shock absorber, and solve it all over again? Not, we simply turn a dial, and number two shock absorber number three, so we get a more shock absorber. The bumpers are better—All right, we try less. The bumpers are still worse; we change the stiffness of the spring (dial 17), and we do not all these things electronically, with merely the turn of a knob.

This is called an *analog computer*. It is a device where it isolates the problem that we want to solve by making another situation, which has the same equations, but in another circumstance of nature, and which is easier to build, to measure, to adjust, and to destroy.

25.6 Series and parallel impedances

Finally, there is an important item which is not quite at the center of review. This has to do with an electrical circuit in which there's more than one element. For example, when we have an inductor, a resistor, and a capacitor connected as in Fig. 24.3, we note that all the charges went through every one of the three, but the current is such a singly connected thing as the sum of all potentials along the wire. Since the current is the same at each node, the voltage across R is iR , the voltage across C is $Q_0/(iC)$, and so on. So, the overall voltage is the sum of these, and this leads to Eq. (25.15). Using complex numbers, we find that we could solve the equation for the steady state solution in response to v & q_0 .

oppositional force. We have found that $V = RI$. Now R is called the *impedance* of the particular circuit. This means that if we apply a sinusoidal voltage V , we get a current I .

Now suppose we have a more complicated circuit which has two pieces, where by definition these contain impedances, Z_1 and Z_2 , and we put them in series (Fig. 25-5a) and apply a voltage. What happens? It is now a little more complicated, but if I is the current through Z_1 , the voltage difference across Z_1 is $V_1 = IZ_1$. Likewise, the voltage across Z_2 is $V_2 = IZ_2$. The current I just goes through both. Therefore the total voltage is the sum of the voltages across the two sections and is equal to $V = V_1 + V_2 = (Z_1 + Z_2)I$. This means that the voltage on the complete circuit can be written $V = \bar{Z}I$, where the \bar{Z} of the combined section in series is the sum of the two Z 's of the separate pieces:

$$\bar{Z} = Z_1 + Z_2. \quad (25.6)$$

This is not the only way things may be connected. We may also connect them in another way, called *parallel connection* (Fig. 25-5b). Now we see that a given voltage across the terminals, if the connecting wires are perfect conductors, is effectively applied to both of the impedances, and will be the same across each independently. Therefore the current through Z_1 is equal to $I_1 = V/Z_1$. The current in Z_2 is $I_2 = V/Z_2$. It is the same voltage. Now the total current which is supplied to the terminals is the sum of the currents in the two sections: $I = I_1 + I_2 = V/\bar{Z}$. This can be written as

$$V = \frac{I}{(1/\bar{Z}_1) + (1/\bar{Z}_2)} = \bar{Z}I.$$

Thus

$$1/\bar{Z}_t = 1/\bar{Z}_1 + 1/\bar{Z}_2. \quad (25.7)$$

More complicated circuits can sometimes be simplified by taking pieces of them, working out the successive *impedances* of the pieces, and combining the circuit together step by step, using the above rules. If we have any kind of circuit with three impedances connected in π , since it ways, and if we include the voltage in the form of three generators having no impedances (where we pass charge through it, the generator adds a voltage V), then the following principles apply. (1) At any junction, the sum of the currents into a junction is zero. That is, I , the current which comes in must come back out. (2) Two carry a charge around my loop, and back as when it starts, the net work done is zero. These rules are called *Kirchhoff's laws* for electrical circuits. Their systematic application to complicated circuits often simplifies the analysis of such circuits. We mention them here in connection with Eqs. (25.6b) and (25.17). In fact you have already come across such things as you need to discuss in laboratory work. They will be discussed again in more detail next year.

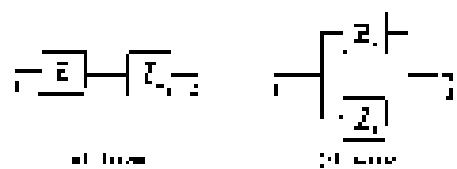

Fig. 25-5. Two impedances, connected in series and in parallel.

Appendix The Principle of Least Time

26-1 Light

This is the first of a number of chapters on the subject of electrodynamics. Light which we see is only a small part of the spectrum of the same kind of thing, the various parts of this spectrum being distinguished by different values of a certain quantity which varies. This variable quantity can be called the "wavelength," *A*. As *A* varies in the visible spectrum, the light apparently changes color from red to violet. If we explore the spectrum systematically, from long wavelength toward short ones, we shall begin with what are usually called *radio waves*. Radiations of relatively long *A* are in every range of wavelength, once even longer than those used in regular broadcasts. Next come waves whose wavelengths are approaching the limit 900 microns. Then there are the waves of higher energy, i.e., *radio waves*, *micrometers*, and so on. There are no actual boundaries between one range of wavelength and another, because not all *A* are present together with the *A*'s just before. The numbers associated with a given name for the waves are only approximate and, of course, so are the ranges we give in the different ranges.

From a long way down through the millimeter waves, we come to what we call the infrared, and thence to the visible spectrum. Then going in the other direction, we get into a region which is called the ultraviolet. When the wavelength *A* goes into the x-ray region, we cannot define precisely where this is; it is roughly at 10^{-3} m. or 10^{-4} μ . These are "soft" x rays, even there are extremely hard, and very hard x rays, too. In the x rays, and so on, for smaller and smaller values of *A*, dimension called the wavelength.

Within the last range of wavelengths, there are also some regions of approximation which are especially interesting. If one of these conditions exists so that the wavelengths involved are very small compared with the dimensions of the equipment available for their study, for instance the photon energies, and perhaps the energy density, in small comparison with the energy sensitivity of the equipment. Under these conditions we can make a rough but approximation by a method called *geometrical optics*. This is either *lens* or *ray* optics. In one circumstance, in the dimensions of the equipment, when it is difficult to manage with visible light but easier with x rays, the photon energies are still negligibly small, there is a very useful approximation to be made by studying the behavior of the waves without distinguishing the exact nature of the photons. This method is based on the classical theory of electromagnetic radiation, which will be discussed in a later chapter. Next, if we go to very small wavelengths where we can disregard the wave character but the photons have a very large energy compared with the sensitivity of the equipment, comes just a simple ray. This is the single photon you are which we will discuss very, very roughly. The complete theory, which handles the photons into account, will not be available to us for a long time.

In this chapter our discussion is limited to the geometrical optics region in which we forget about the wavelength and the photon character of the light, which will all be explained later on. We do not even feel it necessary to say what the light is, but just think. And it follows on a little while subsequently with the dimensions of apparatus. All this must be said in order to emphasize the *classical* part we are going to talk about, is only a very rough approximation; it is one of the subjects that we shall have to return to again and again, very quickly unless it becomes we shall almost immediately go to the more accurate method.

26-1 Light

26-2 Reflection and refraction

26-3 Fermat's principle of least time

26-4 Applications of Fermat's principle

26-5 A more precise statement of Fermat's principle

26-6 How it works

Although geometrical optics is just an approximation, it is of very great importance technically and it can also be historically. We shall present this subject more historically than some of the others in order to give some idea of the development of a physical theory or physical idea.

First, light is, of course, familiar to everybody, and has been familiar since long immemorial. Now our problem is, by what process do we see light? There may be many answers, but it usually settles down to one which is that there is scattering, which enters the eye—which becomes an object into the eye. We have heard that idea so long that we accept it, and it is easier, impressive for us, to realize that every intelligent machine must do something like scattering to come out of the second look for the object. For example, some other important idea is this: more than as light goes from one place to another, it goes in straight lines; if there is nothing in the way, and that the rays do not say to interfere with one another. That is, light is scattering in all directions at the room, but the light that is passing across our line of vision does not affect the light that comes to us from some object. This was once a very powerful argument against the corpuscular theory; it was used by Huygen. If light were like a lot of arrows shooting along, how could other arrows pass through them easily? Such philosophical arguments are not of much weight. One could always say that light is made up of arrows which go through each other.

24-2 Reflection and refraction

The discussion above gives enough of the basic view of geometrical optics—now we have to go a little further into the quantitative aspects. This is, we have light going only in straight lines between two points, now we want to study the behavior of light when it hits various materials. The simplest object is a mirror, and the basic idea is this: when the light hits the mirror, it does not continue in a straight line, but bounces off the mirror into a new set of light lines, which change when we change the inclination of the mirror. The question for consideration now, what is the relation between these angles? This has been a problem for a long time. The light striking a mirror bounces in such a way that the two angles, between each beam and the mirror, are equal. For some reason, it is customary to measure the angle from the normal to the mirror surface. This is the standard law of reflection is

$$n_r = n_i \quad (24.1)$$

This is a simple enough proposition, but a more difficult problem is this: when light goes from one medium into another, for example from air into water, where also we see that it does not go in a straight line. In the water the ray is bent, or bent to its path in the air; if we change the angle i , so that it comes even more nearly vertically, then the angle of "refraction" is not so great. But we tilt the beam of light at quite an angle, then the deviation angle is very large. The question is, what is the relation of one angle to the other? This also provided the excuse for a long time, and here they never found the answer! It is, however, one of the few places, in all of Greek physics that one may find a systematic and exact table. Almagest, written by Ptolemy, made a list of the angle in water, for each of a number of different angles in air. Table 24-1 shows the angle in the air, in degrees, and the corresponding angle as measured in the water. (Gibson says that the Greek scientist never did any experiments. But it would be impossible to explain this table of values without knowing the right law, except by experiment. It should be noted, however, that these do not represent independent measurements for each angle but only a few measurements taken from a few measurements, so they all fit perfectly in a paragraph.)

This, then, is one of the important steps in the development of physical science: we observe an effect, then we measure it and list it in a table; then we try to find the rule for which one thing can be connected with another. The classic one is that table was made in 140 A.D., but it was not until 1811 that someone finally found the rule connecting the two angles. The rule, found by Malus and

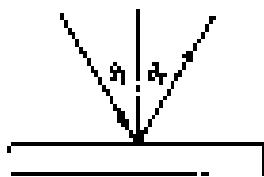

Fig. 24-1. The angle of incidence is equal to the angle of reflection

50°	35°
60°	40.1°
70°	44.1°
80°	48°

Snell's Dutch mathematician, is as follows: if θ is the angle in air and ϕ is the angle in the water, then it is known that the sine of θ is equal to some constant multiple of the sine of ϕ :

$$\sin \theta / \sin \phi = \text{const}$$

In water the number c is approximately 1.33. Equation (26.2) is called Snell's law; it permits us to predict how the light is going to bend when you go from air into water. Table 26-2 shows the angles in air and in water according to Snell's law. Note the remarkable agreement with Fizeau's law.

26-3 Fermat's principle of least time

Now let us further develop our discussion; we want to have the law of reflection. First we have an observation, then we have numbers that we measure, then we have a law which summarizes all the numbers. But the real object of science is that we can find a way of thinking with that the law is evident.

The last way of thinking that made the law about the behavior of light evident was discovered by Fermat in about 1660, and it is called the principle of least time, or Fermat's principle. The idea is this: "Without all possible paths it is only one in just from one point to another. Light takes the path which requires the shortest time."

Let us first show that this is true for the case of the mirror, i.e., this simple principle exists as both the law of straight line propagation and the law of the mirror. So we are going in a circle, shouldn't that be true? And the solution to the following problem: In Fig. 26-3 are shown two points A and B , and a plane mirror MN . What is the way to get from A to B ? In the easiest case? The answer is to go straight from A to B . But now we do the exercise that the light has to strike the mirror and come back to the shortest time. It is somewhat difficult. One way would be to go as quickly as possible to the mirror and then go to B from the point $A'AB$. Of course, we then have a long path $A'B$. If we move just a little to the right, to C , we slightly increase the travel distance, but we greatly decrease the speed, and so the total path length and therefore the travel time, is less. Thus can we find the point C for which the time is the shortest? We can find it very nicely by a geometrical trick.

We construct on the other side of MN an artificial point B' . What is the significance of the point B' ? As the point B is above the line. Then we draw the line BB' . Now because MN is a right angle and $AB \perp MN$, AB is equal to $B'B$. There is the second construction, $A'E \perp ED$, which is proportional to the time it will take if the light travels with constant velocity, is also the sum of the two angles $AED + EBD$. Before the problem becomes, when is the sum of these two lengths the least? The answer is easy: when the line goes through point C or a longer line from A to B . In other words, we have to find the point where we go toward the central point, and that will be the corner point. Now if $A'C'B$ is a straight line, then angle BCE is equal to angle $B'CE$ and hence to angle ACB . Thus the statement that the angle of incidence equals the angle of reflection is equivalent to the statement that the light goes to the center in such a way that it comes back to the point B in the least possible time. Originally, this statement was made by Hero of Alexandria that the light travels in such a way that it goes to the mirror and to the other point in the shortest possible distance, so it is not a modern theory. It was this the original Fermat imagined, himself! That we have reflection operated on a similar basis. (In refraction, light obviously does not use the path of shortest distance, so Fermat cited the law that it takes the shortest time.)

Before we go on to analyze refraction, we should make one more remark about the mirror. If we have a source of light at the point B and it sends light toward the mirror, then we see that the light which goes to A from the point B comes to A in exactly the same manner as it would come from A if there were an object at B' and no mirror. Now of course the wave fronts with the light which enters it physically can't be here in object B and a mirror which makes the light come

Table 26-2

Angle in air	Angle in water
0°	0°
30°	19°
45°	22°
60°	26°
75°	30°

70°	43°
60°	48°

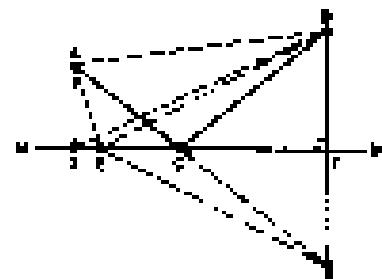

Fig. 26-3. Illustration of the principle of least time.

into the eye is exactly the same manner as it would have come into the eye if the object were at s' , then the eye-brain system interprets each, assuming it does not know how much, as being an object at s' . So the illusion is that there is an object behind the mirror is nearly due to this. See that the light which is entering the eye is entering it exactly the same manner, physically, as it would have entered had there been an object back there; except for the effect of the mirror, and our knowledge of the existence of the mirror, and so on, which is corrected in the brain.

Now let us demonstrate that the principle of least time will give Fermat's law of reflection. We must however, make an assumption about the speed of light in water. We shall assume that the speed of light in water is lower than the speed of light in air by a certain factor, say μ .

In Fig. 26-4, our position is again to go from A to B in the shortest time. To illustrate that the best thing to do is not just to go at a straight line, let us imagine that a beautiful girl has fallen out of a boat, and she is swimming back up to the shore at point X . The line material back, swimming, we are supposed to be land, and we set the distance and we can run and swim, say a . But we can run faster than we can swim. What should we do? Should we swim in a straight line? (You're doubtful.) However, by using a little more intelligence we would realize that we could be advantageously to travel a little greater distance in land in order to decrease the distance in the water, because we go or must slower in the water. Following the line of reasoning out, we would say the right thing to do is to run until we come fully into the water, and then the path becomes the curve case of all possible paths. If it is the shortest path, that means until we take any other, it will be longer. Since we were going the time it takes against the position of point X we want to get a curve something like that shown in Fig. 26-5, where point C corresponds to the shortest of all possible times. This means that if we move the point X to point X' , in the first approximation there is essentially no change in time because the slope is zero at the bottom of the curve. So our way of thinking the time will be unchanged. Then we move the place by a very small amount, and to showed that there be essentially no change in time. (Of course there is an infinitesimal, except of a second order, we ought to have a positive increase in displacement in either direction from C .) So we consider a nearby point X' and we calculate how long it would take to go from A to X' by the two paths, and compare the new path with the old path. It is very easy to do. We note the differences. Assume to be really very small, if the distance AC is short. First look at the path on land. If we drop a perpendicular to AC , we see that this path is supposed to be parallel to EC . Let us say we go t_1 using AC distance. On the other hand, in the water, by dropping a corresponding perpendicular, CF , we find that we have to go the extra distance CF , and that is equal to AC . Or, in view we split the time it would have taken to go the first part AC , but we have the time it would take to go the distance CF . Those times must be equal since, at the first approximation, there is no change in time. But supposing that in the water the speed is μ times as fast as it is air, then we must have

$$AC^2 = \mu \cdot CF \quad (26-3)$$

Therefore we see that when we have the light point Y in XYC — $c \cdot t_1$ on AC or, canceling the common c by c because lengths AC and CF are equal, that

$$XYC = CCF \quad \text{and} \quad YCF = XYC - t_1 \quad (26-4)$$

we have

$$\sin \theta_1 = \lambda \sin \theta_F \quad (26-5)$$

So we need to go from one point to another in the least time when the ratio of speeds is λ , the light should enter at such an angle that the ratio of the sines of the angles, λ , and λ , is the ratio of the speeds in the two media.

26-4 Applications of Fermat's principle

Now let me consider some of the interesting consequences of the principle of least time. First is the principle of reciprocity. If we go from A to B we have found the path of the least time; the light path in the aggregate, returning back again goes at the same speed in any direction; the return path will be the same path and therefore, if light can be sent one way, it can be sent the other way.

Another application is a glass block with plane parallel faces at an angle to a light beam. Light, in going through the block from a point A to a point B (Fig. 26-6) does not go through in a straight line, but instead it deviates. The law is the same by making the angle in each block the same, so though it does a little bit in the air, the beam is simply displaced parallel to itself because the angles it makes are the same.

A third interesting phenomenon is the fact that when we see the sun setting, it is actually below the horizon! It does not look as though it is below the horizon, but it is (Fig. 26-7). The earth's atmosphere is thin at the top and denser at the bottom. Light's wavelength changes with density of atmosphere, and so the light you see can get to points a beyond the horizon more easily. Instead of going in a straight line, it will follow a curve where it goes slowly by going through there at a steeper angle. When it appears to be below the horizon, it is actually already well below the horizon. Another example of the phenomenon is the rising sun, one lesson... while looking up at the sky. One sees "water" on the horizon when he gets there, it is as dry as the desert! The phenomenon is the following. What we are really seeing is the sky light "reflected" in the sunlight from the sky, heading P . The ray can end up in the eye, as shown in Fig. 26-8, when the air is very hot just above the ground but it is cooler up higher. Hence, air is more rarefied than cooler air is thinner, and this does reduce the speed of light here. That is to say, light goes faster in the hot region than in the cool region. Therefore, instead of the light proceeding to come in the straightforward way, it also has a lateral displacement, by which goes into the region where it is faster for awhile, in order to come in. See it is going in the eye.

An even more important example of the principle of least time, suppose that we could live in a strange situation where we have all the light. Let us suppose at point P , collected back together at another point P' (Fig. 26-9). But notice, of course, that the light can go in a straight line from P to P' . That is all right. But how can we arrange that naturally? i.e., i. given a light, let's say P , let the light starting out from the point P go to this spot P' ? We want to reflect all the light back to whatever collimator. How? If the light always takes the path of least time, then certainly it is much too hard to get over all those other paths. The only way then the path can be perfectly correct is take several separate paths and to make those times exactly equal! Otherwise, it would violate the law of least time. Hence here the problem of making a focusing system is merely bringing a desire + that it is to be the same time for the light to go on all the different paths!

This is easy to do. Suppose that we add a piece of glass in which light goes slower than it does in the air (Fig. 26-10). Now consider a ray which goes in P in the path PQP' . That is a longer path than from P directly to P' and no doubt looks a longer time. But if we were allowed to travel close to just the right thickness we shall be able figure in some thick iron ring, to compensate the extra time that it would take the light to go at a angle! In those circumstances we can arrange so that the iron ring will take the straight, smooth path from P to P' ; it is too long in the path PQ . Travelling since the ray QP' is not yet required, it is not quite as long as PQP' , and we do not have to compensate as much as for the straight-line, but we do have to compensate somehow... With an iron ring of a piece of glass (as shown in Fig. 26-10), PQ is this shape, so the light which comes from P will go to P' . This, of course, is well known to us, and we call such a device a lens and that lens. In terms of $\sin \theta$, we shall try to calculate what shape the lens has to have to make a perfect focus.

Take another example. Suppose we wish to change some distance so that the light from P always goes to P' (Fig. 26-11). For every part Q you'd come in mirror

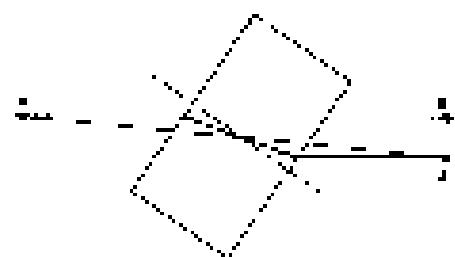

Fig. 26-6. A beam of light refracted as it passes through a transparent block.

Fig. 26-7. Near the horizon, the upper path is lighter than the true path by about $1/2$ degree.

Fig. 26-8. A prism.

Fig. 26-9. An optical "block box."

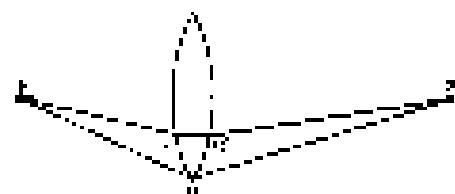

Fig. 26-10. A focusing optic, a lens.

and comes back, and r_1 -times must be equal. Here the light always travels in air, so the time and the distance are proportional. Therefore the distances d_1 , all the times are the same; it is the same as the statement that the total distance is the same. Thus the sum of the two distances r_1 and r_2 must be a constant. An ellipse is that curve which has the property that the sum of the distances from two points is a constant, for every point on the ellipse, thus we can be sure that the light from one focus will come to the other.

The second principle applies for us in finding the light of a star. The great 20th-century Poincaré principle is built on the following principle. Imagine a series billions of rays coming; we would like to cause all the light that comes in to come to a focus. Of course we cannot do the rays one by one all the way up to the star, but we still want to know whether the times are equal. Of course we know that when the various rays arrive at some place SF , perpendicular to the rays, all the times to this place are equal (Fig. 24-11). The rays must then come down to the mirror and proceed toward their equal times. That is, we find a curve which has the property that the sum of the distances $XF = SF + SF'$ is a constant, no matter where X is chosen. A ready way to find it is to extend the length of the line SF even to a plane CC' . Now if we arrange our curve so that $A'X' = AF$, $B'X' = BF$, $C'X' = CF$, and so on, we will have our curve, because then obviously $A'X' + A'X' = AF + BF = BC + CF$ will be constant. This curve is called a *parabola*; the name is made in the shape of a parabola.

The above examples illustrate the principles upon which such optical devices can be designed. The exact curves can be calculated using the principle and, to focus perfectly, the travel times must be exactly equal for all light rays, as well as being less than for any other energy path.

We have discussed these focusing optical devices, but now let me next discuss the further development of the theory. When we use the first principle of the principle of least time, our first inclination might be to say, "Well, I am not going to do it; it is delightful; but the question is, does it help us in understanding the subject?" Somebody may say, "Yes, look at how many things we can understand!" Another says, "Very well, but I can understand without that. I needn't know such things; every singer who makes equal angles with C is a singer." Then figure out a lens, too, because obviously the singer is in front through an angle given by Snell's law. Rightly he statement of least time and the sentence, "But angles are equal on reflection, and that the ratios of the angles are proportional on reflection, are the same." So is it merely a philosophical question, or one of utility? That can be argued on both sides.

However, the importance of a powerful principle is that it provides new things.

It is easy to show that there are a number of new things predicted by Fermat's principle. First, suppose that there are three media, water, and air, and we perform a refraction experiment, and measure the index of refraction between them. Let us call n_{12} the index of air against water, (2) , n_{23} the index of air against glass, (3) , if we measured water against glass, we would find another index, which we shall call n_{13} . But there is no reason why there should be any connection between n_{12} , n_{23} , and n_{13} . On the other hand, according to the idea of least time, there is a certain relationship. The index n_{13} is the ratio of two things, the speed in air to the speed in water, v_{air}/v_{water} , is the ratio of the speed in air to the speed in glass, v_{glass} , is the ratio of the speed in water to the speed in glass. Therefore we can tell that $n_{13} = n_{12} \cdot n_{23}$.

$$n_{13} = \frac{v_2}{v_3} = \frac{n_{12}}{v_{air}/v_{water}} = \frac{n_{12}}{n_{23}}. \quad (24.5)$$

In other words, we predict the refractive index for a new pair of materials can be obtained from the indices of the individual materials with respect to air or vacuum. So if we measure the speed of light in *n* materials, and have this get a single number for each material, namely its index relative to vacuum, called n , then

Fig. 24-11. An elliptical mirror.

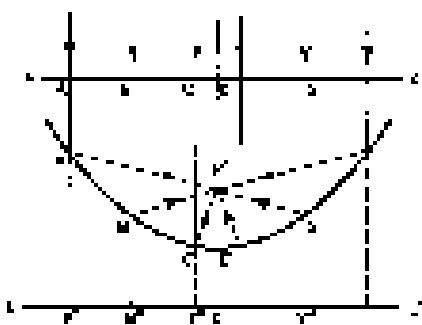

Fig. 24-12. A paraboloid mirror.

v_w is the speed in water, v_a is the speed in air, etc.). Then our formula is easy. The index for July 1st materials hand is

$$n_w = \frac{v_a}{v_w} = \frac{c_w}{c_a}. \quad (26-6)$$

Using only Snell's law, the basis for a principle of this kind,⁴ But of course this prediction works. The relation (26-6) was known very early, and was a very strong argument for the principle of least time.

Another argument for the principle of least time, another prediction, is that if we measure the speed of light in water, it will be lower than in air. This is a prediction which is completely different. Yet it is a brilliant prediction, because all we have so far measured is a single law which is a "familiar" part of which is quite different from the observations from which Descartes deduces the rule of least time. In fact, it is true that the speed in water is lower than the speed in air, by just the proportion that is needed to get the right index!

26-5 A more precise statement of Fermat's principle

Actually, we must make the statement of the principle of least time a little more carefully. It was not stated correctly above. It is now often called the principle of least time and we have gone along with the incorrect statement for so long that we don't even see what the error is! Let me illustrate. Suppose we had a mirror as in Fig. 26-1. When asked, "Is light sent in? Does it go to the mirror?" The path of least time is clearly AB. So some people might say, "Sometimes it is a question of time." It is a minimum in time, but as certainly as π is π , π could have a still longer value! The correct statement is the following: a ray going in a certain particular path has the property that if we make a small change (say a tiny horizontal shift) in the ray in any manner whatsoever, say in the location at which it comes to the mirror, or the shape of the mirror, or anything, the ray will have "second-order" change in the time. There will be only a second-order change in the time. In other words, the principle is that light takes a path such that there are many other paths nearby which take almost exactly the same time.

The difficulty is another difficulty with the principle of least time, and one which people who do not like this kind of a theory might never stomach. With Snell's theory we can "understand" light. Light goes along, it goes *in* surface, it bounces back, it goes *out* of the surface. The idea of causality, that it goes from one point to another and *arrives* at one point, is very comfortable. But the principle of least time is a completely cut-and-dried philosophical principle about the way nature works. Instead of saying "It is causal," it is causal *but* when we do something, something else happens, and this is always the worse up the situation, and nothing else would in the shortest time, or the extreme one, and choose that path. If we reverse it, it does not fit "calvin". That is itself the best he can find and check them against each other. He cannot say, "It is causal," in this way. This is the feature which, of course, not known to geometer, optics, and which is involved in consideration of investigating the meaning of it's to approximately how far away the light must "travel" the path in order to obtain the best performance. It's feasible to do this with light, because the wave-lengths are so terribly short. But with radio waves, say 10 m waves, the distances over which the radio-waves are checking the paths. If we have a source of radio-waves, a detector, are a slit, something (Fig. 26-13). The rays of light, we go from S to D because it is a straight line. And if we move down the slit a little bit—they still go—but now if we move the slit a little bit to D', the waves will not go through the wide slit from S to D', because they come several picoseconds apart, and very, very, very small. They all can expand to different times. On the other hand, if we prevent the radiation from spreading. To get the closing the slit down to a very narrow slit. Then there is but one path available, and the

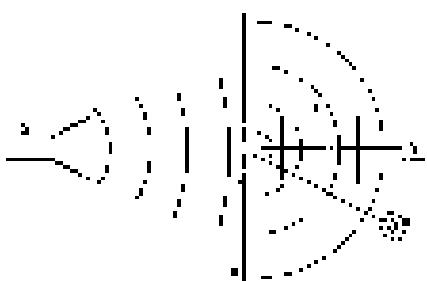

Fig. 26-13. The passage of radio-waves through a narrow slit.

⁴ Although a common feature of the standard assumptions is made, but adding a bit of common sense to the entire assumption makes it stronger: the actual angle of refraction is too little in size.

radiation passes it. With a narrow slit, more radiation reaches Dr. Jinn's needles, i.e. with a white slit.

One can do the same thing with light, but it is hard to synchronize all the parts. The best can be done with the following simple construction. Find a small, bright light, say an incandescent bulb in a street light far away in the direction of the sun in a curved automobile lamp. Then put two fingers in front of the lens, so as to break it much the most, and try to see the light source very clearly. You will see that the rays of the light, which were parallel before, becomes quite elongated, and even stretches into a long line. The reason is that the things are very close together, and the light which is supposed to come in a straight line is spread out; it is single, so rays which comes in at the eye it comes from several directions. Also you will notice, if you look very closely, side by side a lot of fringes along the edge line. Furthermore, the whole thing is colored. All of this we've explained in our time, but for the present I want to emphasize that light does not always go in straight lines, and it is not true is very easily demonstrated.

26-4 How it works

Finally, we give a very crude view of what actually happens. *How* the whole thing really works. Let us assume we now believe in an older, quantum, experimentally accurate viewpoint, but of course only qualitatively described. In following the light from A to B in Fig. 26-3, we find that the light does not seem to travel the form of waves of light. Instead, the rays seem to be made up of photons, and they actually produce clicks in a photon counter if we are using one. The total power of the light is proportional to the average number of photons that come in per second, and what we calculate is the chance that a photon goes from A to B, as by hitting the counter. The law for this chance is the following: *law of a wavelet*. Take any point here for the time t_0 that puts there make a complex number, or wave-like complex vector, $e^{i\theta}$, where angle θ is proportional to the time. The number of counts you would get is the frequency of the light. Now, the counter will not have, say, just at a different time, on the same spot it is armed through a calculating logic. The angle θ is always proportional to the time. Take all the wavelets along the path, and to you for each one, then the answer is that the chance of arrival of a photon is proportional to the *square* of the length of the light vector, from the beginning to the end.

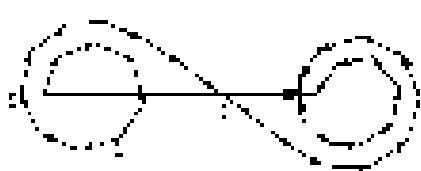

Fig. 26-14. The summation of probability amplitudes for many neighboring paths.

Now let us show how this follows the principle of least time for a mirror. We consider all rays, i.e., possible paths, A-B-C-D-E, etc., in Fig. 26-3. The path A-B-C has a certain *a priori* contribution, but the next path, A-E-B, has a quite different final angle θ quite different, but to say the point C corresponds to minimum time, where if we change the θ to be times of set change. So take while the time derivative, and then they begin to change less and less as we go near point C (Fig. 26-14). So the paths which are having added to contribute to it, the same angle for while near C and then gradually the time lag is increasing again, and the paths go around the other way, and so on. Incidentally, the time lag is light like. The total probability is the sum of them out and to the other, squared. Almost all of these successive probabilities occurs in the same order and the amplitudes in the same direction (as in the same phase). All the contributions from the paths which have very different times we change the point, cancel themselves out by going in different directions. That is why it works. Furthermore, parts of the mirror itself reflects almost exactly. This is, because all we did was to to put a piece of the diaphragm inside the spiral ends, and that makes only a very small change in the light, so this is the situation between the aluminum plates. The paths will a probability, which depending on an accumulation of errors, and the principle of least time.

Geometrical Optics

27-1 Introduction

In this chapter we shall discuss some elementary applications of the ideas of the previous chapter to a number of practical devices, using the approximation called geometrical optics. This is a most useful approximation in the practical design of many optical systems and instruments. Geometrical optics is often very complicated, so we are content to consider it either when it is perfectly good, or when it is good enough so that we can design instruments roughly, using rules that we can easily meet that with failure not at all, since they are practically of high school level. Of course, if we want to know about the small errors of lenses and similar devices, the subject goes on considerably; that is, we also must go beyond geometrical optics. There has been a great deal written in the last few years about the subject of aberrations, and it is advised to read about the subject in the simple way that the rays travel through various surfaces. Let us begin with the book tells how to do, using the law of refraction from one surface to another, and so find out where they come out, say, "After four successive lenses." People have said that this is too tedious, but today, with computing machines, it is the right way to do it. One can set up the problem and make the machine do the work, after which it is very easy. So the subject is really ultimately quite simple, and involves no new principles. Furthermore, in addition to the rules of thin lenses, there is a general rule for lenses that is characteristic of other fields, and that is the reason given to follow the subject very far, with me in constant agreement.

The most advanced and the best theory of geometrical optics was worked out by Huygen, and it turns out that this has very important applications in mechanics. It is extremely important, however, to remember that it is in optics that we use Huygen's theory for the subject of diffraction and diffraction gratings, which is studied in the second year or at graduate school. So, representing that geometrical optics contributes very little toward its own sake, we now go on directly to the geometric properties of simple optical systems on the basis of the principles outlined in the last chapter.

In order to go on, we must have some geometrical formulas, which are the following: (1) the real image will be smaller than the object, (2) if it is real, then the magnification will be negative, (3) the difference in size between two different images is proportional to the distance d (Fig. 27-1). These conclusions? The difference $s' - s = d'$ can be found in a number of ways. One way is this. We see that $s'^2 = d'^2 + \Delta^2$, or $(s' - d)^2 = d'^2$. But $s' - d = d' + d - d$. Thus

$$\Delta \propto d^{3/2} \quad (27-1)$$

This is all the geometry we need to compute the magnification of images by curved surfaces!

27-2 The focal length of a spherical surface

The first and simplest situation to discuss is a single refraction in glass, separation, two media with refractive index n_1 and n_2 (Fig. 27-2). We can use the case of arbitrary indices of refraction to the system, because when we always the most important thing is the specific situation, and the problem is very simple to do in this case. Suppose, suppose the n_1 on the left, the n_2 is 1 and on the right it is $1/n$, where n is the index of refraction. The light travel's more slowly in the glass by a factor n .

27-3 Introduction

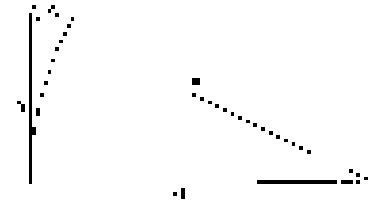

Figure 27-1

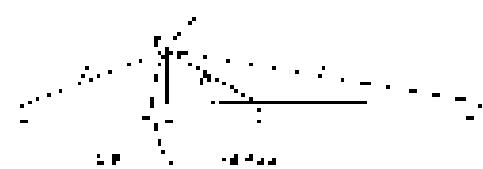

Figure 27-2. Refraction by a single refracting surface.

Now suppose that we have a point at O , at a distance a from the front surface of the glass, and another point O' at a distance b inside the glass, and we desire to design the curved surface in such a manner that, even ray from O which hits the surface, at any point P , will be bent so as to pass through the point O' . For that to be true, we have to design the surface in such a way that the time taken for the ray to go from O to O' , that is, the distance $OP + O'P$ divided by the speed of light (the speed being c units), plus $c \cdot OP$, which is the time it takes to go from P to O' , is equal to a constant independent of the point P . This condition applies however only for determining the surface. The answer is that the surface is a very complicated function of x and y , and that a student may entertain himself by trying to calculate it by any other geometry. It is simpler to try a graphical construction, namely to $c = \infty$, because then the curve is a two-dimensional circle and is more recognizable. It is interesting to compare this curve with the parabolic curve we found for a focusing mirror when the light is coming from infinity.

By the proper surface cannot easily be made to focus the light from one point in another, requires a rather complicated surface. It turns out in practice that we do not try to make such complicated surfaces actually, but instead we make a compromise. Instead of trying to get all the rays to come to a focus, we suppose that only the rays fairly close to the axis OO' come to focus. The farther ones may deviate if they want to, under any circumstances the surface is complicated, and we use instead a spherical surface with the light curvature in the axis. It is much easier to calculate a sphere than other surfaces, than it is preferable for us to find out what happens to rays striking a spherical surface, supposing that only the ones near the axis are going to be focused perfectly. These rays of distance near the axis are sometimes called *convergent rays*, and what we are analyzing are the conditions for the focusing of parallel rays. We shall discuss after the analysis for this interested by the fact that the rays are not always close to the axis.

Thus, supposing P lies on OO' and we drop a perpendicular PQ such that the height PQ is a . For a moment, we imagine that the surface is a plane passing through O . In that case, the time needed to go from O to O' would exceed the time from Q to O' , and also, the time from P to O' would exceed the time from Q to O' . But that is why the glass must be curved, because the total excess time must be compensated by the delay in passing from P to Q . Now the excess time along route QQ' is a^2/c^2 , and the excess time on the other route is (b^2/c^2) . This excess time, which must be covered by the delay in going from PQ , differs from what it would have been in a vacuum, because there is a "medium" present. In other words, the time to go from P to Q is less as if it were straight in the air, but it is slower by the factor n , so the excess delay is n times greater than a^2/c^2 . And how large is n ? If the point O' is the center of the sphere and its radius is R , we see by the same formula that the distance PQ is equal to $b^2/2R$. Therefore we discover that the law $(n - 1)ab^2/2R = a^2/c^2$, and that gives us the radius of curvature R of the surface that we need.

$$(n^2/2) + (nv^2/c^2) = (n - 1)b^2/2R \quad (27.2)$$

or

$$C/n = C/v = (v - 1)c/b. \quad (27.3)$$

If we have a position O and another position O' , and want to focus light from O to O' , then we can calculate the required radius of curvature R of the surface by this formula.

Now it turns out interestingly that the same lens with the same curvature R , will focus for other distances, namely, for any pair of distances such that the sum of the two distances, multiplied by n , is a constant. This is a given fact, will you keep it we limit ourselves to assume rays from infinity from $O \approx O'$, but between an infinite number of other pairs of points, so long as those pairs of points have the characteristic $b_1/n + b_2/n$ is a constant, characteristic of the lens.

In particular, an interesting case is that in which $b \rightarrow a$. We can see from the formula that as one a increases, the lens decreases. In other words, if point O is

goes on to point O' on medium 2 and vice versa. As point O goes toward infinity, point O' keeps moving to the left until it reaches a certain distance, called the focal length, f , from the medium. If parallel rays come in, they will meet at a distance f . Likewise, we could imagine it the other way, if one takes the reciprocity rule ("plus will go from O to O'), of course now the point O' is to O . Therefore, if we have a light source inside the glass, we might want to know where the focus is. In particular, if the light in the glass were an infinity (some problem which would become a focus outside). This distance is called f . Of course, we can do it the other way. If we had a ray source outside the glass, went through the surface, does it break or not as a parallel beam? We can easily find out what f is:

$$n_1 n_2 = (n - 1)/R \quad \text{or} \quad n^2 + R(n - 1) = 1. \quad (27-2)$$

$$1/f = (n - 1)/R \quad \text{or} \quad f = R/(n - 1). \quad (27-3)$$

We see an interesting thing: we divide focal length by the corresponding index of refraction, we get the same result. The question, in fact, is general. It is true of any system of lenses, no matter how complicated, that it is inversing its reciprocal. We could prove here that this general—(we merely noted it for a single surface, but it is general)—is true, in general that the two focal lengths of a system are related in this way. Sometimes Eq. (27-3) is written in the form

$$1/n + 1/n' = 1/f. \quad (27-4)$$

This is more useful than (27-3) because we can move n / n' around so that we can measure the successive indices of refraction of the lens. If we are not interested in inverting a lens... in this is a law, it is the case, but, simply, like all of a field, the interesting quantity is f , not the n 's, the n 's, the R 's, and the d 's.

Now let's take a student exam if it becomes less confusing. What happens there? If $n < 1$, then $n_2 < n_1$, and therefore n' is negative, our equation says that the light will travel only with a negative value of n . Whether this is real? Does mean something very interesting and very difficult. It is still useful to recall, in other words, even when the numbers are negative. What it means is shown in Fig. 27-1. If we draw the rays which are diverging from O , they will be here, if it is true, at the surface, in G . They will not come to a focus, because it is so close at that they are "beyond parallel". However, they diverge as if they had come from a point O' outside the glass. This is an apparent image, sometimes called a virtual image. The image O' in Fig. 27-1 is called a real image. If the light really exists to a point, it is a real image. But if the light appears to be coming from a point, a light can pass different from the actual point, it is a virtual image. So when $n < 1$, we can, negative it, use (27-3) on the other side of the surface, and every thing is $> n$.

Now consider the interesting case where it is equal to infinity, then we have $(1/n) - (1/n') = 0$. In other words, $f = \infty$, which means that if we look from a given medium into a new medium and as a point is in the new medium, it appears to be deeper by a factor n . Likewise, we can use the same equation backwards, so that if we look into a given medium at a distance, that is, d , at the distance outside the glass medium, it will appear as though the light is coming from $n - 1$ to n back (Fig. 27-4). When we look at the bottom of a swimming pool from above, it does not look as deep as really is, by a factor 3/4, which is the reciprocal of the index of refraction of water.

What would you do? Assume to use the spherical mirror. But if one expects me to do it, I would be asked to work it out for himself. Therefore we leave it to the student to work out the formula for the spherical mirror, but we mention that it is well to adopt certain conventions concerning the distances involved:

- (1) The object distance s is positive if the point O is to the left of the surface;
- (2) the image distance s' is positive if the point O' is to the right of the surface;
- (3) The value of curvature R of the surface is positive if the surface is to the left of the surface.

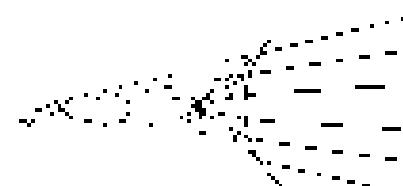

Fig. 27-1. A virtual image

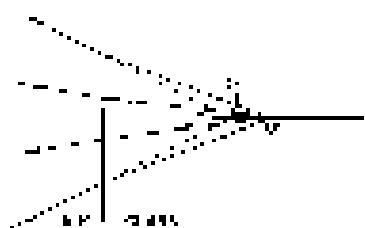

Fig. 27-4. A plane surface image. The light from O to O' .

In Fig. 27-2, for example, n_1 , n_2 , and R are all positive; in Fig. 27-3, n_1 and R are positive, but n_2 is negative. If we had used a concave surface, our formula (27.1) would still give the same result if we merely make it a negative quantity.

To get the right sign for the corresponding formula for a mirror, using the above conventions, you will find that from $p = \frac{R}{n_1 - n_2}$ — I thought the formula (27.1) (as though n_1 were in front of the mirror, had an index -1) the right sign is also obtained.

Although the derivation of Eqs. 27.1 to 27.3 is simple and elegant, using first light rays, you can also work out the static law, along the Snell's law, remembering that the angles are so small that the sines of angles can be replaced by the angles themselves.

27-3 The focal length of a lens.

Now we go on to consider another situation, a very practical one. Most of the lenses that we use have two surfaces and just one. How does this affect matters? Suppose that we have two surfaces of the sort shown in Fig. 27-4, with air filling the space between them (Fig. 27-5). We want to study the problem of focusing from a point O on one side to another point O' . However we do this? The easiest, as this. First, use Formula (27.1) for the first surface, forgetting about the second surface. This will tell us that the light which was emerging from O will appear to be converging or diverging, depending on the sign, from some other point than O' . Now we consider a new problem. We have a second surface, between O' and O , in which rays are converging toward a certain point O' . When will they actually come to O' ? We are in again in trouble again. We find that they converge at O'' . Then, if necessary, we can get through $75 \times$ lenses by just using the same formula in succession, but there is no need!

There are some other high-class techniques that would solving problems like this in the few cases in our lives that we might have to chase the light through ten surfaces, but it is better just to think it through the surfaces when the problem arises, or it is better to use a lot of common sense because it may be we will never have to pass through any surfaces at all!

In any case, the principle is this: when we go through one surface, we find a new position, a new focal point, and then take this point as the starting point for the next surface, and so on. In order to solve problems, since on the second surface we are going from n_1 to n_2 in air rather than from 1 to n_1 , and since in many systems there is more than one kind of glass, so that there are indices n_1 , n_2 , . . . , we usually need a generalization of equation (27.3) for a case where there are two different indices, n_1 and n_2 , rather than only n . Then it is not difficult to prove that the general form of (27.3) is

$$(n_1/n_2) = (n_2/n_1) = (R_2 - R_1)/R. \quad (27.7)$$

The really simple is the special case in which the two surfaces are very close together—so close that we may ignore errors due to the thickness. If we draw the lens as it is in Fig. 27-6, we may ask a question: How fast the lens to be built so as to focus light from O at O' ? Suppose the light comes exactly to the edge of the lens, at point P . Then the excess time in going from O to O' is $(n_1 - n_2) d / c$, if d is the thickness of the lens. Ignoring the momentary presence of the thickness d of glass in front of O , how we take the time for the direct path equal to that for the path $O P O'$? We have to let a piece of glass whose thickness $= d$ be thicker so that the light interested in going through this piece of glass is enough to compensate for the excess time above. Then from the thickness of the lens at the center must be given by the relationship

$$(n_1 d / c) = (n_2 d / c) = (n_2 - n_1) R. \quad (27.8)$$

We can then express the radius of the lens R , and R_2 of the two surfaces. Paying attention to one convention (by taking n_1 to be $n_2 < n_1$ for convex lens),

$$R = (n_1 / 2n_2) + (n_2^2 / 2n_1). \quad (27.9)$$

The above, we finally get

$$(n_1/v) - (n_2/v) = (n_1/n_2)R = \gamma/R_{12} \quad (27.16)$$

Now we can again say that if one of the points is at infinity, the other will be at a point which we will call "the focal length". The focal length is given by

$$1/f = (n_1 - n_2)/R_{12} = \gamma/R_{12} \quad (27.17)$$

where $\gamma = n_2/n_1$.

Note, if we take the *vacuum* case, where n_2 goes to infinity, we see that f is the "focal length" γ^{-1} . This time the focal lengths are equal. (This is another special case of the general rule that the ratio of the two focal lengths is the ratio of the indices of refraction in the two media in which the rays travel.) In the particular optical system, the initial and final media are the same, so the two focal lengths are equal.)

To get the focal length of the second medium, if we bring x_2 over from the *vacuum* region with its radius of curvature and a central index, we could measure the focal length f_2 , by seeing where a point at infinity forms. However, if the focal length f is to be here, we'd have to write our equation in terms of the focal length directly, and this demands the \rightarrow

$$(1/v) - (1/v') = 1/f \quad (27.18)$$

Now let's examine the formulae we've had up to now in different situations. Here it implies that v' is infinite (infinite distance from the lens). This means that $v_2 < R$. Light comes to a distance, and this is *not* defocused. Another interesting thing it says is that light passing a lens in the same direction it came from is defocused. However, if the lens is reversed, And in this I mean that $v_2 & v'$ are equal (they are both equal to R). In other words, if we want a *symmetric* situation, we find that they will both focus at a distance $2R$.

27.4 Magnification

So far we have discussed the forming of real images of points on the axis. Now let's discuss also the forming of *virtual* images away from the axis, but a little at all, so that we can understand the properties of magnification. When we sit right back so as to see a bright filament, e.g., filament under a "pocket" lamp or a screen, we know that on the screen we get a "picture" of the same filament, because of a larger α and it is brighter than the filament. We must remember that the light comes to a focus from each point of the filament. It makes no difference that a lamp is brighter, for us and yet the other less intense radiation is symmetrically. In Fig. 27.7, we come up the following facts:

- (1) A ray that comes in parallel from a point parallel toward a convergent lens will meet at the focus F on the other side of a "ray" from the lens.
- (2) A ray that passes F before it from the lens on one side comes out parallel to the axis on the other side.

This is all we need to establish from us (27.19) by symmetry, is (27.20). Suppose we have an object, a same distance a from the lens; let b be height of the object, α , i.e., then we know that one of the rays, in fact PQ , can be bent so as to pass through the focus F on the other side. Now if a lens will focus just 1.5 or all, we can find out where it will find out where just one converging ray, because the new rays will be when the lens focuses, α , i.e., b . We could try use our ingenuity to find the exact direction of one other ray. If we remember that a parallel ray goes through the lens and the lens does not change through the "axis of" convergent lenses. So we draw ray AB through F . It's true that the actual rays which are being defocused may be much more limited than the two we have drawn, but they are random in figure, so we make believe that we can assume this ray goes on it would come out straight, we draw it by parallel to AB . The intersection is the point we want. This will determine the exact place and the correct height. Let

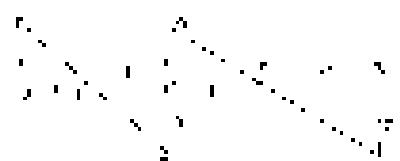

Fig. 27.7. The geometry of focusing by a thin lens.

us call the "focal length" and the distance from the lens, x . Now we may derive a lens formula. Using the similar triangles $\triangle PVY$ and $\triangle XZY$, we find

$$\frac{v}{f} = \frac{x}{x} \quad (27.13)$$

Similarly, from triangles $\triangle WXR$ and $\triangle QYL$, we get

$$\frac{v'}{f'} = \frac{x'}{x} \quad (27.14)$$

Solving each for v and v' , we find that

$$\frac{v}{f} = \frac{v'}{f'} = \frac{x}{x} \quad (27.15)$$

Equation (27.15) is the **focal length formula**. In it is everything we need to know about lenses. It tells us the magnification, in Eq. (27.15), in terms of the object size and the focal lengths. It also indicates the two distances x and x' which

$$xx' = ff' \quad (27.16)$$

which is a much neater form of work over than Eq. (27.13). We leave it to the student to demonstrate that if we let $v = x + f$ and $v' = x' + f'$, Eq. (27.15) is the same as Eq. (27.16).

27-4 Compound lenses

Without actually deriving it, we shall briefly describe the general result when we have a number of lenses. If we have a system of several lenses, how can we possibly analyze it? That is easy. We start with some source and calculate where the first lens, using formula (27.16) or (27.15) or any other calculation formula, or by drawing diagrams. So we find an image. Then we call this image as the source for the next lens, and use the second lens with whatever its focal length; so to again find an image. We simply repeat the foregoing for the successive lenses. That is all there is to it. It is nothing new in principle, we just multiply it out. However, there is a very interesting net result of the effects of any sequence of lenses on light that starts and ends up in the same medium, say air. Any optical instrument—a telescope or a microscope with lots and lots of lenses and mirrors—has the following property: There exist two planes, called the **principal planes** of the system (these do not have to be thin lenses), which have the following properties: (1) If light comes in ... to a system parallel from the left side, it comes out at a certain distance x in front of the second principal plane equal to the focal length; just as though the system were a thin lens located at this plane. (2) If $x > 0$ light comes in the other way, it exits to a focus at the same distance x from the first principal plane, again as though it were there (see Fig. 27.8).

Of course, if we measure the distances x and x' , and y and y' as before, the formula (27.16) has to be modified to take into account the fact that this lens is **assolutely** *thin*—provided that we measure the focal length from the principal planes and not from the center of the lens. It so happens that for a thin lens the principal planes are coincident. It is just as though we could take a thin lens, slice it down the middle, and separate it into two parts. Let it *not* separate. But say that one is *pop-out* immediately on the right side of the second plane from the same point as . . . see also the first plane! The principal planes and the focal lengths must be found either by experiment or by calculation, and then the whole set of properties of the optical system are determined. It is very interesting that this is not too complicated when we deal directly with such a thin, uncomplicated optical system.

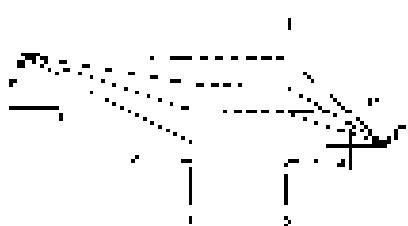

Fig. 27-8. Illustration of the principal planes of an optical system.

27-6 Aberrations

Before we get into what could now marvelous lenses are, we must return to how the different lenses interact with light. Because of the fact that we focus lenses ourselves, gravity causing a point's light rays to converge near the lens. A lens, thus having a finite size will, in general, exhibit aberrations. For example, if the lens is on the side, of course, given enough time, a ray that is parallel to the axis will still converge to the focus very well. But if the lens is inclined, the ray begins to deviate from the focus, perhaps by hitting itself, and a ray striking near the top edge comes down and misses the focus by a few millimeters. So instead of getting a point image, we get a smear. This effect is called *spherical aberration*, because it is a property of the spherical surfaces we used placed in the right shape. This could be remedied, for any specific object distance, by tailoring the shape of lenses to focus on a single point by using several lenses arranged so that the aberrations of the individual lenses tend to cancel each other.

Lenses have another fun type of difference, where two different speeds or different indices of refraction, in the glass, and therefore the focal length of a given lens is different. This is refraction. So if we move away its focal, the images will have colors, because after we focus for one color, the others will be out of focus or vice versa. This is *chromatic aberration*.

There is yet another fun type of aberration that occurs if the focus is off the axis. You'll perfect any more, unless it gets far enough off the axis. The easiest way to verify this is to take a lens and then to see that the rays are bending in at a large angle from the axis. Then the image that is formed will usually be quite blurry and there may be no place where it focuses well. There are thus several kinds of aberrations other than the optical design can't handle by us up more focus to compensate each other's effects.

Now, what if we have to be *geometrically* aberrant? Is it possible to make an absolutely perfect optical system? Suppose we had a multi-lens optical system that is supposed to bring light exactly to a point. Now, say my friend has paid all this effort and can get this lens. Given all how perfect this system has to be, the system can have some kind of an inherent tendency to the light. If we take the first ray from the lens that can escape to the side if the system is perfect (if you like), the first four rays are exactly equal. But nothing is perfect, so the question is, how wrong can the light be for the ray and not be worth calling any "other"? That depends on how perfect we want to make the system. Your supplier can work to make the rays as perfect as is possibly can be made. Then, of course, our impression is that we have to compromise, but many rays follow exactly the same time as possible. But it turns out that this is not true, that beyond a certain point we are trying to do something that is terrible because the theory of geometrical optics does not work!

Remember: that the principle of least time is not an *exact* formulation, under the principle of conservation of energy or the principle of conservation of momentum. The principle of least time is only an approximation, and it is exacting... but there must be a limit that is allowed and will not affect any apparent difference. The answer is that if we ever arranged them later in the system, or, worse yet, if one that is further out, and the central ray, the difference in time is less than about the period of time it spends in the oscillation of the light. Otherwise there is no use arranging it any further. Light is an oscillatory thing with a definite frequency that is related to the wave length, and if we have arranged that the time difference for different rays is less than about a period, there is no use arranging any farther.

27-7 Resolution power

Another interesting question is how important technical question with all cameras, instruments—how much we're going to see, how sharp. If we build a microscope, we want to see the objects that we are looking at. That means, for instance, that if we are looking at a bacterium with a spot on each end, we want to know just

Fig. 12-2 illustrates what we imagined the ... Our singer thus, that all we hope to do is to get enough magnification—well, we always add another lens, and we can always magnify again and again, and with the increases of magnification, all the spherical aberrations and chromatic aberrations can be decreased in ... and there is no reason why we can't keep on magnifying the image. So the limitations of a microscope are not ... it is impossible to build a lens that magnifies every colorchromatic. We can build a system of lenses that magnifies by 100 diameters, but we still could not have one point that are two places beyond because of the limitations of geometrical optics, because of the fact that lens time is not precise.

So suppose we take that telescope now, and that two points have to be on either side of the focal length, so separate points can be seen in a very beautiful way, and we know that the time is taken for each to be on focus. Suppose that we imagined the aberrations now, and I take the faraway object point P (Fig. 12-9); ... the rays from here to focus T_1 ... really are stuck to ... it is not T_1 , because it is not a perfect system, but that is another problem. Now take another nearby point, P' , and ask whether, coming up with the aberration from T_1 . In other words, whether we can tell the difference between them. Of course, according to geometrical optics, there should be two point images, but we can see more than the increased and we may not be able to make out that there are two points. But consider that the second point is different in a distance different from from the first one is that the two times for the two end rays $P-T_1$ and $P'-T_1$ on each side of the lens focusing on the lens to go from one end to the other, must not be equal, from the two possible object points to a given image point. Why? Because, if the times were equal, if we were born Δt off focus at the same point, so the times would going to be equal. But he has much more they were to take so that we can say that is Δt the time to be a constant form, so that we can distinguish the two images, perhaps? The general rule for the resolution of any optical instrument is this: two different point sources can be resolved only if one source is beyond or just a point than the time for the ray from the other source to reach that point, as compared with the time for the ray from the other source to reach that point. It is necessary that the difference in time between the ray from the left-hand ray to the ray from the right exceed a certain minimum number of periods of oscillation of the light.

$$t_2 - t_1 \geq \frac{1}{c} \Delta \phi \quad (12-1)$$

where c is the frequency of the light (number of oscillations per second), expressed in cycles per second; $t_2 - t_1$ is the difference of times of travel of 100,000 points, is called D , and if the ray-angle of the rays is called θ , then one can demonstrate that $(D/c)\theta$ is exactly equivalent to the statement that D must exceed $\lambda/\Delta n$, where Δn is the index of refraction of air and λ is the wavelength. The simplest thing that we can see is that λ is approximately the wavelength of light. A corresponding formula exists for telescopes, which $\Delta \phi$ is the smallest difference in angle between two stars that can just be distinguished.

* The angle is called the "angle D in radians between conjugate rays."

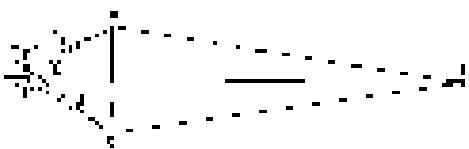

Fig. 12-9. The resolving power of an optical system.

Electromagnetic Radiation

24-1 Electromagnetism

The most Grammatical mistake in the development of physics can occur in which two synonymous words, where phenomena would previously and accustomed to be different are suddenly discovered to be the same. To put it simply, the same thing. That's what Grammatical mistake is. The history of such synthesis, and the basis of the science of physical science is mainly the same as above by synthesis.

Besides the importance of symmetry in the development of basic science, the EMR must also occur. In J. C. Maxwell's time may not be known about the mutual and inverse laws of electricity and magnetism with the laws of the behavior of light. As a result, the properties of light were poorly understood. But still all of the stuff that is so important and interesting was that it was felt necessary to invent a special creation for it in other writing. Grammatical mistake was that he was forced to do this because "Light is electricity and magnetism, and there is light."

For this eliminating moment, he wrote a long paperwork in his private laboratory, containing various laws of electricity and magnetism. This story we shall reserve for detailed study next year. However, the story is, suffice to say, the gradually disappeared of preexisting electricity and magnetism, or electric forces of attraction and repulsion, and of magnetic forces showed that, although these forces were rather complex, they all fell on symmetry as the signs of their existence. We came, for example, but I assume easily, how a stationary charge gives us the electric force field which is inversely proportional to the square of distance. As a consequence, at sufficiently great distances there is very little influence. Thus system of charges is consistent. Maxwell noted that the equations of the laws that had been discovered up to this time were mutually inconsistent. When he tried to put all of them together and in order for the whole system to be consistent, he had to add another term in his equations. With this term, the system became an analog credibility, which was that if the electric and magnetic fields would fall off much more slowly with the distance than the forces do, more rapidly, apparently as the first power of the distance. And so he realized that electric force is to do that can affect other charges far away, also be present of the back effects with which we are familiar, like induction, polarization, and so on.

In summary, it turned that a charge will fly in Europe even, with zero acceleration we'll be heard thousands of miles away in New York. That's it's possible to have a field that not only is not a source, but only precisely as the last center of the source. Finally, that's our light that was recognized to be electric and magnetic in human habitation over vast distances guaranteed by an almost in reality a full visibility of the electrons in the world. All these phenomena we summarize by the word *radiation*, more specifically *electromagnetic radiation*. There being one or two other kinds of radiation also. A man always radiates electromagnetic waves to other

A. G. Thus is the universe *spun together* — the atomic nucleus of a star, that will have sufficient influence at the great distance to set the electrons in motion in myself, and never know about the stars. If this law had not exist, we would not be literally in the dark about the outer world. And the electron comes in a galaxy two billion light years away, which is the farthest object we can see from so far — can still influence in a significant and detectable way the current in the great "Giant" in front of a radio telescope. And so now they work. Listen and the problem

24-1 Electromagnetism

24-2 Radiation

24-3 The Radio Telescope

24-4 Interference

This remarkable phenomenon is what we shall discuss in the present chapter. At the beginning of this course in physics we outlined a broad picture of the world, but we are now better prepared to understand some aspects of it, and so we shall now go over some parts of it again in greater detail. We begin by describing the position of physics at the end of the 19th century. All that was then known about the fundamental laws can be summarized as follows.

First there were laws of forces: one force was the law of gravitation, which we have written down several times: the force on an object of mass m due to another of mass M is given by

$$\mathbf{F} = G m M \frac{\mathbf{r}}{r^3}, \quad (25.1)$$

where \mathbf{r} is a unit vector directed from mass M , and r is the distance between them.

Next, the laws of elasticity and magnetism, as known at the end of the last century, are that: (i) electrical forces acting on a charge q can be described by two fields, called \mathbf{E} and \mathbf{B} , and the velocity v of the charge q by the equation

$$q v \times \mathbf{B} = q(\mathbf{E} + v \times \mathbf{B}), \quad (25.2)$$

To complete this law, we have to say what the formulas for \mathbf{E} and \mathbf{B} are in a given circumstance: if a number of charges are fixed, \mathbf{E} and \mathbf{B} are each the sum of contributions from each individual charge. So if we can find the \mathbf{E} and \mathbf{B} produced by a single charge, we must simply add all these contributions! If no charges in the universe except the field \mathbf{E} and \mathbf{B} . This is the principle of superposition.

What is the formula for the electric and magnetic field produced by one individual charge? It turns out that this is very complicated, and it takes great ingenuity and simplification to appreciate it. But that is not the point. We write down below now only the formula, the reader will be happy to note, and say: "A-ha, that is possibly to summarize all the fundamental knowledge in one page, with no details that he is now familiar with." This law for the field of an individual charge is incomplete and inaccurate; we know (except for quantum mechanics) but it looks rather complicated. We shall not quote all the pieces now; we only wish it shown to give an impression, to show that it can be written, and so that we can see instead of the roughly what's known now. As a matter of fact, the most useful way to write these two laws of electricity and magnetism is not the way we shall now write them, but involves what we call 'field operators', which we shall learn about next year. But the mathematical problems for these are different now, and so we write below in a convenient form for calculation, but in approximations that we now know.

The electric field, \mathbf{E} , is given by

$$\mathbf{E} = \frac{-q}{4\pi\epsilon_0} \left[\frac{\mathbf{r}_P}{r^3} + \frac{v}{c} \frac{d}{dt} \left(\frac{\mathbf{r}_P}{r^3} \right) - \frac{1}{c^2} \frac{d^2}{dt^2} \frac{\mathbf{r}_P}{r^3} \right]. \quad (25.3)$$

What do the various terms mean? Take the first term, $T_1 = -q\epsilon_0/c^2 r^3 \mathbf{r}_P$. That, of course, is Coulomb's law, which we already know: q is the charge that is producing the field, \mathbf{r}_P is the unit vector in the direction from the point P where \mathbf{E} is measured, r is the distance from P to q . But Coulomb's law is wrong. The discoveries of the 19th century showed that influences cannot travel fast. There is a non-instantaneous speed c , which we now call the speed of light. T_1 is incorrect just like Earth is Coulomb's law, not only because it is not possible to know where the charge is now, and so what distance it is now, but also because it is only thing that can affect the field at a given place and time is the behavior of the charge in the past. How far in the past? The time delay, or retardation, associated with the time it takes, at speed c , to get from the charge to the field point P . The delay is r/c .

In to allow for this time delay, we put $+1/c$ in front of T_1 , meaning how far away it was when the information now arriving at P left q . But to remember suppose that the charge carries a light and that the light can only move to P at the speed c . Then when we look at q , we wouldn't see where it is now, of course, but where it was at some earlier time. What appears in our T_1 must be the retarded

direction to the direction it used to be—the sense of retarded direction—and you'll understand distance r . That would be easy enough to understand, yes, but it is also wrong. The whole thing is much more complicated.

There are several more terms. The next term is ω , though we are were trying to allow for retardation. But the effect is retarded, if we neglect ω , it is very crude. In addition there should be added the dipole moment D and add a correction term, which is to take el. charge times the time delay that we use. Nature seems to be stamping in to pass what the field is, the present time is going to be, by taking the rate of change and multiplying by the time that is ω delayed. But we are not yet through. There is a third term—the second derivative, with respect ω , of the unit vector in the direction of the dipole. Now the dipole is finite, and that is all there is to the electric field from an arbitrary moving charge.

The magnetic field is given by

$$\mathbf{B} = \mathbf{B}_0 \propto \mathbf{E}/c. \quad (19.3)$$

We have written these down only for the purpose of showing the beauty of nature even in a way that goes beyond mathematics. We do not pretend to understand why it is possible to write so much in such a small space. In (18.3) and (19.3) contain the machinery by which electric generators work, how light carries all the phenomena of electricity and magnetism. Of course, to complete the story we do need to know something about the behavior of the materials involved, the properties of matter—which we did described briefly by (18.3).

To finish with our description of the world of the 19th century we must mention one other great synthesis which occurred in that century, one with which Maxwell was a great deal involved and that was the synthesis of the phenomena of light and mechanics. We shall study this subject soon.

What had to be added at the 20th century was that the dynamical laws of Newton were found to be not enough, and quantum mechanics had to be introduced to correct them. Newton's laws are approximately valid when the scale of things is sufficiently large. The quantum mechanics laws, combined with the laws of electricity, have only recently been combined to form a set of laws called quantum electrodynamics. In addition, there was discovered a number of new phenomena, of which the first was radioactivity, discovered by Becquerel in 1896—but just accepted it in 1900—the last century. This phenomenon of radioactivity was followed up to produce our knowledge of the atomic nuclei of atoms (i.e., the nucleus), and not electrons, but new particles were different interactions. Doubtless others have still to be discovered.

For those people who know more than you do, who happen to be reading this, we should add that when we say that (19.3) is a complete description of the knowledge of electrodynamics, we are not being entirely accurate. There was a problem that was not quite solved at the end of the 19th century. When we try to calculate the field from all the charges existing in space (say that we want the field to exist at), we get zero from it by trying to find the distance, for example, of a charge from itself, and looking something by that criterion which is zero. The problem of how to recall the part of the field which is generated by one very charge q which we want the field to exist but yet actual exists. So we leave it here; we do not have a complete solution to this puzzle yet, and so we shall avoid the puzzle for as long as we can.

19-2 Radiation

That last is a summary of the world picture. Now let us go on to discuss the phenomena called radiation. To discuss these phenomena, we must extract from eq. (18.3) only that part which is inversely as the distance and goes to the source of the charges. It turns out that when we find the field of a piece, it is completely sufficient that it's legitimate to study forces and electromagnetism in an elementary way by taking it as "by law" of the form the field produced by a moving charge is \mathbf{E} . We shall take it especially as a given law which we will need to use in this next year.

Of the terms appearing in (28) it is the last one evidently goes inversely as the square of the distance, and the second is only a correction for delay, so it is easy to see that, but of them vary inversely as the size of the charge. All of the terms which are important in the first and third term, which is not very important, after all. What can this say to us at the stage and note the direction of the motion? If we can project the end of \vec{r} on the surface of a unit sphere, as the energy waves proceed, the end \vec{r} never wiggles, and the acceleration of the unit vector \vec{r} is also not changing for. That is all. Thus

$$\vec{E} = \frac{q}{4\pi r^2} \frac{\vec{A}_0}{r^2} \quad (28.5)$$

is a statement of the laws of radiation, because that is the only important law in which we get far enough away that the terms the varying inversely as the distance, (the case that the charges have fallen off or more than we are not interested in here).

Now we can go on with the further at studying (28) by to see what it means. Suppose a charge is moving at the moment whatsoever. And we are observing it from a distance. We imagine it is moving that in a straight line. Let's call that true light that we are trying to explain; we imagine it is a little while, that, then we would see this while doing something. But we don't see exactly how it is moving because right now because of the delay that we have been trying to do what counts is the moving source. The unit vector \vec{r} is pointed toward the apparent position of the charge. Otherwise, the end \vec{r} is, goes on a slight curve, because the acceleration has two components. One is the transverse part, because the end \vec{r} is always going along, and the other is radial, please because it stays on a sphere. It is easy to demonstrate that the latter is much smaller than varies as the inverse square of r when r is very great. This is easy to see, for when we imagine that we move a given source farther and farther away, then the wiggles of \vec{r} , look smaller and smaller, inversely as the distance. But the radial component of acceleration is varying more rapidly than inversely as the distance. So for practical purposes \vec{r} we have to do is project the motion on a plane at unit distance. Therefore we get the following rule. Imagine that we look at the moving charge and that we try to see it delayed, like a projector lamp, up to a screen at a distance r at unit distance. A real projector, of course, does not do two account the fact that light is going at a finite speed, but let us do the world as he sees it. We want to see what the picture would look like. So we see a dot, representing the charge, moving about in the screen. The acceleration of this dot is proportional to the electric field. That is $\vec{F} \rightarrow \vec{r}$ we need.

Thus Eq. (28.5) is the complete and correct formula to remember; even velocity effects are all contained in it. However, we often want to apply it to a still situation where \vec{r} either the charges are moving only a bit. Because it is relatively very rare. Since they are moving slowly, they do not move an appreciable distance from where they start, so that the delay time is practically constant. Then the law is still simple, but not the delay time is "well". Thus we imagine the charge is moving a very tiny motion after effectively constant velocity. The delay at the distance r is r/c . The motion becomes the following: if the charged object is moving it is very small motion and it is linearly displaced by the distance r/c , then through the unit vector \vec{r} , is displaced \vec{r}/c , and since it is practically constant, the exponent of r^2 , r^2/c^2 is simply. A cancellation of a factor c^2 is left, in order time, and so finally we get the law as was, which is

$$E(r) = \frac{-q}{4\pi r^2 c^2} \cdot \left(1 - \frac{r}{c}\right). \quad (28.6)$$

Only the exponent of r , perpendicular to the line of sight is important. Let us see why this is. Essentially, if charge is moving in and out straight to us, the direction of that direction does not wobble at all, and it has no acceleration. So it is only the sideways motion which is important, only the motion in that we see projected on the screen.

28-2 The dipole radiator

As part of fundamental "law" of electromagnetism, we said, we are going to assume that (24.5) is true, i.e., that the electric field produced by an accelerating charge which is moving non-relativistically at a very large distance r , appears as $E = q/r^2$. The electric field varies inversely as r^2 and is zero at $r = \infty$; the acceleration of charge q is passed onto the "light" of eight "fingers" or "fingers" which follow today's acceleration, but the idea, which that it did at an earlier time, does not yet delay being a time, etc. In the remainder of this chapter we do a series of tests so that we can understand it better; maybe you know we are going to use it to understand all of the phenomena of light and wave propagation, such as reflection, refraction, interference, diffraction, and scattering. It is to be noted here, and I'll say now, that if you take (24.5) as you're told only up to $\propto r^{-2}$ the $\propto r^{-2}$ is that we could conjecture were (25.6) fits and how well it does.

We shall discuss (28.3) further now, etc. In the meantime, we shall suppose $\propto r^{-2}$ but not the other two terms, here. We may suppose a number of experiments which illustrate the character of this law. At once, to do so, we need to consider a charge. Let this q be a single charge, but if we can make a pair many charges may be used, all in some way, for example, that the field $\propto 1/r^2$ be the sum of the effects of higher order individual charges; we just add the "fingers". And, again, consider two cases of what happened in a generator, as shown in Fig. 28-1. The idea is this: the generator makes a potential difference, $V = E \cdot d$, which pulls electrons away from wire A and pushes them into wire B, in a current, and then, on discharge, in due time, the electrons repel each other, the electrons out of B and jump back to A. If both these two cases except for the two wires are exactly the same, we can disprove in $\propto r^{-2}$ is the current and the momentary energy and waveform dependent. In Fig. 4 and shown out in wire A. The fact that we find two wires in a generator is merely that there is a bus which splits it. For example, that we actually have one potential difference of V because there are two wires in wire A, single wire. And, if the V is very small compared with the distance light travels in one oscillation period \approx about 10^{-15} seconds, etc. Then, etc. Thus we find the voltage, etc. But, we need to apply our law, which is to this case, get the same thing. That is, to do something in instrument to detect the electric field, and the instrument we use is the static thing, a pair of wires like A and B. If no field is field \propto applied to such a device, it will work just as when $V = 0$ will pull the electrons up on both wires or down on both wires. This should be detected by means of a voltmeter, connected between A and B, and a tiny fine microphone for the information into an amplifier where it is amplified so we can hear the positive frequency note with which the radiofrequency is modulated. When this probe feels the electric field, there will be a cold noise, one might call it, because the sound other than the in-phase field driving it. There will be no noise.

Now consider a room in which the wires we are measuring conductive objects in. An electric field will take effect, even in these other objects. And this field makes the other charge-groups there and in going \propto in proportion, these also push or attract our probe. This last successful experiment was just field \propto field \propto field \propto field. So, let the influence from the walls, floor, windows, etc. in different rooms—since they're small, or the phonometer will not turn until appear to be precisely and perfectly to accord with Eq. (28.5), he will believe enough that we can't believe or appreciate the law.

Now we run the generator and one hears the noise of signal. We find a strong test when the detector, A , is parallel to the generator. That point (Fig. 28-2). We find a certain amount of field also at any other point in the loop about A , a lot of noise, and so on, but no signal at A . On the other hand, when the generator is at B the field is zero. That is, right, because we found with that the field \propto rank be the acceleration of the q 's, or projected perpendicular to the line of sight. Therefore when we took them on C , the charge is moving toward and away from D , and there is no effect. So that's when the C and D in (28.5) there's no effect—the charge is not really moving or, secondly, the forces perpendicular to the q 's should be perpendicular to A and at the point of C and D , on (28.5) we put D at C but rotate it 90° , we would see no signal. And this is just what we find. The

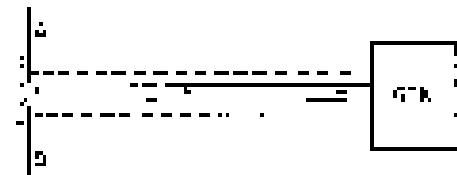

Fig. 28-1. A high-frequency signal source, or other charge up and down in two wires.

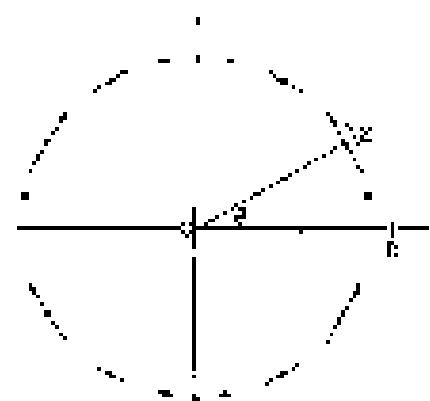

Fig. 28-2. The instantaneous electric field in a closed circuit of a localized, linearly accelerating charge.

electric field is added vertically, and so he is out of phase. When we move S_2 to some intermediate angle, we see the interference again because it is oriented as shown, because although E_2 is vertical, it does not produce a field that is simply parallel to E_1 . It is the projection of the wavefunction perpendicular to the direction of light that counts. This graph is very bad than Fig. 1, because of the projection effect.

28-4 Interference

Now we may ask what happens when we have two sources side by side a few centimeters apart (Fig. 28-3). The law is that the two sources should add their effects in phase. I mean both of the sources are connected to the same generator and are both moving up and down; the source S_1 has, so that the total electric field is the sum of the two fields twice as big as it was before.

Now comes another interesting possibility. Suppose we make the charges in S_1 and S_2 both oscillate up and down, but with the timing of S_2 so that they are 180° out of phase. Then the field produced by S_2 will be in the opposite direction and the field produced by S_1 will be in the opposite direction, but they cancel each other out so we should get no effect at point P . The phase of oscillation is easily adjustable by means of a plug which is carrying the signal to S_2 . By changing the length of the pipe we change the time it takes the signal to arrive at S_2 , and thus we change the phase of that oscillation. By adjusting it, it is easy to cancel indeed the place where there is no more signal left, in spite of the fact that both S_1 and S_2 are moving. The fact that they are both moving can be checked because, "over there out, we can see the motion of the orbit." So the two of them together can produce zero if everything is adjusted correctly.

Now, it is very interesting to show this. We add on all the new fields in the vector addition. We have just checked it for up and down motion, but let's check something else different. First, we restore S_1 to C ; S_2 is in the atmosphere; that is, they are again moving together. But now we turn S_2 through 90°, as shown in Fig. 28-4. Now we should know at point P the sum of two oscillations, one of which is vertical and the other horizontal. The electric field is the vector sum of these two in-phase signals. They are both moving at the same time and go up and zero together, the total field should then be equal to 90°. If you turn S_2 by 90°, maximum value, it should be at about 15°, and not vertical. And if we turn it at right angles to that direction, we should get zero, which is easy to measure. Indeed we observe just such behavior!

Now, how about the "numerical"? How can we determine that? But the signal is constant! We could, with a great deal of equipment, measure the time at which it arrives, but there is another, very simple way. Referring again to Fig. 28-1, suppose that S_1 and S_2 are in phase. They are both moving together, and they produce equal electric fields at point P . But suppose we go to a certain phase θ when S_2 is about 90° and far from S_1 . Then, in accordance with the principle that the acceleration should be balanced by a uniform velocity along θ , the coordinates are not equal; the signal cannot keep in phase. Thus it should be possible to find a position θ at which the distances of P from S_1 and S_2 differ by some amount Δ , in such a manner that there is no net signal. That is, the distance d is to be by distance light goes at one-half the speed of the generator. The time per oscillation, and find a point where the difference is greater by a whole cycle, that is, say, the signal from the last antenna reaches point P with a delay in time that is greater than each of the several periods by just the length of time it takes for the wave to travel to point S_2 once, and we have the condition. This produces at P a signal in phase again. At point S the signal is strong again.

This completes our discussion of the experimental verification of one of the fundamental features of Eq. (30.6). Of course we have not really checked the law according to the electric field strength, or the fact that there is also a magnetic field that goes along with the electric field. To do so would require rather sophisticated techniques that would hardly add much understanding to this point. In any case, we have checked these features that are the two greatest importance for our laser applications, and we shall come back to study some of the subtle properties of electric charges in waves next year.

Interference

29-1 Electromagnetic waves

In this chapter we shall discuss the subject of the passing of waves in electromagnetic fields. We have qualitatively demonstrated that there are transverse and longitudinal oscillation fields in wave motion, and our discussion is based on the field in mathematics, that is, not just qualitatively.

We have already physically analyzed the meaning of formula (28.8) more or less fully, so there are no difficulties to be made about it mathematically. In the first place, if a charge is moving along a straight line, the motion of varying amplitude, the field at some angle θ from the axis of the motion is in a direction normal to the line of sight and in the plane containing both the acceleration and the line of sight (Fig. 29-1). If the motion is uniform, then again the electric field can be computed:

$$\mathbf{E}(t) = -\frac{\omega a(t)}{4\pi\epsilon_0 c^2} \hat{x}(\theta) \sin \theta, \quad (29.1)$$

where $a(t) = a/\omega$ is the constant a at the time $t = \omega/2\pi$, called the retarded value of $a(t)$.

Now it would be interesting to know the nature of the field under different conditions. For this other is interesting, of course, is the behavior of $a(t)$, and to understand it we can take the simplest case, a positive point charge moving uniformly. At the first instant, let's suppose that we start in one position and see how the field there changes with time. The nature of the wave must again be described by field lines. Let us call each describes in space at a given instant. So what we want is a "snapshot" picture which tells us what the field is in different places. Of course it depends upon the acceleration of the charge. Suppose the charge is at rest. And at one particular instant, it was actually standing still, and it suddenly accelerated in some manner, as shown in Fig. 29-2, and then stopped. Then, a little bit later, we measure the field at a distance r ; see that we may expect the field will change, as shown in Fig. 29-3. At each point the field is determined by the acceleration of the charge at an earlier time, the antecedent time, using the delayed a . The field at t , therefore, depends on the retarded acceleration, $a(t)$, at an earlier time. So, in general, Fig. 29-3 is really, in effect, a "reversed" version of the wave equation, in that of course the field has to travel forward in time by a constant wave factor c , which we often take to be unity. This is really just symmetrizing the mathematical behavior of $a(t) = a/\omega$. Evidently if we add a little time to a , we get the same sort of $a(t) = a/\omega$ as we would have if we had only added a little distance, $a = a/2\pi$.

So what do we say if we add a little a to $a/2\pi$, or the retardation $a/\sqrt{1 + a^2/2\pi^2}$? Larger value by exactly a units? $a = a/2\pi$? That is, six times greater? The answer is no, because we are not concerned from the source. That is the lesson why we say only light is passing; it is not true. This is equivalent to saying that the field is delayed, or to saying that the electric field is moving in space as time goes on.

An interesting special case is that where the charge q is moving to and from in an oscillatory manner. The case which we will consider initially is the z -oscillate, we cut in when the displacement and velocity were equal to zero at time $t = \pi/2\omega$, in magnitude. The oscillation time is π/ω . Then the acceleration is

$$a = \omega^2 q \cos \omega t = \omega q \sin \omega t. \quad (29.2)$$

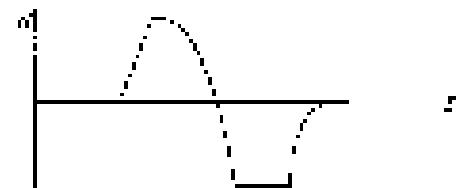

Fig. 29-2. The acceleration of a point charge as a function of time.

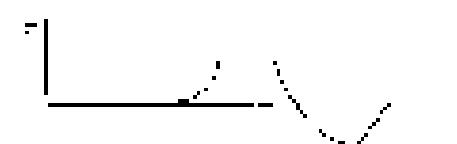

Fig. 29-3. The electric field E as a function of position x at a fixed time. (The y coordinate is ignored.)

where a_0 is the maximum acceleration, $-a^2/k_0$. Putting this formula into (29-1) we find

$$E = -\frac{q^2 a_0}{2 k_0} \sin^2(\theta/2) \cos(\theta/2) = E_0 \sin^2(\theta/2) \quad (29-2)$$

Now, ignoring the angle θ and the constant factors, let us see what just happens. This is a function of position or as a function of time.

29-2 Energy of radiation

First of all, at any particular moment or at one particular place, the strength of the field varies inversely as the distance r , as we have found previously. Now we must point out that the representation of a wave, or the energy effect due to such an effect is "field" can't be *any* proportional to the square of the field, because if it were so, we have some kind of a charge or a cavity or in the steering field, then as we let the field go on, the walls of it makes it move. In this is a linear oscillation. The acceleration, velocity, and displacement, produced by the electric field acting on the charge has all proportionality to the field. So the kinetic energy which is developed in the charge is proportional to the square of the field. So we shall take it that the charge that a field can induce is a quantity proportional somehow to the square of the field.

This means that the energy that the source can deliver decreases as we get further away; it goes down as the square of the distance. But that has a very important preconception if we want to pick up the energy we could from the wave at a certain time at a distance r (Fig. 29-4), and we do the same at another distance r' , we find that the amount of energy we can pick up is proportional to the square inversely as the source of it, i.e., the area of the surface intersected by the cone goes like this as the square of r . So the energy that we can take up while we are within a given spherical angle is the same, no matter how far away we are. In particular, the total energy that we could take out of the whole wave by picking up absorbing oscillators all around is a certain fixed amount. So the fact that the amplitude of E varies as $1/r$ is the same as saying that there is an energy flux which is now $-J_0$, an average value over an area, spreading over a greater and greater effective area. This is not exactly why a charge has oscillated. It has lost some energy which it can never recover; the energy keeps going, but has and has energy within a dimension. So if we are far enough away than our basic approximation is good enough, the charge is still carrying the energy which has been, say, radiated away. Of course the energy still exists somewhere, and is available to be picked up by other systems. We shall study this energy more together in Chapter 32.

Let us now consider more carefully how the wave (29-3) varies as a function of time at a given place, and as a function of position at a given time. Again, we ignore the $1/r$ variation and the constants.

29-3 Sinusoidal waves

First let us fix the position x , and watch the field as a function of time. It is noteworthy at the angular frequency ω . The angular frequency ω can be defined as the rate of change of phase (radians per second). We have already called such a thing, so it should be quite familiar to us by now. The period is the time needed for one oscillation, one complete cycle, and we have worked that out too; it is $2\pi/\omega$. Because a full one period is one cycle of the oscillation.

Now we introduce a new quantity which is used largely in the physics. This has to do with the opposite situation, in which we instead look at the wave as a function of distance x . If you are outside the field, and look inside the wave, (29-3) is the best story. That is, since from Eq. (29-3) we are ignoring the $1/r$ effect, if we change the position x , the intensity with x , we can define a quantity called the phase, represented by kx . This is defined as the rate of change of phase and distance (radians per meter). That is, as we move in space at a fixed time, the phase changes.

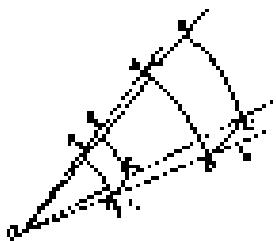

Fig. 29-4. The energy flowing within the zone $OABCD$ is independent of the distance r at which it is measured.

There is another way to state the meaning of the period, and we might say it in the present in space. But it is usually easier to remember, synthesized as it is, to associate both to the distance occupied by one complete cycle. It is easy to see that, for the wavelength λ , the time t is λ/v , because k times t would be the number of waves at that location, multiplying the speed, being the product of the rate of change of the waves per meter, gives the number of cycles, and $k\lambda = v$, and $v = \lambda f$, so $t = \lambda/v = \lambda/f$. It is equally easy to see that $\lambda = v/t$.

Now we turn to a truly wave picture of a radio relationship between the frequency and the wavelength, but the above definition of wave length is really quite general. Let us assume enough and the frequency may now be related to the same wave at other physical circumstances. However, in our circumstance, the rate of change of phase with distance is easily determined, because if we call $\phi = \omega t + \delta\phi$ the phase, and differentiate (physically) with respect to distance x , the rate of change is $d\phi/dx = k$:

$$\left| \frac{d\phi}{dx} \right| = k = \frac{\omega}{v}. \quad (20.4)$$

This is a more wave-like representation than in time, such as

$\nu = 6.7 \times 10^{14}$ Hz	$\lambda = 4.5 \times 10^{-14}$ m
$\nu = 10^9$ Hz	$\lambda = 3 \times 10^{-9}$ m

Why is λ decreasing so much? It is only long, of course, because we still did not wait for one period but took the waves travelling at the speed v . At $\nu = 10^9$ Hz, it takes about 30 cm of distance before there has been just one wavelength.

In a physics sense the entire concept of light ν is not necessarily related to time in simple way. If we call the distance along the direction of the wave front moving from one point to another λ , and if we consider the frequency ν will be given in general as $\nu = c/\lambda$.

Now that we have introduced the idea of wavelength, let me say something you may already know consciousness in which ν is a key factor. In fact, we recall that the field is made up of several waves, one of which carries universally as a carrier wave which is inversely proportional to the wavelength. This would be one such wave, and it dominates the field near the source, but the two important ones, and the other parts are also dropped away. Naturally, the answer is "if we do the averaging away," because some which carry inversely to the square ultimately become negligible compared with one. However, this being "far enough," it is almost as qualitatively, but the other factors are of order λ/c smaller than the first term. Thus, so long as we are beyond a few wavelengths, ν is a good approximation to the field. Sometimes one might say that a few wavelengths is called the "width of the field."

20-4. Two-dipole radiation

Now let us discuss the most basic method for calculating the effects of two dipoles in space. We find the net field at a given point. This is very easy in the two cases that we considered at the previous chapter. We shall first consider the effects qualitatively, and then quantitatively. To start off the simplest case, where the two dipoles are situated with their centers in the same horizontal plane as the center of the line of the dipole a vertical.

Figure 20-5(a) represents the situation of two such dipoles, a , and b , perpendicular to my page and with a wavelength apart in a 90° position, and are oscillating together at the same rate, which we will call ω . Now we would like to know the intensity of the radiation in various directions. This is relatively easy, since the amount of energy radiated need comes positive per second, which is proportional to the square of the field, according to $E = B/c$. So far I look at, when we want to know how bright the light is, is the square of the electric field, not the electric field itself. (The electric field tells the strength of the field but does

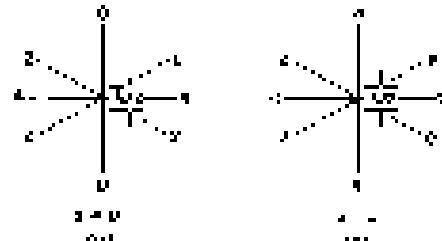

Fig. 20-5. (Left) Intensity in surface directions from two dipole oscillators, one-half wavelength apart. Left: a dipole $A = A_0$. Right: two off-period out-of-phase $B = B_0$.

conductivity change, but the "mean" or energy that is going past, in watts per square meter, is proportional to the square of the field. We shall derive the constant of proportionality in the next chapter.) If we look at the array from the N-S side, both oscillators are phase-shifted $\pi/2$ radians, so the electric field is zero as strong as it would be from a single one-tube. Therefore the intensity is zero there, or twice as it would be if there were only one oscillator. (The numbers in Fig. 29-5 represent how strong the intensity would be in this case, compared with what it would be if there were only one dipole oscillating of unit strength.) Now, if we turn the N-S direction along the line of the oscillators, since they are half a wavelength apart, the effect of one oscillator turns out to be just of phase by exactly half an oscillation from the other, and the total has again odd or zero. At a certain particular intermediate angle (in fact, at 45°) the intensity is 2, and it goes up to 4, 5, 6, and so on. We have to learn how to find it now, when the other angles, 1, 3, & 4 represent of setting two oscillators with different phases.

Let us quickly look at some other cases of interest. Suppose the oscillators are again made $\lambda/2$ wavelength apart, but the phase of one is set back behind the center of its oscillation (Fig. 29-6). In the W direction the intensity is now zero, because one oscillator is "pushing" when the other one is "pulling." But in the S direction the signal from the near antenna lags a certain time, and that of the other comes half a period later. But the latter has already had $\lambda/2$ a prior setting, so it is strong, and therefore it is now exactly in step with the first one, and the intensity in this direction is 4 units. The intensity in the direction at 90° is still 2, as we can prove later.

But we come to an interesting case which shows up a possibly useful feature. Let us remark that one of the reasons the phase relations of oscillators are interesting is for learning radio transmitters. For instance, if we build an antenna system and want to send a radio signal, say to Hawaii, where the antennas are as in Fig. 29-5(a) and we broadcast with our two antennas in phase, Hawaii Hawaii is to the west of us. Then we decide that when you are so far away to broadcast toward Alaska's Canada. Since Canada is to the west, all we have to do is to reverse the phase of one of our antennas, and we can broadcast to the north so we can build an entire system with minimum interference. This is one of the simplest situations; we can send the beams in all directions and send most of the power in the direction in which we wish to transmit, without ever moving the antenna. In lots of the practical cases, however, while we are broadcasting toward Alaska we are moving a lot of power to Texas, Texas, and it would be interesting to ask whether it is possible to send it in only one direction. At least right we might think that, with a pair of antennas of this nature the result is always going to be symmetric. So let us consider a case that is more or less symmetrical, to show the possible variety.

If the antennas are separated by one-quarter wavelength, and if the N one is reinforced behind the $\lambda/2$ one at time, then what happens (Fig. 29-6)? In the W direction was $\pi/2$, so we will see "zero." In the S direction we get zero here for the signal from S because it is "out of time"; but the $\lambda/4$ comes 90° later in, and, being $\lambda/2$, adds 90° behind it. Its beat in phase, therefore it arrives, although $\lambda/2$ out of phase, and there is no effect. On the other hand, in the E direction, the N signal arrives earlier than the S signal by $\lambda/2$ total, so because it is a quarter-wavelength close. But a $\lambda/2$ is set so that it is really in 90° behind in time, that is, one-quarter-wave delay difference, and therefore the two signals begin negative in phase, adding the field strengths twice as large, and the energy four times as great.

Thus, by using some cleverness in spacing and phasing one antenna, we can send the power all in one direction. This is a directional over a great range of angles. But we arrange it so that it is broadest in more sharply in a particular direction. Let us consider the case of the two antennas which we are sending to Texas, but it is spread over quite a wide beam. In other words, if we are still getting half the intensity, we are wasting the power. Can we do better? Can this? Let us take a situation in which the separation is $\lambda/4$ - $\lambda/2$ in Fig. 29-6.

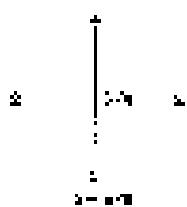

Fig. 29-6. A paired dipole antenna during maximum power in one direction.

29.7), which is more or less comparable to the situation in which we expect that in the $\theta = 90^\circ$ direction, with separation of several wavelengths, there is "almost no effect of a wavelength". Here the picture is quite different.

If the two oscillators are wave lengths apart, we take the important case to have $\theta = 90^\circ$, we see that in the $E \parallel \theta$ direction, they are in phase, and we get a strong intensity, four times what we would get if one of them were there alone. On the other hand, at a very small angle away, the intensities are different by 10% and the intensity is zero. To be accurate, if we draw a line from one oscillator to a distant point and the difference of the two distances is $\lambda/2$, the far oscillation, but they are out of phase, so the distance does not matter. (The figure is not drawn to scale; it is only a rough sketch.) This means that we do indeed have a very good reason in the question we asked, because if we put more than a fifth of a wavelength off the center of the $E \parallel \theta$ direction, because if we put more than a fifth of a wavelength off the center of the $E \parallel \theta$ direction, the intensity would drop to zero. This is why it is better to have the two oscillators as far apart as possible. We will see in the next chapter that this is what happens in the $E \parallel \theta$ direction, and the intensity is zero. This is what we learned in Chapter 28.

Now how can we arrange to get rid of these extra maxima in "phase loss" as you called? We could get rid of the unwanted $E \parallel \theta$ direction in a fairly clever way. Suppose we want to produce a certain ratio of strengths between the two that we already have. That is, the outside ones are at 100, and that between them, say, 10, so we have produced an antenna, and we have them all in phase. These are now six antennas, and if we add up all the intensity of the $E \parallel \theta$ direction, it would not be much higher with six antennas than with one. The field would be six times and the intensity thirty-six times stronger (the square of the field). We get a unity of intensity in that direction. Now if we look at neighboring pairs, we find a wave length, say λ , but if we put it there, we have to move to get a "in-phase pair" we get a much smaller "bump" now—let us try to see why.

The reason is that although we might expect to get a "bump" when the distance is a wave length, it is not then dipole 1 and dipole 2 in phase, and they are in phase, and so operating in trying to get extra strength in that direction. But numbers 3 and 4 are roughly $1/\sqrt{2}$ wavelength apart with 1 and 2, and 5 and 6 roughly $1/\sqrt{2}$ pushed together, and 6 just has the tail, but is opposite phases. Therefore there is very little in every in this direction—but there is something. It does not balance exactly. The kind of thing keeps on increasing, we get very nice humps, and we have a broad beam in the direction where we expect it. Then this pattern is not the same as something else we chosen; namely, since the distance between successive dipoles is 2λ , it is possible to find a range where the distance is between two successive dipoles, say, one wave length, so that the effects from all of them are in phase again. Each one is delayed relative to the next one by $2\pi/2\lambda$, so that all come back in phase, and we have another strong beam in that direction. It is very evident, this pattern is not—it is possible to put the dipoles closer than one wave length apart. If we put it more antennae, closer than one wavelength apart than the same happens. So the lesson is this can happen at certain angles, if the spacing is big enough and we change it, so very interesting are these phenomena in other applications—not radio broadcasting, but in diffraction gratings.

29.5 The mathematics of interference

Now we have finished our analysis of the problem of dipole sources out-of-phase, and we must learn how to analyze them quantitatively. To find the effect of a source's being at a certain angle in the most general case, where the two oscillators have some arbitrary relative phase ϕ in one module and the strengths A_1 and A_2 are not equal, we find that we have two beams having the same frequency, but with different phases. It is very easy to find this phase difference, it is once again $2\pi/2\lambda$ due to the difference in distance, and the difference in the phase of the two oscillators. Mathematically, we have to find the sum of two waves: $A_1 + A_2 \cos(\omega t + \phi_1) + A_2 \cos(\omega t + \phi_2)$. Now let us do it:

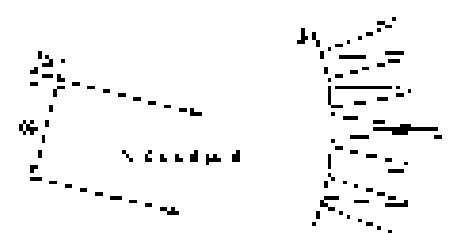

Fig. 29-7. The intensity pattern for two dipoles separated by 10λ .

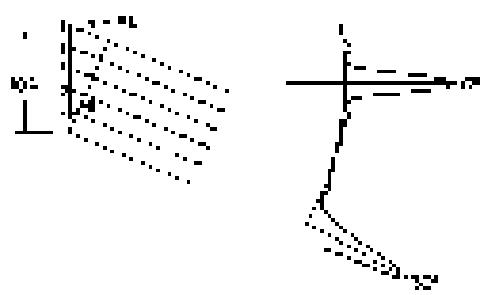

Fig. 29-8. A single dipole antenna in out-of-phase and in-phase intensity patterns.

It is really very easy, and we assume that we already know how to do it. However, we shall outline the procedure in some detail. First, we say if we are given two oscillators and know enough about ceses and laws, it would work it out. If we know two vectors \mathbf{A}_1 and \mathbf{A}_2 , amplitude let us say may be A_1 and A_2 , the phase ϕ_1 and ϕ_2 , let us say may be $\omega t + \phi_1$ and $\omega t + \phi_2$. In such circumstances, for example we could use this the geometrical method of solving the problem, we have

$$R = A_1 \cos(\omega t + \phi_1) + A_2 \cos(\omega t + \phi_2). \quad (29.1)$$

Once, in our trigonometry class, we may have learned the rule that

$$\cos A - \cos B = 2 \cos((A + B)/2) \cos((A - B)/2). \quad (29.2)$$

If we know that, then we can immediately write R as

$$R = A_1 \cos(\omega t + \phi_1) + A_2 \cos(\omega t + \phi_2) = R_0 \cos(\omega t + \phi_0). \quad (29.3)$$

Now first note we have an oscillatory wave with a new phase and a new amplitude. In general, the result will be two oscillators wave with a new amplitude A_0 , which we may call the resultant amplitude, oscillating at the same frequency but with a phase difference ϕ_0 , called the resultant phase. In view of this, our particular case has the following results that the resultant amplitude is

$$A_0 = 2A_1 \cos(\phi_1 - \phi_2), \quad (29.4)$$

and the resultant phase is the average of the two phases, and we have completely solved our problem.

Now suppose that we cannot remember that the sum of 180 degrees is twice the sum of half the sum times the cosine of all the differences. Then we may use another method of analysis which is more geometrical. Any cosine function or sine can be visualized as the harmonic projection of a rotating vector. Suppose there was a vector \mathbf{A}_1 of length A_1 rotating with time, at that angle with the horizontal axis $\omega t = \phi_1$. We shall leave out the unit of time minute, and see that it makes no difference. Suppose that we take a snapshot at the time $t = 0$, although, in fact, the picture is moving at angular velocity ω (Fig. 29-9). The projection of \mathbf{A}_1 along the horizontal axis is precisely $A_1 \cos(\omega t + \phi_1)$. Now at $t = 0$, the second wave would be represented by another vector, \mathbf{A}_2 , of length A_2 and at an angle ϕ_2 , also rotating. They are both rotating with the same angular velocity ω , and therefore the relative positions of the two are fixed. The two just rotate like a rigid body. The horizontal projection of \mathbf{A}_2 is $A_2 \cos(\omega t + \phi_2)$. But we know from the theory of waves that if we add the two vectors in the ordinary way, by the parallelogram rule, and draw the resultant vector \mathbf{A}_0 , the resultant phase of the resultant is the sum of the separate phases of the other two waves. This solves our problem. It is easy to check that the gives the correct result for the special case we treated above, where $A_1 = A_2 = A$. In this case, we see from Fig. 29-9 that the angle between \mathbf{A}_1 and \mathbf{A}_2 and makes an angle $\phi_1 - \phi_2$ with each. The vector we see that $A_0 = 2A_1 \cos(\phi_1 - \phi_2)$, as before. Also, as we see from the a angle, the phase of \mathbf{A}_0 , as it goes around, is the average angle of \mathbf{A}_1 and \mathbf{A}_2 when the two amplitudes are equal. Clearly, we can do the same for the case where the amplitudes are different, just as easily. We can still that the geometrical way of solving the problem.

There is another way of solving the problem, and that is the analytical way. That is, instead of having actually to draw a picture like Fig. 29-8, we can make something done which is to draw this vector in pictures instead of drawing the vectors, we write a complex number to represent each of the vectors. The real parts of the complex numbers are the actual physical quantities. So if $\mathbf{A}_1 = A_1 \cos(\omega t + \phi_1)$ we can write it in the form $A_1 e^{i(\omega t + \phi_1)}$ (just as well as $A_1 \cos(\omega t + \phi_1)$) and $A_2 e^{i(\omega t + \phi_2)}$. Now we can add the two:

$$R = A_1 e^{i(\omega t + \phi_1)} + A_2 e^{i(\omega t + \phi_2)} = (A_1 \cos \theta_1 + A_2 \cos \theta_2) + i(A_1 \sin \theta_1 + A_2 \sin \theta_2). \quad (29.5)$$

or

$$R = A_0 e^{i(\omega t + \phi_0)} = A_0 \cos \theta_0 + iA_0 \sin \theta_0. \quad (29.6)$$

The solves the problem that we wanted to solve, because it represents a resultant as a complex number of magnitude A_2 and phase φ_2 .

To see how this worked out, let me find the amplitude A_2 which is the "length" of \vec{A} . To get the "length" of a complex quantity, we always multiply its quantity by its conjugate (using \ast , which gives the length squared). The complex conjugate is the same expression, but with the sign of one i 's reversed. Thus we have

$$A_2^2 = (A_1 e^{i\varphi_1} + A_2 e^{i\varphi_2}) (A_1 e^{-i\varphi_1} + A_2 e^{-i\varphi_2}). \quad (29.15)$$

In multiplying this out, we get $A_1^2 + A_2^2$ (here the i 's cancel), and for the cross terms we have

$$A_1 A_2 (e^{i\varphi_1 - i\varphi_2} + e^{i\varphi_2 - i\varphi_1}).$$

Now

$$e^{i\varphi} + e^{-i\varphi} = \cos \varphi + i \sin \varphi - \cos \varphi - i \sin \varphi = 0.$$

That is to say, $e^{i\varphi} + e^{-i\varphi} = 2 \cos \varphi$. Our final result is therefore

$$A_2^2 = A_1^2 + A_2^2 + 2 A_1 A_2 \cos(\varphi_2 - \varphi_1). \quad (29.16)$$

As we saw, this agrees with the length of \vec{A}_2 in Eq. 29-9, using the rules of trigonometry.

This the sum of the two effects has the intensity A_2^2 we would get with one of them alone, plus the intensity A_1^2 we would get with the other one alone, plus a correction. The correction we call the interference effect. It is really only the difference we were given directly by adding the intensities, and who's usually interested. We can't interference whether it is positive or negative. Interference in ordinary language usually suggests opposition or hindrance, but in physics we often do not consider going the way it was originally designed! If the interference term is positive, we call that case constructive interference, because enough intensity seems to anybody other than a physicist! The opposite case is called destructive interference.

Now let us see how to apply our general formula (29.16) for the case of two oscillators to the specific situations which we have discussed qualitatively. To apply the general formula, it is only necessary to find the phase difference $\varphi_2 - \varphi_1$ exists between the signals arriving at a given point. (It depends only on the source difference, of course, and not on the phase itself.) So let us consider the case where the two oscillators, of equal amplitude, are separated by some distance d and have an increasing velocity phase ωt . (When ωt is at phase zero, the phase of the other is $\pi/2$). Then we ask what the phase will be in some time with distance d from the E-W line. [Note: the ωt is not the same θ as appears in (29.1). We are doing *vector* using the rectangular symbol, here θ ; or the semi-circular symbol ϑ (Fig. 29-10);? The phase relation is $\theta = \omega t$ and we know that the difference in distance from it to the two oscillators is d on θ so that the phase difference is $\omega d / \lambda$. The wave velocity is c on θ so that the phase difference is $\omega d / c$. The number of wavelengths is d/λ , so that the phase difference is $2\pi(d/\lambda)$. Those who are more sophisticated might want to multiply the wave number k , which is the rate of change of phase with distance, by d/λ since k is nearly the same.] The phase difference due to the distance difference is thus $2\pi(d/\lambda)\sin(\omega t)$, but, due to the timing of the oscillators, there is an additional phase α . So the phase difference at any instant will be

$$\varphi_2 = \varphi_1 - \alpha + 2\pi(d/\lambda)\sin(\omega t). \quad (29.17)$$

Let's look at some cases. Thus if, we have to do, we substitute this expression into (29.16) for the case $A_1 = A_2$, and we can calculate all the various cases of two sources of equal intensity.

Now let us see what happens in our various cases. For lesson #6, for example, the intensity is 2 at 20° in Fig. 29-5 is the following. The two vectors are at $\omega t = 10^\circ$, down $\sqrt{3}/2$, down $1/2$. Their sum $= A_1 = \sqrt{3}/2$ at 20° , and so the interference term is zero. (We are adding two vectors at 90° .) The result is the hypotenuse of a 45° right-angle triangle, where $1/\sqrt{2}$ is the unit amplitude A_1 going in, we get with the intensity of one just along there. All the other cases can be worked out in this same way.

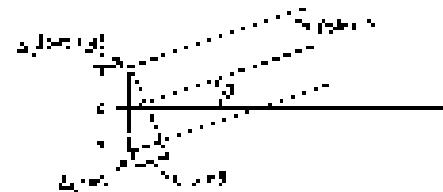

Fig. 29-10. Two oscillators of equal amplitude, with a phase difference α between them.

Diffraction

30-1 The resultant amplitude due to *n* equal oscillators

This chapter is a direct continuation of the previous one, although the name has been changed from *Interference* to *Diffraction*. No one has ever been able to define the difference between interference and diffraction satisfactorily. It is just a question of usage, and there is no specific, important physical difference between them. The fact we can do, roughly speaking, is to say that when there are only a few sources, say two, interfering, then the result is usually called interference, but if there is a large number of them, it seems that the word diffraction is more often used. So, we shall not worry about whether it is interference or diffraction, but continue directly from where we left off in the middle of the subject in the last chapter.

Thus we shall now discuss the situation where there are *n* equally spaced oscillators, all of equal amplitude but different from one another in phase, either because they are driven differently in phase, or because we are looking at them at an angle such that there is a difference in time delay. For one reason or another, we have to add something like this:

$$R = A[\cos(\omega t + \phi_0) + \cos(\omega t - \phi_1) + \cos(\omega t - 2\phi_2) + \cdots + \cos(\omega t + (\pi - 1)\phi_n)], \quad (30.1)$$

where ϕ is the phase difference between our oscillator and the last one as seen in a $\phi/2$ later direction. Specifically, $\phi = \alpha - 2\pi d \sin \theta/\lambda$. Now we must add all the terms together. We shall do this geometrically. The first one is of length A , and it has zero phase. The next is also of length A and it has a phase equal to ϕ . The last one is again of length A and it has a phase equal to 2ϕ , and so on. So we are evidently going around an equiangular polygon with n sides (Fig. 30-1).

Now the vertices, of course, all lie on a circle, and we can find the net amplitude most easily if we find the radius of that circle. Suppose that Q is the center of the circle. Then we know that the angle OQS is just a phase angle ϕ . (This is because the radius QS bears the same geometrical relation to A_2 as QO bears to A , so they form an angle ϕ between them.) Therefore the radius r must be such that $A = 2r \sin \phi/2$, which fixes r . But the large angle OQT is equal to $\pi\phi$, and we find that $A_N = 2r \sin \pi\phi/2$. Combining these two results to eliminate r , we get

$$A_N = A \frac{\sin \pi\phi/2}{\sin \phi/2}. \quad (30.2)$$

The resultant intensity is thus

$$I = I_0 \frac{\sin^2 \pi\phi/2}{\sin^2 \phi/2}. \quad (30.3)$$

Now let us examine this expression and study some of its consequences. In the first place, we can check it for $n = 1$. It checks: $I = I_0$. Next, we check it for $n = 2$: writing $\sin \phi = 2 \sin \pi/2 \cos \phi/2$, we find that $A_N = 2A \cos \phi/2$, which agrees with (20.12).

Now the idea that led us to consider the addition of several sources was that we might get a much stronger intensity in one direction than in another; that the nearby maxima which would have been present if there were only two sources will have gone down in strength. In order to see this effect, we plot the curve that results from (30.3), taking π to be extremely large and plotting the cosine term

$\phi = 0$. In the first place, if ϕ is exactly 0, we have 0/0, but if ϕ is infinitesimal, the ratio of the two sines squared is simply n^2 , since the sine and the angle are approximately equal. Thus the intensity of the maximum of the curve is equal to n^2 times the intensity of one oscillator. That is easy to see, because if they are all in phase, then the little vectors have no relative angle and all of them adding so the amplitude is n times, and the intensity n^2 times stronger.

As the phase ϕ increases, the size of the two sines begins to fall off, and the first time it reaches zero is when $n\phi/2 = \pi$, because $\sin \pi = 0$. In other words, $\phi = 2\pi/n$ corresponds to the first minimum in the curve (Fig. 20-2). In view of what is happening with the arrows in Fig. 20-1, the first minimum occurs when all the arrows come back to the starting point; that means that the total sum of vector angle in all the arrows, the total phase difference between the first and last oscillator, must be 2π to go up the loop.

Now we go to the next maximum, and we want to see that it's really much smaller than the first one, as we had hoped. We shall not go precisely to the maximum position, because both the numerator and the denominator of (20.3) are zero, and $\sin n\phi/2$ varies quite slowly compared with $\sin n\phi/2$ when ϕ is large, so $\sin n\phi/2 = 1$ we are very close to the maximum. The next maximum of $\sin^2 n\phi/2$ comes at $n\phi/2 = 3\pi/2$, or $\phi = 3\pi/2n$. This corresponds to the arrows having traversed the circle one and $1/2$ full turns. On putting $\phi = 3\pi/2n$ into the formula to find the size of the maximum, we find that $n^2/5\pi/2 = 1$ in the numerator (which is why we picked this angle), and in the denominator we have $\sin^2 3\pi/2n$. Now if n is sufficiently large, then this angle is very small and the sine is equal to the angle; so for all practical purposes, we can put $\sin 3\pi/2n = 3\pi/2n$. Thus we find that the intensity at this maximum is $I = I_0(4\pi^2/9\pi^2)$. But $4\pi^2/9\pi^2$ was the maximum intensity, and so we have $4/9\pi^2$ times the maximum intensity, which is about 0.017, less than 5 percent of the maximum intensity. Of course, but we're decreasing intensities farther out. So we have a very sharp central maximum with very weak subsidiary maxima on the sides.

It is possible to prove that the area of the whole curve, including all the little bumps, is equal to $2\pi n I_0$, or twice the area of the dotted rectangle in Fig. 20-2.

Now let us consider further how we may apply Eq. (20.3) in different circumstances, and try to understand what's happening. Let us consider our sources to be all on a line, as drawn in Fig. 20-3. These are n of them, all spaced by a distance a , and we shall suppose that the intrinsic relative phase, due to the next, is θ . Then if we are observing in a given direction θ from the normal, there is an additional phase $2\pi d \sin \theta/a$ because of the time delay between each successive row, which we talked about before. Thus

$$\begin{aligned}\phi &= \phi + 2\pi d \sin \theta/a \\ &= \phi + 2\pi d \sin \theta\end{aligned}\quad (20.4)$$

First, we shall take the case $\theta = 0$. That is, all oscillators are in phase, and we want to know what the intensity is as a function of the angle θ . In order to find out, we merely have to put $\phi = 2\pi d \sin \theta$ into formula (20.3) and see what happens. In the first place, there is a maximum at $\theta = \phi = 0$. That means that when all the oscillators are in phase there is a strong intensity in the direction $\theta = 0$. On the other hand, an interesting question is, where is the first minimum? That occurs when $\theta = 2\pi/n$. In other words, when $2\pi d \sin \theta/a = 2\pi/n$, we get the first minimum of the curve. If we get rid of the 2π 's so we can look at it a little better, it says that

$$nd \sin \theta = \lambda. \quad (20.5)$$

Now let us understand physically why we get a minimum at that position. nd is the total length l of the array. Referring to Fig. 20-3, we see that $nd \sin \theta = l \sin \theta = l - \theta$. What (20.5) says is that when θ is equal to our wavelength, we get a minimum. Now why do we get a minimum when $\theta = \lambda$? Because the contributions of the various oscillators are then uniformly distributed in phase from 20-2

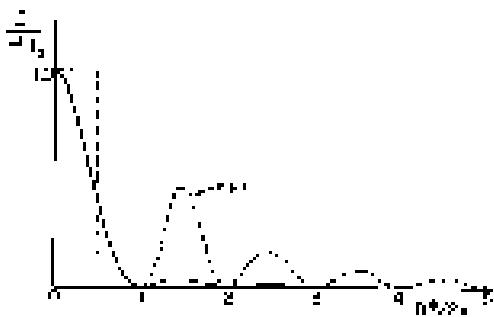

Fig. 20-2. The intensity as a function of phase angle for a large number of oscillators of equal strength.

Fig. 20-3. A linear array of n equal oscillators, driven with phases $\omega_t = \omega$.

AMF. The arrows (Fig. 30-1) are going around a whole circle—we are adding equal vectors in all directions, and each π sum is zero. So when we have an angle such that $A = \lambda$, we get a minimum. That is the first minimum.

There is another important feature about formula (30.3), which is that if the angle ϕ is increased by any multiple of 2π , it makes no difference to the formula. So we will get other strong minima at $\phi = 3\pi, 4\pi, 6\pi$, and so forth. Near such of these great maxima the pattern of Fig. 30-2 is repeated. We may ask ourselves, what is the geometrical circumstance that leads to these other great maxima? The condition is that $\phi = 2m\pi$, where m is any integer. That is, $2\pi d \sin \theta/2 = 2m\pi$. Dividing by 2π , we see that

$$d \sin \theta = m\lambda. \quad (30.6)$$

This looks like the other formula, (30.5). No, that formula was $d \sin \theta = \lambda$. The difference is that here we have to look at the individual sources, just when we say $d \sin \theta = m\lambda$, that means that we have an angle θ such that $\delta = m\lambda$. In other words, each source is now contributing a certain number, and successive rays are out of phase by a whole multiple of 360° , and therefore are contributing in phase, because out of phase by 360° is the same as being in phase. So they all contribute in phase and produce just as good a maximum as the one for $m = 0$ that we discussed before. The subsidiary beams, the whole shape of the pattern, is just like the one near $\phi = 0$, with exactly the same radiation envelope, etc. Thus such an array will send beams in various directions—each beam having a strong central maximum and a certain number of weak “side lobes.” The various strong beams are referred to as the zero-order beam, the first-order beam, etc., according to the value of m . m is called the order of the beam.

We call attention to the fact that if d is less than λ , Eq. (30.6) can have no solution except $m = 0$, so that if the spacing is too small there is only one possible beam, the zero-order one centered at $\theta = 0$. (Of course, there is also a beam in the opposite direction.) In order to get subsidiary exact maxima, we must have the spacing d of the array greater than one wavelength.

30-2. The diffraction grating

In technical work with antennas and wires it is possible to arrange that all the phases of the little oscillators, or antennas, are equal. The question is whether and how we can do a similar thing with light. We cannot at the present time literally make little optical-frequency radio stations and hook them up with infinitesimal wires and drive them all with a given phase. But there is a very easy way to do what amounts to the same thing.

Suppose that we had a lot of parallel wires, equally spaced at a spacing d , and a radio-frequency source very far away, practically at infinity, which is generating an electric field which arrives at each one of the wires at the same phase (it is so far away that the time delay is the same for all of the wires). (One can work out cases with curved arrays, but let us take a plane one.) Then the external electric field will drive the electrons up and down in each wire. That is, the field which is coming from the original source will shake the electrons up and down, and in moving, these represent new generators. This phenomenon is called scattering; a light wave from some source can induce a motion of the electrons in a piece of material, and these motions generate their own waves. Therefore all that is necessary is to set up a lot of wires, equally spaced, drive them with a radio-frequency source far away, and we have the situation (let us wish, without a whole lot of special wiring). If the incidence is normal, the phases will be equal, and we will get exactly the circumstances we have been discussing. Therefore, if the wire spacing is greater than the wavelength, we will get a strong intensity of scattering in the normal direction, and in certain other directions given by (30.6).

This can also be done with light! Instead of wires, we use a flat piece of glass and make notches in it such that each of the notches scatters a little differently than the rest of the glass. If we then shine light on the glass, each one of the notches

will represent a source, and if we space the lines very finely, but not closer than a wavelength (which is technically almost impossible anyway), then we would expect a rather curious phenomenon: the light will only pass straight through, but there will also be a strong beam at a finite angle, depending on the spacing of the notches! Such objects have actually been made and are in common use—they are called *diffractive gratings*.

In one of its forms, a diffractive grating consists of notching but a plane glass sheet, transparent and colorless, with scratches on it. There are often several hundred scratches to the millimeter, very carefully arranged so as to be equally spaced. The effect of such a grating can be seen by arranging a projector so as to throw a narrow, vertical line of light (the image of a slit) onto a screen. When we put the grating close to the beam, with its scratches vertical, we see that the line is still there but, in addition, on each side we have another strong patch of light which is colored. This, of course, is the slit image spread out over a wide angular range, because the angle θ_{m} (30.6°) depends upon λ , and lights of different colors, as we know, correspond to different frequencies, and therefore different wavelengths. The longest visible wavelength is red, and since $d \sin \theta = \lambda$, that requires a larger θ . And we do, in fact, find that red is at a greater angle from the central image. There should also be a beam on the other side, and indeed we see one on the screen. There, though, be another solution of (30.6) when $m = -1$. We do see that there is something vaguely there—very weak—and there are even other beams beyond.

We have just argued that all these beams ought to be of the same strength, but we see that they actually are not and, in fact, not even the first ones on the right and left are equal! The reason is that the grating has been carefully built up to do just this. How? If the grating consists of very fine notches, uniformly wide, spaced evenly, then all the intensities would indeed be equal. But, as a matter of fact, although we have taken the simplest case, we could also have considered an array of pairs of antennas, in which each member of the pair has a certain strength and some relative phase. In this case, it is possible to get intensities which are different in the different orders. A grating is often made with little "sawtooth" cuts instead of little symmetrical notches. By carefully arranging the "sawtooths," more light may be sent into one particular order of spectrum than into the others. In a practical grating, we would like to have as much light as possible in one of the orders. This may seem a complicated point to bring in, but it is a very clever thing to do, because it makes the grating more useful.

So far, we have taken the case where all the phases of the sources are equal. But we may have a formula for ϕ when the phases differ from one to the next by an angle α . That requires adding up our intensities with a slight phase shift between each one. Can we do that with light? Yes, we can do it very easily, for suppose that there were a source of light at infinity, at an angle such that the light is coming in at an angle θ_0 , and let us say that we wish to discuss the scattered beam, which is scattered at an angle θ_{sc} . The θ_{sc} is the same as we have had before, but the θ_0 is merely a means for arranging that the phase of each source is different: the light coming from the distant driving sources first hits one scratch, then the next, then the next, and so on, with a phase shift from one to the other, which, as we see, is $\alpha = d \sin \theta_0 / \lambda$. Therefore we have the formula for a grating in which light both comes in and goes out at an angle:

$$\phi = 2\pi d \sin \theta_{\text{out}} / \lambda - 2\pi d \sin \theta_0 / \lambda. \quad (30.7)$$

Let us try to find out where we get strong intensity in these circumstances. The condition for strong intensities is, of course, that ϕ should be a multiple of 2π . There are several interesting points to be noted.

One case of rather great interest is that which corresponds to $m = 0$, where d is less than λ ; in fact, this is the only solution. In this case we see that $\sin \theta_{\text{sc}} = \sin \theta_0$, which means that the light comes out in the same direction as the light which was entering the grating. We might think that the light "goes right through." No, it is *different* light that we are talking about. The light that goes right through is from the original source; what we are talking about is the new light which is

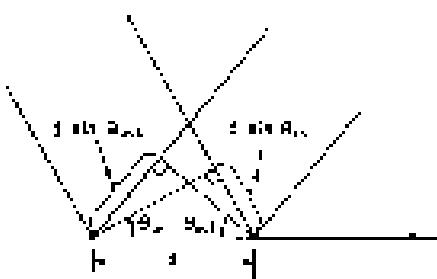

Fig. 30-4. The path difference for rays scattered from adjacent rulings of a grating is $d \sin \theta_{\text{sc}} - d \sin \theta_0$.

generated by scattering. It turns out that the scattered light is going in the same direction as the original light, in fact it can interfere with it—a feature which we will study later.

There is another solution for this same case. For a given $k_{\text{sc}} R_{\text{out}}$ (say) as the supplement of θ_{sc} . So not only do we get a beam in the same direction as the incoming beam but also one in a vector direction, which, if we consider it carefully, is such that the angle of incidence is equal to the angle of separation. This we call the reflected beam.

So we begin to understand the basic geometry of reflection: the light that comes in generates motions of the atoms in the reflector, and the reflector then regenerates a new wave, and one of the solutions for the description of scattering, the anti-scatterism if the spacing of the scatterers is small compared with one wavelength, is that the angle at which the light comes out is equal to the angle at which it comes in.

Next, we discuss the special case when $d \rightarrow 0$. That is, we have just a solid piece of material, so to speak, but of finite length. In addition, we want the phase shift from one scatterer to the next to go to zero. In other words, we put more and more oscillators between the other ends, so that each of the phase differences is varying smaller, but the number of scatterers is increasing in such a way that the total phase difference, between one end of the bar and the other, is constant. Let us see what happens to (10.3) if we keep the difference in phase $\pi\phi$ from one end to the other constant (say $\phi = 45^\circ$), letting the number go to infinity and the phase shift α of each one go to zero. But now α is so small that $\sin \phi = \phi$, and if we also recognize $\pi^2 J_0$ as I_0 , the maximum intensity at the center of the beam, we find

$$I = 4I_0 \sin^2 \frac{\pi d}{\lambda} / \pi^2. \quad (10.8)$$

This limiting case is what is shown in Fig. 30-2.

In such circumstances we find the same general kind of a picture as for finite spacing with $d > \lambda$; all the side lobes are practically the same as before, but there are no higher-order maxima. If the scatterers are all in phase, we get a maximum in the direction $\theta_{\text{out}} = 0$, and a minimum when the distance λ is equal to π , just as for finite d and n . So we can even analyze a continuous distribution of scatterers or oscillators, by using integrals instead of summing.

As an example, suppose there were a long line of oscillators, with the charge oscillating along the direction of the line (Fig. 30-3). From such an array the greatest intensity is perpendicular to the line. There is a little bit of intensity up and down from the equatorial plane, but it is very slight. With this result, we can handle a more complicated situation. Suppose we have a set of such lines, each producing a beam only in a plane perpendicular to the line. To find the intensity in various directions form a series of long wires instead of infinitesimal wires, is the same problem as it was for infinitesimal wires, so long as we are in the central plane perpendicular to the wires; we just add the contribution from each of the long wires. That is why, although we actually analyzed only tiny antennas, we might as well have used a grating with long, narrow slots. Each of the long slots produces an effect only in its own direction, not up and down, but they are all aligned to give a other horizontally, so they produce interference that way.

Thus we can build up more complicated situations by having various distributions of scatterers in lines, planes, or in space. The first thing we did was to consider scatterers in a line, and we have just extended the analysis to strips: we can work it out by just doing the necessary summations, adding the contributions from the individual scatterers. The principle is always the same.

30-3 Resolving power of a grating

We are now in a position to understand a number of interesting phenomena. For example, consider the use of a grating for separating wavelengths. We noticed that the whole spectrum was spread out on the screen, so a grating can be used as an instrument for separating light into its different wavelengths. One of the

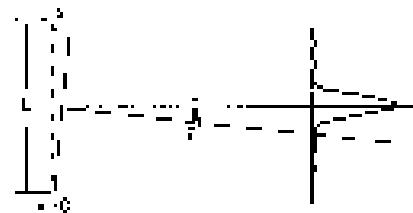

Fig. 30-5. The intensity pattern of a continuous line of oscillators has a single strong maximum and many weak "side lobes."

interesting question is: supposing that there were two sources of slightly different frequency, or slightly different wavelength, how close together in wavelength could they be such that the grating would be unable to tell that there were really two different wavelengths? The red and the blue were clearly separated. But when one wave is red and the other is slightly redder, very close, how close can they be? This is called the *resolving power** of the grating, and one way of analyzing the problem is as follows. Suppose that for light of a certain color we happen to have the maximum of the diffracted beam occurring at a certain angle. If we vary the wavelength the phase $2\pi d \sin \theta / \lambda$ is different, so of course the maximum occurs at a different angle. That is why the red and blue are spread out. How different in angle must it be in order for us to be able to see it? If the two maxima are exactly on top of each other, of course we cannot see them. If the maximum of one is far enough away from the other, then we can see that there is a double hump in the distribution of light. In order to be able to just make out the double hump, the following simple criterion, called Rayleigh's criterion, is usually used (Fig. 30-6). It is that the first minimum from one bump should sit at the maximum of the other. Now it is very easy to calculate, when one minimum sits on the other maximum, how much the difference in wavelength is. The best way to do it is geometrically.

In order to have a maximum for wavelength λ' , the distance d (Fig. 30-3) must be λ'/m , and if we're looking at the n th-order beam, it is $m\lambda'/d$. In other words, $2\pi d \sin \theta / \lambda' = 2\pi m, \text{or } \sin \theta, \text{ which is } \Delta, \text{ is } N \text{ times } n, \text{ or } m\lambda/d$. For the other beam, of wavelength λ , we want to have a minimum at this angle. That is, we want Δ to be exactly one wavelength λ more than even. That is, $\Delta = m\lambda - \lambda = m\lambda/d$. Thus if $\lambda' = \lambda + 1/\Delta$, we find

$$m\lambda/d = 1/\Delta; \quad (30.9)$$

The ratio λ/Δ is called the *resolving power* of a grating; we see that it is equal to the total number of lines in the grating, times the order. It is not hard to prove that this formula is equivalent to the formula that the error in frequency is equal to the reciprocal times the difference between extreme path differences (lower to take account

Fig. 30-6. Illustration of the Rayleigh criterion. The maximum of one pattern falls on the first minimum of the other.

In fact, that is the best way to remember it, because the general formula works not only for gratings, but for any other instrument whatsoever, while the special formula (30.9) depends on the fact that we are using a grating.

30-4 The parabolic antenna

Now let us consider another problem in resolving power. This has to do with the antenna of a radio telescope, used for determining the position of radio sources in the sky, i.e., how large they are in angle. Of course if we use any old antenna and find signals, we would not know from what direction they came. We are very interested to know whether the source is in one place or another. One way we can find out is to lay out a whole series of equally spaced dipole wires on the Australian landscape. Then we take all the wires from these antennas and feed them into the same receiver, in such a way that all the delays in the feed lines are equal. Thus the receiver receives signals from all of the dipoles in phase. Then it adds all the waves from every one of the dipoles in the same phase. Now what happens? If the source is directly above the array, at infinity or nearly so, then its radio waves will excite all the antennas in the same phase, so they all feed the receiver together.

Now suppose that the radio source is at a slight angle θ from the vertical. Then the various antennae are receiving signals a little out of phase. The receiver adds all these out-of-phase signals together, and so we get nothing, at the angle

* In our case $T = \lambda/c = \omega/c^2$, where c is the speed of light. The frequency $\nu = c/T$, so $\Delta\nu = c\Delta\lambda/\lambda^2$.

θ is too big. How big may the angle be? Answer: we get zero if the angle $\theta/L \approx 0$ (Fig. 20-4) corresponds to a 180° phase shift, that is, if λ is the wavelength λ . This is because the vector contributions form together a complete polygon with zero resultant. The smallest angle that can be resolved by an antenna array of length L is $\theta = \lambda/L$. Notice that the receiving pattern of an antenna such as this is exactly the same as the intensity distribution we would get if we turned the receiver around and made it into a transmitter. This is an example of what is called a *reciprocity principle*. It turns out, in fact, to be generally true for any arrangement of antennas, a radio, and so on, that if we first work out what the relative intensities would be in various directions if the receiver were a transmitter instead, then the relative directional sensitivity of a receiver with the same collection of dipoles, the same array of antennas, is the same as the relative intensity of emission would be if it were a transmitter.

Some radio antennae are made in a different way. Instead of having a whole lot of dipoles in a long line, with a lot of feed wires, we may arrange them not in a line but in a curve, and put the receiver at a certain point where it can detect the scattered waves. This curve is cleverly designed so that if the radiowaves are coming down from above, and the wires scatter, making a new wave, the wires are so arranged that the scattered waves reach the receiver all at the same time (Fig. 26-12). In other words, the curve is a parabola, and when the source is exactly on its axis, we get a very strong intensity at the focus. In this case we understand very clearly what the resolving power of such an instrument is. The arranging of the antennae on a parabolic curve is not an essential point. It is only a convenient way to get all the signals to the same point with no relative delay and without feed wires. The angle such an instrument can resolve is still $\theta = \lambda/s$, where s is the separation of the first and last antennae. It does not depend on the spacing of the antennae and they may be very close together or in fact be all one piece of metal. Now we are describing a telescope in, of course. We have found the resolving power of a telescope! (Sometimes the resolving power is written $\theta = 1.22\lambda/D$, where D is the diameter of the telescope. The reason that it is not exactly λ/D is this: when we worked out that $\theta = \lambda/D$, we assumed that all the lines of dipoles were equal in strength, but when we have a circular telescope, which is the way we usually imagine a telescope, not as much signal comes from the outside edges, because it is cut like a square, where we get the same intensity all along a side. We get somewhat less because we are using only part of the telescope there; thus we can appreciate that the effective diameter is a little shorter than the true diameter, and that is what the 1.22 factor tells us. In any case, it adds a little pedantic to put such precision into the resolving power formula.)

20-5 Colored films; crystals

The above, then, are some of the effects of interference obtained by adding the various waves. But there are a number of other examples, and even though we do not understand the fundamental mechanism yet, we will see day, and we can understand even now how the interference occurs. For example, when a light wave hits a surface of a material with an index n , let us say at normal incidence, some of the light is reflected. The reason for the reflection we are not in a position to understand right now; we shall discuss it later. But suppose we know that some of the light is reflected both on entering and leaving a reflecting medium. Then, if we look at the reflection of a light source in a thin film, we see the sum of two waves; if the thicknesses are small enough, these two waves will produce an interference, either constructive or destructive, depending on the signs of the phases. It might be, for instance, that for red light, we get an enhanced reflection, but for

* This is because Rayleigh's criterion is a rough idea in the first place. It tells you where it begins to get very hard to tell whether one image was made by one or by two stars. Actually, if sufficiently careful measurements of the exact intensity distribution over the diffracted image (that can be made), the fact that two stars can make the spot can be proved even if $\lambda < k$, that is, even if λ/L .

blue light which has a different wavelength), perhaps we get a destructively interfering reflection, so that we see a bright red reflection. If we change the thickness, i.e., if we look at another place where the film is thicker, it may be reversed; the red interfering and the blue not, so it is bright blue, or green, or yellow, or whatever. So we see colors when we look at thin films and the colors change if we look at different angles, because we can appreciate that the thicknesses are different at different angles. Thus we suddenly appreciate another hundred thousand situations involving the colors that we see on oil films, soap bubbles, etc., at different angles. But the principle is all the same: we are only adding waves at different phases.

As another important application of diffraction, we may mention the following. We used a grating and we saw the diffracted images on the screen. If we had used monochromatic light, it would have been at a certain specific place. Then there were various higher-order images also. From the positions of the images, we never tell how far apart the lines on the grating were, if we knew the wavelength of the light. From the difference in intensity of the various images, we could find out the shape of the grating scratches, whether the grating was made of wires, scratches, matches, or whatever, without being able to see them. This principle is used to discover the positions of the atoms in a crystal. The only complication is that a crystal is three-dimensional; it is a repeating three-dimensional array of atoms. We cannot use ordinary light, because we must use something whose wavelength is less than the space between the atoms or we get no effect; so we must use radiation of very short wavelength, i.e., x-rays. So, by shining x-rays into a crystal, and observing how intense is the reflection in the various orders, we can determine the arrangement of the atoms inside without ever being able to see them with the eye. It is in this way that we know the arrangement of the atoms in various substances, which permitted us to draw those pictures in the first chapter, showing the arrangement of atoms in salt, and so on. We shall later come back to this subject and discuss it in more detail, and therefore we say no more about this most remarkable idea at present.

30-6 Diffraction by opaque screens

Now we come to a very interesting situation. Suppose that we have an opaque sheet with holes in it, and a light on one side of it. We want to know what the intensity is on the other side. What most people say is that the light shines through the holes, and produces no effect on the other side. It will turn out that are gets the right answer, in an excellent approximation, if one assumes that there are sources distributed with uniform density across the open holes, and that the phases of these sources are the same as they would have been if the opaque material were absent. Of course, actually there are no sources at the holes, in fact that is the only place that there are certainly no sources. Nevertheless, we get the correct diffraction pattern by assuming the holes to be the only places that there are sources; that is a rather peculiar fact. We shall explain later why this is true, but for now let us just suppose that it is.

In the theory of diffraction there is another kind of a situation that we should briefly discuss. It is usually not discussed in an elementary book so early as this, only because the mathematical formulas involved in deriving these results are rather elaborate. Otherwise it is exactly the same as we have been doing all along. All the interference phenomena are the same; there is nothing very much more or less involved, only the circumstances are more complicated and it is harder to add the waves together. That is all.

Suppose that we have light coming in from infinity, casting a shadow of an object. Figure 30-7 shows a screen on which the shadow of an object AB is made by a light source very far away compared with our wavelength. Now we would expect that outside the shadow, the intensity is all bright, and inside it, it is all dark. As a matter of fact, if we plot the intensity as a function of position near the shadow edge, the intensity rises and then overshoots, and wobbles, and oscillates about in a very peculiar manner near the edge (Fig. 30-8). We now shall discuss the reason for this. If we use the theorem that we have not yet proved, then we can

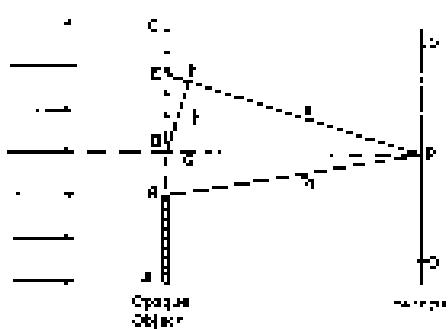

Fig. 30-7. A distant light source casts a shadow of an opaque object on a screen.

replace the actual problem by a set of effective sources uniformly distributed over the open space beyond the object.

We imagine a large number of very closely spaced antennas, and we want the intensity at some point P . That looks just like what we have been doing—very quiet; because our screen is at ∞ . Yet quiet; because our screen is at ∞ . We do not want the intensity at infinity, but, at a finite point. To calculate the intensity at some particular place, we have to add the contributions from all the antennas. First there is an antenna at D_1 , exactly opposite P ; if we go up a little bit in angle, let us say a height h , then there is an increase in delay (there is also a change in amplitude because of the change in distance, but this is a very small effect if we are at ∞ , far away, and is much less important than the difference in the phase). Now the path difference $\Delta P = DP$ is $h^2/2c$, so that the phase difference is proportional to the square of how far we go from D , while in our previous work it was infinite, and the phase difference was linearly proportional to h . When the phases are linearly proportional each vector adds at a constant angle to the next vector. What we now need is a curve which is made by adding a lot of infinitesimal vectors with the requirement that the angle they make shall increase, not linearly, but as the square of the length of the curve. To construct that curve involves slightly advanced mathematics, but we can always construct it by actually drawing the arrows and measuring the angles. In any case, we get the marvelous curve (called Cornu's spiral) shown in Fig. 30-8. Now how do we use this curve?

If we want the intensity, let us say, at point P , we add a lot of contributions of different phases from point D on up to infinity, and from D down only to point D_2 . So we start at D_2 in Fig. 30-8, and draw a series of arrows of ever-increasing angle. Therefore the total contribution above point D_2 all goes along the spiraling curve. If we were to stop integrating at some place, then the total amplitude would be a vector from D to that point; in this particular problem we are going to infinity, so the right answer is the vector B_{ext} . Now the position on the curve which corresponds to point D_2 or the object depends upon where point P is located, since point D , the reference point, always corresponds to the position of point P . Thus, depending upon where P is located above D , the beginning point will fall at various positions on the lower left part of the curve, and the resultant vector B_{ext} will have many maxima and minima (Fig. 30-9).

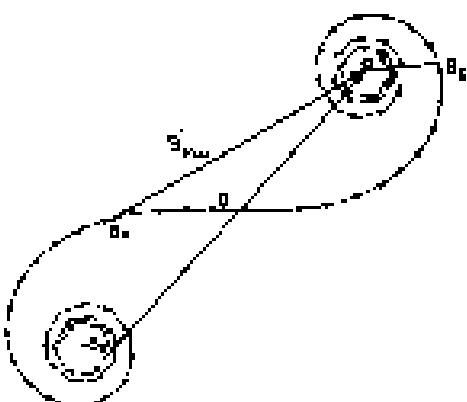

Fig. 30-8. The addition of amplitudes for many in-phase oscillators whose phase delays vary as the square of the distance from point D of the previous figure.

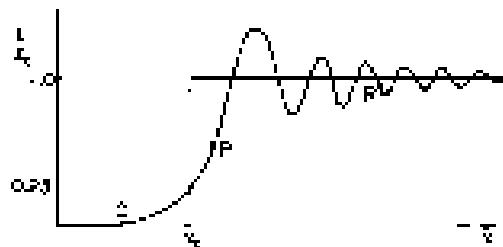

Fig. 30-9. The intensity near the edge of a shadow. The geometrical shadow edge is at x_0 .

On the other hand, if we are at Q , on the other side of P , then we are using only one end of the spiral curve, and not the other end. In other words, we do not even start at D , but at D_2 , so on this side we get an intensity which continuously falls off as Q goes further into the shadow.

One point that we can immediately calculate with ease, to show that we really understand it, is the intensity exactly opposite the edge. The intensity here is $1/4$ that of the incident light. Reason: Exactly at the edge (at the endpoint D of the arrow in Fig. 30-8) we have half the curve that we would have had if we were far into the bright region. If our point R is far into the light we go from one end of the curve to the other, that is, one full unit vector; but if we are at the edge of the shadow, we have only half the amplitude $\cdot 1/4$ the intensity.

In this chapter we have been finding the intensity produced in various directions from various arrangements of sources. As a final example we shall derive a formula which we shall need for the next chapter on the theory of the index of refraction. Up to this point relative intensities have been sufficient for our purpose, but this time we shall find the complete formula for the field in the following situation.

30-7 The field of a plane of oscillating charges

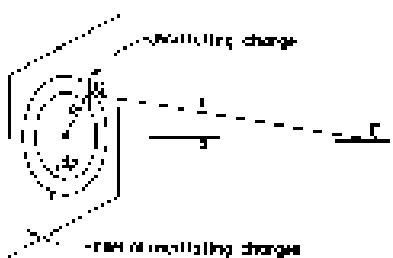

Fig. 30-10 Radiation field of a sheet of oscillating charges.

Suppose that we have a plane full of sources, all oscillating together, with their motion in the plane and all having the same amplitude and phase. What is the field at a finite, but very large, distance away from the plane? (We cannot get very close, of course, because we do not have the right formulae for the field close to the sources.) If we let the plane of the charges be the XY-plane, then we want to find the field at the point P far out on the Z -axis (Fig. 30-10). We suppose that there are n charges per unit area of the plane, and that each one of them has a charge q . All of the charges move with simple harmonic motion, with the same direction, amplitude, and phase. We let the motion of each charge, with respect to its own average position, be $x_1 e^{i\omega t}$. Or, using the complex notation and remembering that the real part represents the actual motion, the motion can be described by $x_1 e^{i\omega t}$.

Now we find the field at the point P from all of the charges by finding the field there from each charge q , and then adding the contributions from all the charges. We know that the radiation field is proportional to the acceleration of the charge, which is $-i\omega^2 x_1 e^{i\omega t}$ (and is the same for every charge). The electric field that we want at the point P due to a charge at the point Q is proportional to the acceleration of the charge q , but we have to remember that the field at the point P at the instant t is given by the acceleration of the charge at the earlier time $t - \tau = t - c/\rho$, where c/ρ is the time it takes the wave to travel the distance ρ from Q to P . Therefore the field at P is proportional to

$$-i\omega^2 x_1 e^{i\omega(t-\tau)} \quad (30.10)$$

Using this value for the acceleration to scan from P in our formula for the electric field at large distances from a radiating charge, we get

$$\left(\frac{\text{Electric field at } P}{\text{from charge at } Q} \right) = \frac{q}{4\pi\varepsilon_0 c^2} \frac{i\omega^2 x_1 e^{i\omega(t-\tau)}}{r} \text{ (approx.).} \quad (30.11)$$

Now this formula is not quite right, because we should have used c for the acceleration of the charge but for components perpendicular to the line QP . We shall suppose, however, that the point P is so far away, compared with the distance of the point Q from the axis (the distance ρ in Fig. 30-9), that those changes that we need to take into account, that we can leave out the cosine factor (which would be nearly equal to 1 anyway).

To get the total field at P , we now add the effects of all the charges in the plane. We should, of course, make a vector sum. But since the direction of the electric field is nearly the same for all the charges, we may, in keeping with the approximation we have already made, just add the magnitudes of the fields. To an approximation the field at P depends only on the distance ρ , so all charges at the same ρ produce equal fields. So we add, first, the fields of those charges in a ring of width $d\rho$ and radius ρ . Then, by taking the integral over all ρ , we will obtain the total field.

The number of charges in the ring is the product of the surface area of the ring, $2\pi\rho d\rho$, and n , the number of charges per unit area. We know, then,

$$\text{Total field at } P = \int_{\rho=0}^{\infty} \frac{q}{4\pi\varepsilon_0 c^2} \frac{i\omega^2 x_1 e^{i\omega(t-\tau)}}{r} \cdot n \cdot 2\pi\rho d\rho. \quad (30.12)$$

We wish to evaluate this integral from $\rho = 0$ to $\rho = \infty$. The variable r , of course, is to be held fixed while we do the integral, so the only varying quantities are ρ and n . Leaving out all the constant factors, involving the factor $i\omega^2$ for the moment, the integral we wish is

$$\int_{r=0}^{\infty} \frac{e^{-i\omega\tau}}{r} r^2 dr. \quad (30.13)$$

To do this integral we need to use the relation between r and ρ ,

$$r^2 = \rho^2 + z^2. \quad (30.14)$$

Since ϕ is independent of p , when we take the differential of this equation, we get

$$2r dr = 2a dp,$$

which is lucky, since in our integral we can replace $a dp$ by $r dr$ and the r will cancel the one in the denominator. The integral we want is thus the simpler one

$$\int_{r=0}^{r=\infty} e^{-\sigma r^2} dr. \quad (30.15)$$

To integrate an exponential is very easy. We divide by the coefficient of r in the exponent, and evaluate the exponential at the limits. But the limits of r are not the same as the limits of p . When $p = 0$, we have $r = \infty$, as the limits of r are $\pm\infty$ to infinity. We get for the integral

$$\int_0^\infty [e^{-\sigma r^2} - e^{-\sigma(\infty)^2}] dr, \quad (30.16)$$

where we have written ∞ for $(\infty)r$, since these both just mean a very large number!

Now $e^{-\infty}$ is a mysterious quantity. Its real part, for example, is $\cos(-\infty)$, which, mathematically speaking, is completely indefinite (although we would expect it to be everywhere—or everywhere (δ) —between -1 and $+1$). But in a physical situation, it can mean something quite reasonable, or usually can just be taken to be zero. To see that this is so in our case, we go back to consider again the original integral (30.15).

We can understand (30.15) as a sum of many small complex numbers, each of magnitude Δr and with the angle $\theta = -\sigma r^2$ in the complex plane. We can try to evaluate the sum by a graphical method. In Fig. 30-11 we have drawn the first five pieces of the sum. Each segment of the curve has the length Δr and is placed at the angle $\theta = -\sigma r^2$ with respect to the preceding piece. The sum for these first five pieces is represented by the arrow from the starting point to the end of the fifth segment. As we continue to add pieces we shall race off clockwise until we get back to the starting point (approximately) and then start around once more. Adding more pieces, we just go round and round, staying close to a circle whose radius is easily shown to be c/a . We can see now why the integral does not give a definite answer!

But now we have to go back to the effects of the situation. In any real situation the plane of charges cannot be infinite in extent, nor must it sometime stop. If it slopes suddenly, and was exactly circular in shape, our integral would have some value on the circle in Fig. 30-11. (If, however, we let the number of charges in the plane gradually taper off at some large distance from the center, or else stop suddenly but in an irregular shape so far larger p , the entire ring of width dp no longer contributes), then the coefficient a in the exact integral would decrease toward zero. Since we are adding smaller pieces but still going through the same angle, the graph of our integral would then become a curve which is a spiral. The spiral would eventually end up at the center of our original circle, as drawn in Fig. 30-12. The physically correct integral is the complex number A , in the figure represented by the interval from the starting point to the center of the circle, which is just equal to

$$\frac{c}{\infty} e^{-\sigma(\infty)^2}, \quad (30.17)$$

as you can work out for yourself. This is the same result we would get from Eq. (30.16) if we set $a = 0$.

(There is also another reason why the contribution to the integral drops off for large values of r , and that is the factor we have omitted for the projection of the acceleration in the plane perpendicular to the line $F(r)$.)

We are, of course, interested only in physical situations, so we will take c/a equal to zero. Returning to our original formula (30.12) for the field and putting

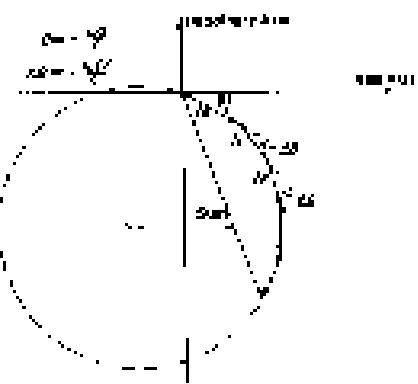

Fig. 30-11. Graphical solution of $\int_0^\infty e^{-\sigma r^2} dr$.

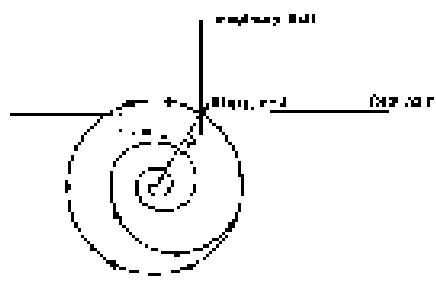

Fig. 30-12. Graphical solution of $\int_c^0 e^{-\sigma r^2} dr$.

Add all of the factors along with the integral, we have the result

$$\text{Total field at } P = -\frac{\lambda^2}{2\epsilon_0 c} \cos(\omega t) \quad (30.18)$$

(remembering that $\lambda = -\lambda$)

It is interesting to note that $\cos(\omega t)$ is just equal to the velocity of charge, so that we can also write the equation for the field as

$$\text{Total field at } P = -\frac{\lambda v}{2\epsilon_0 c} (\text{velocity of charge}) \cos(\omega t) \quad (30.19)$$

which is a little strange, because the reference is not to the distance r , which is the distance from P to the plane of charges. But that is the way it comes out—fortunately a rather simple formula. (We may add, by the way, that although our derivation is valid only for distances far from the source of oscillatory charges, it turns out that the formula (30.18) or (30.19) is correct at very distance r , even for $r < \lambda$.)

The Optics of the Refractive Index

31-1 The index of refraction

We have seen that light goes slower in water than in air, and slower again in air than in vacuum. This effect is described by the index of refraction n . Now you would like to understand how such a slower velocity could come about. In your lecture, we may try to see whether our current known physical assumptions or statements are violated; nothing, what were the following:

- That the total electric field in any physical circumstance can always be represented by the sum of the fields from all the charges in the universe.
- The charge field from a single charge is given by a mathematical calculation with a relationship to the speed c , namely (from the Coulomb field):

But, for a piece of glass, you might think, "Oh, no, you could modify all this. You might say it is retarded at the speed c/n ," thus, however, is not right, and we have no understanding why it is not.

It is approximately true that light or any other real wave does appear to travel at the speed c in a vacuum, whose index of refraction is 1. The field is proportional to the motion of all the charges. Including the charges moving in the material—and with these basic contributions of the field travelling at the speed of light c . Our problem is to understand how the apparently slower velocity comes about.

We shall try to understand the effect in a very simple case. A source which we shall call "the central source" is placed a large distance away from a thin plane of transparent material, say glass. We imagine that the field at a large distance R is the opposite side to the plane. The situation is illustrated by the diagram of Fig. 31-1, where S and P are imagined to be very far away from the plane. According to the principles we have stated earlier, the electric field E_0 where S is located, due to moving charges is the vector sum of the fields produced by the external source on S and the fields produced by each of the charges in the sheet of glass, every one due to propagation according to the retardation. Remember that the contribution of each charge is not changed by the presence of the other charges. Therefore our basic p analysis. The field at P can be written thus:

$$\mathbf{E} = \sum_{\text{charges}} \mathbf{E}_{\text{due to } S} \quad (31-1)$$

$$\mathbf{F} = \mathbf{E} = \sum_{\text{charges}} \mathbf{F}_{\text{due to } S} \quad (31-2)$$

where E_0 is the field due to the source alone and would be precisely the field if S were a stationary particle. We expect the field at P to be different from E_0 if there are any other moving charges.

Why should there be charges moving in the glass? We know that all the metal consists of atoms which contain e electrons. When the electric field of the source acts on these atoms it drives the electrons up and down, because it can be a force on the electrons. And moving charges can generate a field. They constitute new currents. These new currents are related to the source as E because they are driven by the field of the source. The total field is not just the field of the source E_0 but it is modified by the additional contribution from the other moving charges. This means that the field is not the same as the one at S was there before the glass was there but is modified. And it turns out that it is modified in such a way that

31-6 Diffraction of light by a screen

Fig. 31-1. Electric waves passing through a sheet of transparent material.

the field inside the glass appears to be moving at a different speed. That is the β which we would like to work out quantitatively.

Now this is, in the exact case, actually impossible, because although we have said that all the other moving charges are driven by the source field, but is not quite true. If we think of a permanent charge, it feels only the source, but the rest of the world, it feels all of the other charges that are moving. It feels, in particular, the charges that are moving somewhere else in the glass. So the total force which it feels on a particular charge is a sum of two fields from the outside space, whose relative magnitudes from the permanent source is β/β_0 . You can see that it would need a complete set of equations to get the complete and exact formula. I say only today that we postpone this problem till next year.

Instead we shall work out a very simple case in order to understand what the physical principles very clearly. We take a circumstance in which the effects from the other source is very small compared to the effects from the source. In other words, we take a medium, in which the field is not modified very much by the motion of the other charges. That is, it appears to a charge in which the index of refraction is very close to 1, which will happen, for example, if the density of the source is very low. Our calculation will be valid for any case in which the index is for any reason very close to 1. In this way we shall avoid the complications of the more general, complete equation.

Finally, you should notice that there is another effect caused by the motion of the charges in the plane. These charges will also cause waves back toward the source. This backward-going field is the light we see reflected from the surfaces of prepared materials. It does not come from just the surface, but backward radiation comes from everywhere in the interior, but it has to escape the bulk after being equivalent to reflection from the surface. These reflection effects are beyond our approximation at the moment, because we shall be limited to calculating the material with an index so close to 1 that very little light is reflected.

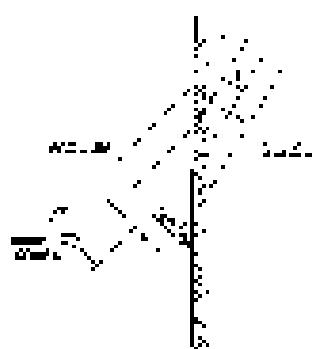

Fig. 37-2. Relation between reflection and refraction and velocity changes.

Let us proceed with our theory of how the index of refraction corresponds. We should understand first of all that it is caused by multiple reflections to understand why the apparent wave velocity is different in different materials. The bending of light rays comes when just because the effective speed of the waves is different in the materials. To remind you how that comes about we have drawn in Fig. 37-2 several successive parts of an acoustic wave which arises from a wave source not too far from a block of glass. The time is proportional to the wave crest indicates the direction of travel of the wave. Now, oscillations in the wave crest have the same frequency. (We have seen that light oscillates over the same frequency as the living source.) This means, then, that the wave crests in the wave can both cross the surface without loss of speed along the surface since they must travel together, so that a charge sitting at the boundary will feel only one frequency. The average distance between crests of the wave, however, is the wave length which is the velocity divided by the frequency. On the air side it is $\lambda_0 = v/v_0$, and on the other side it is $\lambda_1 = v/v_1$. From previous, $v_1 = c/n$ is the velocity of the wave. Since the light is taken out this is the only way for the wave to "fit" properly at the boundary is for the waves in the material to be traveling at a definite angle with respect to the surface. From the geometry of the diagram you can see that for $n > 1$ we must have $\lambda_1 < \lambda_0$, or $v_1 < v_0$, or $c/n < v_0$, which is usually true. We shall, for the rest of our discussion, consider only c/v , light has an effective speed of c/n in the rest of index n , and an longer way, in this chapter, about the bending of the light directions.

We go back now to the situation shown in Fig. 37-1. We see that what we have to do is to calculate the field produced by all the oscillating charges in the glass plate. We shall call this part of the field E_1 , and it is just as was written, as the second term in Eq. (37-2). When we add it to the field E_0 , due to the source, we will have the total field as E .

This is probably the most common misconception among students going into this year, but it is important to note that there are many pieces and have to be put together, each piece, however, is very simple. It's like when we build a model we say, "Forget the orientation, just look at the overall," in this case we don't need the orientation of each of the directions. In other words, the drag or retardation now is the physical machinery for the production of the index.

To see what we are going to do, let us take first of all what the "true current field" E_0 would have to be if the plate had no E_1 . It is going to look like this because from the source that is skewed down while passing through the thin plates. If the plate had no effect on it, the field of a wave travelling to the right (along the x -axis) would be

$$E_0 = E_0 e^{i(kx - \omega t)} \quad (31.3)$$

or, using the exponential notation,

$$E_0 = E_0 e^{i(kx - \omega t)} \quad (31.4)$$

Now what would happen if we were to pull more slowly in going through the plate? Let us call the slowness of the plate α . If the plate is constant there will be wave without train. It would not be in the true field. But it appears to travel at the speed of light it would take the longer time $\Delta t = \alpha$ in the additional time $\Delta t = \alpha = \Delta x/c$. After that it would continue to travel at the speed of light. We can take into account the extra delay by putting enough the index by replacing β in Eq. (31.4) by $\beta + \Delta t/c$ or by $\beta + (\alpha - 1) 2\pi/c$. So the wavefield in front of the plate should be written

$$E_{\text{travelled}} = E_0 e^{i(k(x - \Delta x) - \omega(t - \Delta t))} \quad (31.5)$$

We can also write this expression as

$$E_{\text{travelled}} = e^{-i\omega\Delta t} E_0 e^{i(kx - \omega t)} \quad (31.6)$$

which says that the wave after the plate is obtained from the wave which would exist without the plate, i.e., from E_0 , by multiplying by the factor $e^{-i\omega\Delta t}$. Now we notice that multiplying or dividing something like $e^{\beta x}$ by a factor $e^{\alpha x}$ just gives us the change the phase of the wave divided by the angle α , which is of course, where the extra delay is passing through the medium. So instead of this retarded field please let the amount add $(\alpha - 1) 2\pi/c$ (neglected, however, of the minus sign) in the exponent.

We have said earlier that the plate should add a field E_1 to the original field $E_0 = E_0 e^{i(kx - \omega t)}$, but we have found instead that the effect of the plate is to multiply the field by a factor $e^{-i(\omega\Delta t - k\Delta x)}$. However, that is really a right because we can get the same result by adding a suitable complex number. It is particularly easy to find the right number to add in this case since α is small. Do you still remember that if a is a small number then e^a is nearly equal to $1 + a$? We can write, therefore,

$$e^{-i(\omega\Delta t - k\Delta x)} = 1 - ik\Delta x - \frac{1}{2}k^2\Delta x^2 \quad (31.7)$$

Using this equality in Eq. (31.6), we have

$$\text{Cylinder} = E_0 e^{i(kx - \omega t)} - \frac{i\omega\Delta x - 1}{2}k^2\Delta x^2 E_0 e^{i(kx - \omega t)} \quad (31.8)$$

The first term is just the field from the source and the second term must just be equal to E_1 , the field produced to the right of the plate by the net trailing charges on the plate—represented here in terms of the index of refraction α , and depending, of course, on the slowness of the wave from the source.

What we have seen today is easily visualized. See back of the cylinder containing E_0 in Fig. 31.3. We first draw the number E_0 (not drawn to scale, but it is not too far from horizontal), but this is unnecessary). The easy thing to

Fig. 31.3. Diagram for the transmission of a wave through a cylinder.

slowing down in the plates would affect the phase of this number. That is, it would rotate E_0 through a negative angle. But this is equivalent to adding a small vector to E_0 roughly right angles to E_0 . But that is just what the factor $-is$ there in the second term of Eq. (31.8). It says that if E_0 is real, then E_0 is negative imaginary or, in general, E_0 and E have a right angle.

31-2 The field due to the anodes.

We now have to work out the field E_0 , which fits in the second term of Eq. (31.8) the kind we would expect from oscillating charges in the plates. If we can carry this on, we will then have calculated what the index s should be! (Since s is the only nondimensional number in Eq. (31.8).) We don't know exactly what field E_0 the charges in one anode will produce. (To help you keep track of the many symbols we have used up to now, and without having to do most of the calculation, we have put them all together in Table 31-1.)

Table 31-1
Symbols used in the calculations

E	= field from the source
E_0	= field produced by charges in the plate
dr	= distance of the plate
a	= perpendicular distance from the plane
n	= index of refraction
ω	= frequency (angular) of the oscillation
N	= number of charges per unit volume in the plate
q	= number of charges per unit area of the plate
q_0	= charge on an electron
m	= mass of an electron
v_0	= received frequency of an electron beam in an atom

If the source S (of Eq. 31-1) is to drift to the left, then the field E_0 will have the same phase everywhere in the plane, so we can write that to the right hand side of the plate

$$E = E_0 e^{i(\omega t - \phi)} \quad (31.9)$$

Right of the plate, where $a = 0$, we will have

$$E_0 = E_0 e^{i\omega t} \text{ (at the plate)} \quad (31.10)$$

All of the electrons in the chains of the plate will feel this electric field and will be driven up and down (assuming the direction of v_0 is vertical) by the electric force qeE . To find who moves we expect the electrons, we will assume again among the little oscillators, that is, that the electrons are confined elastically to the plate, which means that if a force is applied to an electron its displacement from its normal position will be proportional to the force.

You may think that this is a fairly simple model of an atom. You have heard some electrons whirling around in orbits. But that is just an oversimplified picture. The correct picture of an atom, which is given by the theory of wave mechanics, says that, as far as problems involving light are concerned, the electrons behave as though they were held by springs. So we shall suppose that the electrons have a linear restoring force, which, together with their mass m , makes them behave like little oscillators with a resonant frequency ω_0 . We have already studied such oscillators, and we know that the equation of their motion is written this way:

$$m \left(\frac{d^2y}{dt^2} + \omega_0^2 y \right) = F_0 \quad (31.11)$$

Where F_0 is the driving force.

For our problem, the driving force comes from the electric field of the wave from the source, given by (31.1), we

$$F = q_0 E_0 = q_0 \epsilon_0 E_0^{\text{ext}}, \quad (31.12)$$

where q_0 is the electric charge on the electron and for E_0 , we use the expression $E_0 = E_0^{\text{ext}}$ from (31.1). Our equation of motion for the electron is then

$$m \left(\frac{d^2 r}{dt^2} + \omega_0^2 r \right) = q_0 \epsilon_0 E_0^{\text{ext}}. \quad (31.13)$$

We have solved this equation before, and we know that the solution is

$$r = r_0 e^{i\omega t}, \quad (31.14)$$

where, by substituting in (31.13), we find that

$$\omega_0 = \frac{q_0 E_0}{m(\omega_0^2 - \omega^2)}, \quad (31.15)$$

so that

$$r = \frac{q_0 E_0}{m(\omega_0^2 - \omega^2)} e^{i\omega t}. \quad (31.16)$$

We have just we needed to know—*the motion* of the electrons in the plate. And it is the same in every electron wave, that the mean position (the “*dc*” of the motion) is, of course, different for each electron.

Now we are ready to find the field E_0 that these atoms produce at the point x . Because we have already worked out (in the end of Chapter 20) what field is produced by a sheet of charges that all move together. Referring back to \mathbf{E}_0 (30.19), we see that the field E_0 at x is just a negative constant times the velocity of the charges, divided by time the amount a_0 . Substituting r_0 in Eq. (31.16) to get the velocity, and sticking in the substitution r_0 just putting r_0 from (31.15) into (30.19) yields

$$E_0 = -\frac{q_0}{2a_0} \left[\ln \frac{q_0 E_0}{m(\omega_0^2 - \omega^2)} e^{i\omega_0 a_0/\omega} \right]. \quad (31.17)$$

Just as we expected. To draw the line of the electrons produced an excited wave which travels to the right (that is what is factor $e^{i\omega_0 a_0/\omega}$ does), and the amplitude of the wave is proportional to the number of atoms per unit area in the plate (proportional to n) and is proportional to the strength of the electric field (the factor E_0). Then there are some factors which depend on the atomic properties (e.g., m) and which we should expect.

The most important thing, however, is that this formula (31.17) for E_0 looks very much like the expression for E_0 that we got in (27.10.6) by solving (27.10.6) when we was defined a positive dielectric material with an index of refraction n . The two expressions are, in fact, identical if

$$(n - 1)^2 = \frac{\omega^2}{2\epsilon_0 m(\omega_0^2 - \omega^2)}. \quad (31.18)$$

Hence the field E_0 is proportional to Δn , since n , which is the number of atoms per unit area, is equal to $\Delta n N$, where N is the number of atoms per unit volume of the metal. So, returning to (31.16) and changing the frequency from ω , result, a formula for the index of refraction in terms of the properties of the atoms of the material—and of the frequency of the light:

$$n = 1 + \frac{q_0^2}{2\epsilon_0 m(\omega_0^2 - \omega^2)}. \quad (31.19)$$

This equation is very similar to the “*drift-disk*” of the index of refraction that we wished to obtain

31-3 Dispersion

In the last section we have obtained something very interesting. For we have not only assumed that the index of refraction which can be computed from the basic optical quantities, but we can also learned how the index of refraction should vary with the frequency ω of the light. This is something we could never understand from the simple statement that "light travels slower in a transparent material." We still have the problem, of course, of knowing how many oscillations per unit of time there are, and what is their natural frequency ω_0 . We do not know this just yet, because it is different for every different material, and we cannot yet get a general theory of the way. Recomputing our general theory of the properties of different substances their natural frequencies and comparing with quantum atomic mechanics. Also, different materials have different properties and different indexes, so we cannot expect, anymore, to get a general formula for the index which will apply to all substances.

However, we shall discuss the formula we have obtained in various possible circumstances. First of all, for most ordinary gases (for instance, for air), these values ω_0 (hydrogen, helium, and so on) the natural frequencies of the electron orbits will correspond to visible light. These frequencies are higher than the frequencies of visible light, that is, ω_0 is much larger than visible light, and so if this appears more or less transparent, we can dispense ω^2 in comparison with ω_0^2 . Then we find that the index is nearly constant. So for a gas, the index is nearly constant. This is also true for some other transparent substances like glass. If we have a gas, especially a little more closely, however, we notice that as we take away a little bit more away from the denominator, the index decreases. It decreases slowly with frequency. The index is higher for blue light than for red light. That is, the reason why we perceive the light more in the blue than in the red.

The phenomenon that the index depends upon the frequency is called the phenomenon of dispersion, because it is the basis of the fact that light is "dispersed" by a prism into a spectrum. The expression for the index of refraction as a function of frequency is called a dispersion equation. So we've now derived a dispersion equation. (In the past few years "dispersion equations" have been finding a new use in the theory of elementary particles.)

Our dispersion equation suggests other interesting effects. If we have a natural frequency ω_0 which lies in the visible region, or if we measure the index of refraction of a material like glass in the ultraviolet, where ω_0 is probably ω_0 , we can take frequencies which are lower than the natural frequency. Then the index will automatically be large because the denominator will go to zero. Next, suppose that ω is greater than ω_0 . This would mean, for example, if we take a material like glass, say, and shingle it with aluminum. In fact since many metals which are opaque to visible light, like graphite for instance, are transparent to X-rays, we can also talk about the index of refraction of graphite to X-rays. All the natural frequencies of the carbon atoms would be moved lower than the frequency we are using in the process, since ω_0 is still too small at a very high frequency. The index of refraction is thus given by our dispersion equation if we set ω_0 equal to zero (we neglect ω^2 , compared with ω_0^2).

A similar situation could occur if we beam electrons (or light) on a gas of free electrons. Let us again suppose electrons and like nuclei to be stationary by ultraviolet light from the sun. They will strip there as free electrons. Our free electrons are subject to electric accelerating forces. Setting $m_e = 1$, the dispersion equation after years the correct formula for the index of refraction for ultraviolet to the ultraviolet, where this corresponds to the density of free electrons (must be zero in practice) in the ultraviolet. (C. let me look again at the calculation. If we take ω to be the frequency of radio waves, or the ultraviolet, the term $(\omega - \omega_0)^2$ becomes negative, and we obtain the result that it is less than one. That means that the effective speed of the wave in the substance is faster than c. Can that be correct?)

It is correct. Despite of the fact that it is said that you cannot send signals with the speed of light, it is nevertheless the case that a signal of frequency ω can travel at a particular frequency even faster than c. See this page.

just receive the "radio wave" which is produced by the two train lights now to side, positive or negative. It can be shown, however, that the speed at which you can send a signal is not determined by the frequency or the frequency, but depends on what the index is for waves frequencies. What the index tells us is the speed at which the waves (or crests) of the wave travel. The wave you have is not a signal by itself; it is a radio wave, which has no oscillations of its kind, i.e., which is a steady oscillation, you cannot call it a radio wave; if so, you cannot send them a timing signal. In order to send a signal you have to change the wave somehow, add to it something in it, make it a little bit faster or slower. That means that you have to have more than one frequency in the wave and it can be seen that the speed of which which travels is not dependent upon the radio signal but upon the wave, that the index changes with the frequency. This subject we must also delay until Chapter 45. Then we will calculate for you the exact speed of signals through such a piece of glass, and you will see that it will not be faster than the speed of light, although the index, when the mathematical point, does not exceed twice the speed of light.

Now, to give a slight hint as to how this happens, you will note that the field definitely goes with the fact that the responses of the charge are opposite to the field, i.e., the sign has gone around well. Thus in our expression for \ddot{x} (Eq. 31.15) the displacement of the charge is in the direction opposite to the driving field. And it is there that the phase of the transmitted field can appear in the advanced wave respects the source wave. It is this advance property which is true, either we say that the "phase velocity" or velocity of the nodes is greater than c . In Fig. 31-4 we give a schematic idea of how the wave might look for a case where the wave is suddenly increased to take a signal. You will see from the diagram that the signal (i.e., the part of the wave) is run earlier in the wave which ends up with an advance in phase.

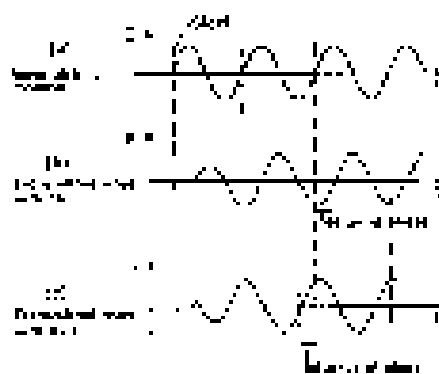

Fig. 31-4. Wave "signals."

Let us now look again at our previous equation. We should remark that on any kind of quantitative index gives a result that is somewhat simpler if we could actually find in nature. To be completely accurate we ought to make refinements. First, we should expect that our mass of the charge in oscillation should have some damping forces (like viscous forces), if we go with a force, and we do not expect that to happen. We have worked out before (Eq. 31.8) the motion of a damped oscillator and the result is not the last number in Eq. (31.6b), and therefore in (31.10), is changed from $(\omega_0^2 - \omega^2)$ to $(\omega_0^2 - \omega^2 + \gamma\omega)$, where γ is the damping coefficient.

We shall now add (31.10) to take care of this. In fact that there are several resonant frequencies for a particular kind of system. It is very important

Dispersion is got by imagining that there are several different kinds of oscillators, but each has a different frequency, and so we simply add the contributions of all the oscillators. Let us say that there are N_1 electrons per unit of volume whose natural frequency is ω_1 and whose damping factor is γ_1 . We would then have the sum dispersion equation

$$n = 1 + \frac{c^2}{\omega_1^2} \sum_{k=1}^{\infty} \frac{N_k}{\omega_k^2 + \gamma_{k,0}^2}. \quad (31.20)$$

We have finally a complete expression which describes the index of refraction that is observed for many substances.⁴ The index described by this formula varies with frequency non-linearly, as the curve shows in Fig. 31-3.

You will notice that so long as it is close to one of the natural frequencies, the slope of the curve is positive. Such a positive slope is referred to as "normal" dispersion (as it is clearly the most common occurrence). However, the natural frequencies, however, there is a range of ω for which the slope is negative. Such a negative slope is often referred to as "anomalous" dispersion (also called dispersive), because it was not known when it was first observed, long before anyone ever knew there were such things as electrons. From our point of view both slopes are quite "normal".

31-4 Alternating

Perhaps you have noticed something a little strange about the form (Eq. 31.20) we obtained for our dispersion equation. Because of the term (γ) we put in to take account of damping, the index of refraction is now a complex number. What does that mean? By working out what the real and imaginary parts of n are we could write

$$n = n' - i n'', \quad (31.21)$$

where n' and n'' are real numbers. (We use the minus sign in front of the $i n''$ because then, if n'' turns out to be a positive number, as you can show for yourself, n

will be a *real* number and a complex index of refraction, by going back to Eq. (31.6), which is the equation of the phase shift in passing through a plate of material with thickness d . If we put $n = n' + i n''$ in the equation, and do some rearranging, we get

$$\text{Phase shift} = e^{-i k d} = e^{-i \frac{2 \pi}{\lambda} n' d} e^{-\frac{2 \pi}{\lambda} n'' d \cos^2 \theta}, \quad (31.22)$$

The last factors, marked " i " in Eq. (31.22), are just the form we had before, and again describe a wave whose phase has been delayed by the angle $\omega n'' = -1/2 \pi$ in traversing the material. The first term (n') is now written as exponential factor with a non-exponent, because there are γ 's that are canceled. Also, the exponent is negative, so the factor is a real number less than 1. It describes a decrease in the magnitude of the field due to the absorption by an amount which is more the larger ω is. As the wave goes through the material, it is weakened. The material is "dissipating" part of the wave. The wave carries no energy, so it will lose energy. You won't be surprised at this, because the damping we put in (γ) for one reason is indeed a loss of energy and must be expected to cause a loss of energy. We see that the "imaginary part" of a complex index of refraction represents an absorption (or "dissipation") of the wave. In effect, n'' is sometimes referred to as the "absorption index".

We may also point out that an imaginary part of the index corresponds to breaking the arrow \vec{E}_0 in Fig. 31-3 toward the origin. It is clear why the unamplified field is then decreased.

⁴ Actually, although the present analysis (Eq. 31.20) is still valid, its interpretation is somewhat different. In general, oscillators can have very wide band widths and often have several natural frequencies. Therefore N_k is not really the number of electrons having the frequency ω_k ; it is N_k divided by N , where N is the number of electrons, with N_k small. It is called a *weight* or *strength* that tells how strongly the mean velocity v of electrons of frequency ω_k .

Normally, the index as in glass, the absorption of light is very small. The δ factor reported from our Eq. (11.20), however, the imaginary part of the dielectric, δ_{abs} , is much smaller than the term $(\omega - \omega_0)$. But if the light frequency is very close to ω_0 , then the resonance term $(\omega - \omega_0)^2$ can become large compared with δ_{abs} and the index becomes almost completely imaginary. The absorption of the light becomes very dominant. It is just this effect that gives the dark lines in the spectrum of light which we receive from the sun. The light from the solar surface has passed through the sun's atmosphere (as well as the earth's) and the light has been strongly absorbed at the resonant frequencies of the atoms in the solar atmosphere.

The observation of such spectral lines in the sunlight allows us to tell the chemical composition of the atoms and hence the chemical composition of the atmosphere. These multi-wavelength observations tell us about the materials at the stars. From such measurements we know that the chemical elements in the sun and in the stars are the same as those we find at the earth.

11-5 The energy carried by an electric wave

We have seen that the imaginary part of the index means absorption. We shall now use this knowledge to find out how much energy is carried by a light wave. We have given earlier an argument that the energy carried by light is proportional to $\overline{E^2}$, the time average of the square of the electric field in the wave. The decrease in Δ due to absorption must mean loss of energy, which would go into the motion of the electrons and, we might guess, would end up as heat in the material.

If we consider a light arriving at a unit area, say one square centimeter, to compute in Eq. (31.1), then we obtain the following energy input per unit time (if we assume that energy is conserved, as we do):

$$\text{Energy in per sec} = \text{energy out per sec} = \text{work done per sec.} \quad (11.21)$$

For the first term we can write $\alpha \overline{E^2}$, where $\alpha \gg 1$ is yet another constant of proportionality which defines the average value of the energy being carried by the second term we must include the part from the radiating atoms of the material, so we should use $\alpha \overline{E^2} + N \sqrt{\epsilon}$, or rewriting the equation slightly $\overline{E^2} (\overline{E^2} + \Sigma E)$.

A lot of calculations have been made for a thin layer of material whose index is not too far from 1, so that δ , which is much less than E , just to make the calculations easier. In keeping with our approximate terms, we should, therefore, leave out the term ΣE , because it is much smaller. Only $\overline{E^2}$. You may say: "Then you should leave out $\alpha \overline{E^2}$, too, because it is much smaller than E ." I agree that $\overline{E^2}$ is much smaller than E , but we must keep $\alpha \overline{E^2}$ or our approximation will not be exact. Just as well apply if we neglected the presence of the material completely! One way of checking the calculations is to consider Δ to see that we always keep terms which are proportional to $N \delta z$, the areal density of atoms in the material, but we know a lot more which are proportional to $(N \delta z)^2$ or are higher powers of $N \delta z$. That is what would be called a "second-order approximation."

In the same spirit, we might remark that an energy injection has reflected the energy in the reflected wave. But this is OK because this term is also proportional to $N \delta z$, since the amplitude of the reflected wave is proportional to δz .

For the last term in Eq. (11.21) we wish to compute the rate at which the incoming wave is doing work on the electrons. We know that work is force times distance, so the rate of doing work (or emitted power) is $F \cdot V$, where V is the velocity. I, I, I, and $F \cdot V$, but we do not need to worry about the dot product when the velocity and force are along the same direction as they are here (except for a possible minus sign). So for each atom we have $\frac{1}{2} m v^2$ for the average rate of

doing work. Since $\nabla \cdot \mathbf{E} = 0$ at ∞ , as in a free space, the last term in Eq. (31.27) drops to 0 . Thus, our energy equation looks like

$$dE_t = dE_0 + 2\pi k_e E_0 + N \Delta \epsilon_0 E_0. \quad (31.28)$$

The E_0 is measured, and we have

$$2\pi k_e E_0 = N \Delta \epsilon_0 E_0. \quad (31.29)$$

We now go back to Eq. (31.27), and we notice that due to $\nabla \cdot \mathbf{E} = 0$,

$$\Delta \epsilon_0 = \frac{N \Delta \epsilon_0}{2k_e}, \text{ neglecting } \epsilon_0^2. \quad (31.30)$$

(noticing that $\epsilon_0 = N \Delta \epsilon_0$). Putting Eq. (31.30) into the left-hand side of (31.27), we get

$$2\pi \frac{N \Delta \epsilon_0}{2k_e} \overline{\epsilon_0(\vec{r}, t)} = \text{neglect } \epsilon_0^2.$$

However, $\epsilon_0(\vec{r}, t) \leq \mathcal{E}_0$ (at $t = 0$) multiplied by ϵ_0/ϵ_0 . Since the average is independent of time, it is the same quantity as calculated by ϵ_0/ϵ_0 , or is $\mathcal{E}_0(t)$ along \vec{r} , the same average that appears on the right-hand side of (31.28). The two sides are therefore equal to

$$\frac{1}{2} \epsilon_0 \mathcal{E}_0^2 = 1, \quad \text{or} \quad \mathcal{E}_0^2 = 2\epsilon_0. \quad (31.31)$$

We have discovered that if energy is to be conserved, the energy started in an infinite wavelet at $t = 0$ is now per unit time (frequency) we have called the intensity, and is given by $\epsilon_0/2\epsilon_0$. If we call the intensity I , we have:

$$I = \begin{cases} \text{Intensity} \\ \text{or} \\ (\text{energy}/\text{area}/\text{time}) \end{cases} = \epsilon_0/2\epsilon_0. \quad (31.32)$$

which further proves the law of energy. We have a similar message from quantum theory of the electrons indeed!

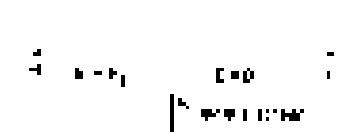

Fig. 31-4. Diffraction by a screen.

31-4. Diffraction of Light by a screen

It is now a good time to take up a somewhat different question which we can handle well: the machinery of this chapter. In the last chapter we said that when you have a discontinuity of the light cone coming through a screen, the direction of an electric field, the diffraction pattern, could be obtained by imagining instead that the holes were replaced by sources (positive or negative) distributed over the holes. In other words, the reflected wave is the same as though the hole were a new source. We learned earlier that the screen functioned, because the hole is, of course, just where there are no charges, where there are no canceling charges.

Let us first ask, "What is an opaque screen?" Suppose we have a completely opaque screen between a source S and an observer at P , as in Fig. 31-4(a). If the screen is "opaque" there is no field at P . Why is there no field there? According to the basic principle of superposition the field \mathbf{E}_{ext} at the point P is the sum of the fields delayed since the field from S the other charges provided. \mathbf{E}_{ext} , as we have seen above, the charges at the screen will be set to motion by the field \mathbf{E}_0 , and these charges generate a new field which, if the screen is opaque, must cancel exactly the field \mathbf{E}_0 on the back side of the screen. You say: "Well, it's a miracle that it becomes opaque!" Suppose it was not exactly right! If it were not exactly right, (remember that this opaque screen has some thickness), the field beyond the rear part of the screen would not be exactly zero. So, we being wise, it would set into motion some other charges on the inner side of the screen, and this makes \mathbf{E}_{ext} more \mathbf{E}_0 trying to get the total field near zero. So if we make the screen more and more opaque, there is no residual field, because there is enough opportunity to totally get the thing quieted down. Just as when S on page 5 above we should say that is 31-10

screen does not yield image rays, so we have a reflected expansion of the light source. This shows, however, that this enough of the incident material, even gold, is transparent.

Now let us see what happens with an opaque screen which has holes in it, as in Fig. 37.3(b). What do we expect for the field? The field at P can be approximated as a sum of two parts: the first due to the source, E_{source} , the field E_{wall} of the wall, i.e., due to the motions of the charges in the walls. We might expect the motions of the charges in the wall to be negligible, but we can find out this first very quickly in a rather simple way.

Suppose that we were to take the same screen but just up to the index, illuminated in just the left of the figure. We imagine that no charge moves by the entire distance to the wall. And if you look at the places where the holes were at least λ . Now let us calculate the field at P . The field E_{source} is necessarily zero in case (b), but there *is* a change in the field from the source plus the field due to the motions of the atoms in the wall and in the plug. We can write the following equations:

$$\text{Case (b)}: E_{\text{at } P} = E_{\text{t}} + E_{\text{wall}},$$

$$\text{Case (c)}: E_{\text{at } P} = 0 = E_{\text{t}} + E_{\text{wall}} - E_{\text{plug}},$$

where the signs refer to the case where the plug is in place, b, or is of no use, the same as both cases. Now, if we subtract the two equations, we get

$$E_{\text{at } P} = (E_{\text{wall}} - E_{\text{t}}) - E_{\text{plug}},$$

Now if the holes are not too small (say many wavelengths in size), we would not expect the presence of the plug to change the backward arrow of the wall except possibly for a little bit around the edges of the holes. Neglecting this small effect, we expect $E_{\text{wall}} = E_{\text{t}}$ and obtain that

$$E_{\text{at } P} = -E_{\text{plug}},$$

We have the result that the field at P when there are holes in a screen (case (b)) is the same (except for sign) as the field that is produced by that portion of a complete screen with which is located near the hole and of the sign is just right which, since we are usually interested in intensity, which is proportional to the square of the field. It seems like an amazing result and it is no argument. It is, however, not only this approximately true, but too sure holding, but useful, and is the justification for the usual theory of diffraction.

The field E_{plug} is computed in any particular manner by considering all the motion of the charge wherever in the screen is just right which will cancel out the field E_{t} on the back of the screen. Once we know the motions, we add the radiating fields at P due just to the charges in the plug.

We remark again that this theory of diffraction is only approximate, and will be good only if the holes are not too small. For holes which are too small the E_{plug} will not be small and then the difference between E_{wall} and E_{t} , (which difference we have to be zero) will be comparable to or larger than the small E_{t} , hence our approximation will no longer be valid.

Radiation Decaying, Radio Scattering

32-1 Radiation redshift

In the last chapter we learned that when a system is oscillating, energy is carried away, and we derived a formula for the energy which is radiated by an oscillating system. If we know the electric field, then the average of the square of the force times a_0 is the amount of energy that passes per square meter per second through a surface normal to the direction in which the radiation is going.

$$S = \text{cav}(E^2). \quad (32.1)$$

Any oscillating charge radiates energy; for instance, a short antenna radiates energy. If the system radiates energy, then in order to account for the conservation of energy we must add that power is being delivered along the wires which feed into the antenna. That is, in the driving circuit the antenna acts like a transformer, or a power source, energy can be "lost" if the energy is not really lost, it's really radiated out, but as far as the circuit is concerned, the energy is lost. In an ordinary resistance the energy which is "lost" goes into heat. In this case the energy which is "lost" goes out in a wave. So, from the standpoint of circuit theory, without considering how the energy goes, the net effect on the circuit is heating—energy is "lost" from the circuit. Therefore the circuit appears to the generator as having a resistance, even though it may be made will be hard, good copper. In fact, if it is well built it will appear as almost a pure inductor with very little inductance or capacitance because we would like to radiate as much energy as possible out of the system. This resistance that an antenna shows is called the radiative resistance.

If a current I is going in the antenna, then the average rate of stored power S delivered to the antenna is the average of the square of the current times the resistance. The rate at which power is radiated by the antenna is proportional to the square of the current, in the antenna, of course, because all the fields are proportional to the currents, and the energy losses are proportional to the square of the field. The coefficient of proportionality between radiated power and (I^2) is the radiative resistance.

An interesting question is, what is this radiative resistance due to? Let us do a simple calculation, let us say that currents are carried up and down in an antenna. Well, first that we have to put work in. If the antenna is to radiate energy, if we take a charged body and accelerate it up and down it radiates energy; if a proton, charged, would radiate energy. It is one thing to calculate from the conservation of energy that energy is lost, but another thing to answer the question, against whom are we doing the work? That is an interesting and very difficult question which has been incompletely and satisfactorily answered for electrons, although it has been for photons. What happens is this: in an antenna, the fields generated by the moving charges in one part of the antenna react on the moving charges in another part of the antenna. We can calculate these forces and find out how much work they do, and so find the right rule for the radiation resistance. When we say "We can calculate," that is not quite right—we cannot, because we cannot yet calculate the laws of electrodynamics, at least not now, and, at best, certainly do we know what the electric field is. We know the formula (23.1), but in present

is not considered how to calculate the fields inside the wave zone. Of course, energy conservation of energy is valid, we can calculate the result all right without knowing the fields at short distances. This is another of the reasons why using this argument is difficult. Thus, we can't find the formula for the forces at short

32-2 Radiation resistance

32-2 The rate of radiation of energy

32-3 Radiation damping

32-4 Independent sources

32-5 Scattering of light

distance a , by knowing the field at every large distance, by using the law of conservation of energy, he can go larger or smaller than zero.

The problem is the case of a single electron & this, if the e is only one charge, what can the force be? It has been proposed in current string theory, that the charge e is a little ball and that one part of the charge acts on the other part. Because of the decay in the collision across the fine electron, the front is not exactly in phase with the medium. That is, if we know the electric scattering shift, we know the "position" of the source. So the various internal forces are constant and there is no net force. But if the electron is accelerating, the front of it, the time delay Δt , the front which is moving on the front from the back, the back is not exactly due to the force on the back & the front, because of the delay in the effect. This leads to the situation, that is a lack of the effect, or a small effect, the thing holds itself back by its own traps. This model of the origin of the resistance to acceleration, the radiation resistance of a moving particle, has now many difficulties, because this present view of the electron is, that it is very little ball. If this problem has never been raised. Nevertheless we can conclude exactly, what the net radiation resistance is, and that is, how much loss. It is, must be with the accelerated charge, in spite of not knowing directly the mechanism of how that loss comes.

32.2 The rate of radiation of energy

Now we can calculate the total energy radiated by an accelerating charge. To keep the discussion general, we shall take the case of a charge moving in any which way, but nonrelativistically. At a moment when the acceleration a , say, vertical, we know that the electric field that is generated is the charge multiplied by the projection of the velocity vector, divided by the dielectric. So we know the electric field at any point, and we therefore know the square of the electric field and also the energy $c^2 E^2$ passing through a unit area per second.

This quantity $c^2 E^2$ is quite often in experiments involving radiation proportional to the square of frequency, and it is an easy number. For instance, it is the result for $\nu = 337$ ohm. So the power, or work per second, is equal to the average of the field squared, divided by 4π .

Using our expression (32.1) for the electric field, we find that

$$S = \frac{e^2 c^2 \sin^2 \theta}{mc^2 \epsilon_0 \pi r^2} \quad (32.2)$$

is the power per second, radiated in the direction θ . We notice that it goes down as the square of the distance, as we said before. Now, if we wanted the total energy radiated at all directions, then we must integrate (32.2) over all directions. First, we multiply by the $d\Omega$. To find the solid angle, it flows $d\Omega$ in a little angle $d\Omega$ (F_θ). Now, we need the area of a spherical sector. The way to think of it is this: there is the radius, then the width of the annular segment is $r d\theta$, and the circumference is $2\pi r \sin \theta$, because $\sin \theta$ is the radius of the circle. So the area of the little piece of the sectors is $2\pi r \sin \theta d\theta \cdot r d\theta$.

$$dA = 2\pi r^2 \sin \theta d\theta \quad (32.3)$$

By multiplying the term (32.2) the power per surface meter, by the area in square meters included in the small angular section $d\Omega$, the amount of energy that is liberated in this small bin between $\theta = 0 - d\theta$, then we integrate this over all the angles from 0 to 2π :

$$J = \int_{0}^{2\pi} S d\Omega = \frac{c^2 e^2}{512 \pi \epsilon_0 r^2} \int_{0}^{\pi} \sin^2 \theta d\theta \quad (32.4)$$

By writing $\sin^2 \theta = (1 - \cos^2 \theta)/2$ and using $\int_0^\pi \cos^2 \theta d\theta = \pi/2$. Using this fact, we finally get

$$P = \frac{dE/dt}{4\pi r^2 c^2} \quad (32.5)$$

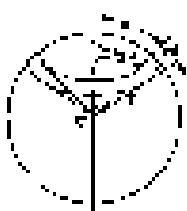

Fig. 32.1. The case of a spherical object of $2\pi r^2 \sin \theta d\theta$.

This expression deserves some remarks. First of all, since the value of $\langle \hat{w}^2 \rangle$ depends on the a^2 in (32.5) we shall be too scared of the vector \mathbf{w} , that is, \sqrt{a} , the length of the vector squared. Secondly, the flux (32.2) was calculated using the mean ω , acceleration; that is, the acceleration at the time t at which the energy was passing through the sphere was radiated. We might like to say that the energy was in the lines of \mathbf{E} at this time. This is not exactly true, it is only an approximation. The exact time when the energy is released can not be deduced precisely. All we can really calculate precisely is what happens in a complete motion, like an oscillation or something where the acceleration finally comes. Then when we find is that the total energy flux per cycle is the average of acceleration squared, for a complete cycle. This is what should really appear in (32.2), i.e., if it is radiation with an acceleration that is finite, y and finally zero, then the total energy loss per second is the time integral of (32.2).

To illustrate the consequences of formula (32.2) let us have an oscillating system in mind, what happens if the displacement x of the mass goes oscillating so near the acceleration $a = -\omega_0^2 x/c^2$? The average of the acceleration squared over a cycle trembles and we have to be very careful with the square things that get arising in our calculation. It really is the cosine, and the average of \cos^2 is obviously unity.

$$\langle x^2 \rangle = \langle x^2(t) \rangle$$

Integration:

$$P = \frac{q^2 \omega_0^2 / c^2}{12 \pi^2 f^3}. \quad (32.6)$$

The formulas we are now discussing are relatively advanced and more or less modern; they date from the beginning of the twentieth century, and they are very famous. Because of their historical value, it is important for us to be able to understand them in older books. In fact, the older books also used a system of units different from our present-day system. However, all these complications can be avoided easily in the final formulas derived with electrons by the following rule. The quantity q^2/c^2 , where q is the electronic charge (in coulombs), and, naturally, being greater or c^2 , it is very easy to calculate it even in the old system as numerically equal to 1.5158×10^{-16} , because we know that, numerically, $q_e = 1.60205 \times 10^{-19}$ and $c = 2.99792 \times 10^8$. Therefore we shall often use the convenient old notation

$$P = \frac{q^2}{c^2 \pi r}. \quad (32.7)$$

If we use the above numerical values of q at the basic frequencies and frequencies though they were written in mks units, we will get the right numerical results. For example, the older than 25 years is $P = 90^2 \pi^2 / c^2 \cdot 4 \text{ cm} \cdot 1 \text{ psec} = 6.67 \text{ erg/sec}$ at a polder and at the most distance $r = d^2/4\pi c^2$ or d^2/λ , with $d = 1.3183 \times 10^{-14}$ mks.

32.3 Radiation damping

Now, let's first consider a system that loses a certain energy without reason. If we put a charge on the end of a spring (one electron in an atom which has $\omega_0^2 \gg 1$) imagine ω_0 , and we start it oscillating and let's say it will do oscillate forever, even if it is in empty space nothing comes from anything. There is no oil, no resistance, in an empty space we "vibrate". But, nevertheless it will not oscillate, as we might once have said. However, however if it is charged it is radiating energy, and therefore the oscillation will slowly stop on. How about? What is the ζ of such an oscillator caused by the electrodynamic effects, the so-called radiation resistance or radiation damping of the system? The ζ of any oscillating system is the least energy content of the oscillation at any time divided by the energy loss per radian:

$$\zeta = \frac{\dot{E}}{dE/dt}.$$

Or another way to write it, since $dE/dt = -dE/dt$, $(dE/dt)/(\omega_0/\Delta\omega) = -dE/dt/\Delta\omega/2$.

$$R = \frac{dE}{d\omega_0/\Delta\omega} \quad (12.8)$$

For a given dE/dt it tells us how the energy of the oscillator varies with $\omega_0/\Delta\omega = -\langle E \rangle / Q^2 \omega_0^2$, which are the variables $R^2 = -dE/d\omega_0/\Delta\omega$. If E_0 is the initial energy at $t = 0$,

To find the $\langle E \rangle$ for a radiator, we go back to (12.8) and use (12.6) too and find

Now what do we use for the energy E_0 of the oscillator? The kinetic energy of the oscillator is $\frac{1}{2}mv^2$, and the zero kinetic energy is $m\omega_0^2 r_0^2/4$. But we remember that for the total energy of an oscillator, we have one-half its kinetic and half its potential energy, and so we divide our result, and find for the total energy of the oscillator

$$E = \frac{1}{2}mv^2 \omega_0^2 \quad (12.9)$$

What do we use for the frequency in our formulae? We use the natural frequency ω_0 , because for all practical purposes, that is the frequency at which our atom is radiating, and for v we use the electron mass m_e . Then, making the necessary corrections and cancellations, the formula comes down to

$$\frac{1}{Q} = \frac{4\pi v^2}{\lambda c m_e^2} \quad (12.10)$$

In order to see it better and in a more justified form, we write it using in place of v^2/m_e , c^2 , and the factor $4\pi^2/3$, which has been written as $2\pi^2/3$, since Q is dimensionless. The combination c^2/m_e^2 would be a quantity only of the electron charge and mass, an intrinsic property of the electron, and it must be a length. It has been given a name, the *characteristic radius*, because its early atomic students at first were inclined to equate the radiation resistance to the size of the atom. One part of the electron is acting, on the other parts, it needs to have an electron whose dimensions are of this general order of magnitude. However, this quantity no longer has the significance that we had, but the electron really has size 4 radius. Numerically, the magnitude of this radius is

$$r_0 = \frac{c^2}{m_e^2} = 3.82 \times 10^{-16} \text{ m} \quad (12.11)$$

Now let us actually calculate. In Q of an atom that is emitting light, λ , say 6500 angstroms. For a sodium atom, the wave length is roughly 6000 angstroms, in the yellow part of the visible spectrum, and has a typical wavelength. This

$$Q = \frac{c^2}{\lambda m_e^2} \approx 5 \times 10^9 \quad (12.12)$$

so the Q of an atom is of the order 10^9 . The mean total resistance of an oscillator will oscillate for 10^9 radiations about 10^9 oscillations, before its energy falls by a factor $1/e$. The frequency of oscillation of light corresponding to 6000 angstroms, $\nu = c/\lambda \approx$ on the order of 10^{14} cycles/sec, and therefore the lifetime, the time it takes for the energy of a radiating atom to fall off by a factor $1/e$, is on the order of 2×10^{-10} sec. In ordinary circumstances, radio emitting sources usually take about 10¹⁰ sec to radiate. This is only for atoms which are in empty space, not being disturbed in any way. If the electron is in a solid and it has to go through some of other electrons, then there are additional resistances and different damping.

The effective resistance term, γ , in the resistor $R = R_0 + \gamma$, the resistance can be found from the relation $1/Q = \gamma \omega_0^2$, and we remember that the size of γ determines how wide the resonance curve is (Fig. 11-2). Thus we have just computed the width of spectral lines for freely radiating atoms. Since $R = R_0 + \gamma \omega_0^2$, we find

$$\begin{aligned} \gamma \omega_0 &= 2\pi \cdot 6000^2 \cdot 10^9 \cdot 4\pi^2/3 = 2\pi c^2/3\omega_0 \\ \gamma \cdot 2\pi \cdot 6000/3 &= 1.18 \times 10^{-11} \text{ m} \end{aligned} \quad (12.13)$$

9.1 Interference sources

In preparation for our second topic, the scattering of light, we must now discuss a certain feature of the phenomenon of interference that we neglected or discussed previously. This is the question of when interfering does not occur. If we have two sources S_1 and S_2 , with amplitudes A_1 and A_2 , and we make an observation in a direction \hat{r} (in which the phases ϕ_1 and ϕ_2 of the two signals are ϕ_1 and ϕ_2 (a combination of the actual time of arrival from and the delay time, depending on the position of observation), then the energy that we receive can be found by summing over the two complex numbers $A_1 e^{i\phi_1}$ and $A_2 e^{i\phi_2}$ (as in Chapter 6) and we find that the resultant energy is proportional to:

$$A_R^2 = A_1^2 + A_2^2 + 2A_1 A_2 \cos(\phi_1 - \phi_2). \quad (9.1.1)$$

Now if the cross term $2A_1 A_2 \cos(\phi_1 - \phi_2)$ were not there, then the total energy that would be emitted in a given direction would simply be the sum of the energies, $A_1^2 + A_2^2$, and it would be like adding two waves separately, which is what we usually expect—that is, the combined intensity of light coming to somewhere from two sources is the sum of the intensities of the two lights. On the other hand, if we have things just right and we have some form of interference, because there is also some coherence, then there are circumstances in which this term is of no importance; that is, we could say the interference is approximately lost. Of course, in nature it is always there, but we may not be able to detect it.

Let us consider some examples. Suppose first that the two sources are $7000 \text{ km}/\text{sec}$ apart, as in an interplanetary experiment. Then in a given direction it is true that there is a very definite value of cross source elements. And, on the other hand, if we are just using, i.e., one dimension of wave-lengths, which is no distance at all (or a very, almost, but not quite, negligible one), we are averaging the effects over a range very wide compared with one wavelength, from one edge of the celestial plane and the other, and so very rapidly. If we take the average of the intensity over a long enough time interval, which goes plus minus, plus, minus, as we move around, averages to zero.

So if we average over a long time, when the phases change very rapidly with position, we get no interference.

Another example. Suppose that the two sources are two independent radio transmitters—no single one star being fed by two wires, which you know that the phases are kept together—but two independent sources—and that they are, for example, constant at the same frequency f . It is very hard to make them at exactly the same frequency without slightly varying them together. In this case we have what we call two independent sources. Of course, since the frequencies are not exactly equal, although they started in phase, one of them begins to get a little ahead of the other, and pretty soon they are out of phase, and then it goes off further ahead, and so the two start to be in phase again. So the phase difference between the two is gradually changing with time. But if one observes for a long time, we cannot see that little time. If we average over a much longer time, even with c the velocity very well and fully like δt at the 10^{-12} "heads" in seconds, if these settings and turnings are too rapid for our equipment, before changing this way and coming

back to the first one, the phases shall average out, we get no interference.

One has many books which say that two random light sources never interfere. This is not a statement of physics, but is merely a statement of the degree of consistency of the technique of the experiments at the time the book was written. What happens is a light source is radiating one atom radius, then another atom radius, and so forth, and we have just seen that atoms radiate a train of waves only for about 10^{-12} sec; after 10^{-12} sec, some atoms have probably taken over, then another atom takes over, and so on. So the phases can really only stay the same for about 10^{-12} sec. Therefore, if we average for very much more than 10^{-12} sec, we do not see any interference from two different sources, because they cannot link their phases steady for longer than 10^{-12} sec. With phototubes, very high-speed ones, in

is possible, and one can show that there is an interference which varies with time, up and down, in about 10^{-8} sec. But most detection equipment, of course, does not look at such fine time intervals, and thus was no interference. Only with the eye, which has a length of a second, averaging time, there is no chance whether or not seeing an interference, because two coherent waves may cancel.

Recently it has become possible to make light sources which get around this difficulty by making all the photons fit together to travel. The laser which does this is very complicated thing, and has to be understood in a quantum-mechanical way. It is called coherent, and it is possible to produce from a laser a source in which the interference frequency, the instant which the phase is kept constant, is very much larger, say 10^{12} sec. This is sort of the order of a hundredth, a tenth, or even one second, and so, with ordinary binoculars one can pick up the frequency between two different lasers. One can easily detect the pulsing of the lasers between two sources. Some day, right, someone will have to demonstrate an audience through a wall, in which the laser can show that there is some change. In you are asked.

Another case in which the interference averages out is that in which, instead of having only two sources, we have many. In this case, we would write the expression for A_0 as the sum of a whole lot of amplitudes, complex numbers, a_1 to a_n , and we would get the square of each one, all added together, if there were no interaction between each pair, and if the a_i 's were not real, that the total average out, there were no interference of individual ones. It may be that the various sources are arranged in such fashion that this may, although the phase difference between a_1 and a_2 , etc., is considerable, it is very different from that between a_1 and a_3 , etc. So we might get a whole lot of waves, many plus minus signs all averaging out.

So it is that in many cases, when we do not see the effects of interference, this is only a collective effect in every equal to the sum of all the intensities.

22-5 Scattering of light

The above leads us to the fact which occurs in all cases as a consequence of the interaction of photons with charges. When we were discussing the index of refraction, we saw that an incoming beam of light will make the atoms vibrate, the electric field of the incoming beam drives the electrons up and down, and they radiate because of their motion, too. This scattered radiation contributes a wave in the same direction as the incoming beam, but at somewhat different phases, and this is the origin of the index of refraction.

But what can we say about the interaction of scattered light in some other direction? Obviously, if the atoms are very haphazardly located in a rock for example, it's easy to find that we get nothing in a long distance. However, if we are adding a lot of waves, and their phases always changing, and the result comes to zero. If the object is, however, located, then the total intensity in any direction is the sum of the intensities that are scattered by each atom, as we have just discussed. You remember, the atoms in a gas are in actual motion, so that although the relative phase of wavelet to a definite atom does the same, will be quite different and therefore the wave coming from will average out. Therefore, the final intensity in light is scattered in a given direction by a gas, we get that only the effects of one atom is multiplying 10²³ intensity, it comes by the number of atoms.

Earlier we remarked that the propagation of scattering of light of various wavelengths along the line of sight. The sun light goes through the air, and when we look to one side of the sun, say at 40° to the sun, we see blue light, and we now have to calculate whether such light we see are with it is also.

If the incident beam has the electric field $\mathbf{E} = E_0 e^{i\omega t}$ at the point where the atom is located, we know that an atom in the atom will vibrate up and down in response to this \mathbf{E} (Fig. 22-2). From Eq. (22.3) the amplitude will be

$$\mathbf{a} = \frac{e}{m(\epsilon_0 + m^2/\omega^2)} \mathbf{E} \quad (22.13)$$

We could include the damping, and the possibility for the wave to be scattered by different frequency and size over the various frequencies, but the simplicity let us just take one oscillation and neglect the damping. Then the response to this constant electric field, which we have already read in the calculation of the index of refraction, is simply

$$\mathbf{x} = \frac{q_0 E_0}{m\omega^2} \quad (32.16)$$

We could now easily calculate the intensity of light that is emitted if we know ω , because, using formula (32.5) and the answer to our question in the diagram, it is given by

For the time being this however, we shall simply calculate the total amount of energy scattered in all directions just to save time. The total amount of light energy scattered, scattered in all directions by the single atom, is of course given by Eq. (32.7). So, putting together the various pieces and regrouping them, we get

$$\begin{aligned} P &= (\epsilon_0^2 n^4 / 16 \pi c^2) q_0^2 E_0^2 / (m^2 \omega^4 - \lambda_0^2) \\ &= 1.602 \times 10^{-24} \text{ ergs} / (16 \pi^2 n^4 m^2) \lambda_0^4 / (\omega^4 - \lambda_0^2) \\ &\propto \epsilon_0^2 n^4 \lambda_0^4 / (\omega^4 - \lambda_0^2) \end{aligned} \quad (32.17)$$

In other words, power is emitted in all directions.

We have written the result in the above form because it is then easy to remember: First, the total energy that is scattered is proportional to the square of the incident wave. What does that mean? Obviously, the source of the incident field is zero orthogonal to the energy which is being transferred. In fact, the energy incident on ω , at a certain per cent, is sent into the energy (ω^2) of the scattered field, and if Δ is the maximum value of Δ , then $\omega^2 = \frac{1}{2}\Delta^2$. In other words, the total energy scattered is proportional to the energy per second into that angle i.e., the "light" density of the scattering is the very bright or the very bright to low.

Next, what fraction of the incoming light is scattered? Let us imagine "the angle" with a certain area, let us say a , in the beam to be the material target because this would catch light, and so on; we need an imaginary area a in the space. The total amount of energy that would pass through this surface in a given dimension is proportional, both to the incoming intensity and to a , and it would be

$$P = I_0 A \epsilon_0 N / 4\pi \quad (32.18)$$

Now we iterate on this, we say that the amount of the total amount of intensity which is the amount which would fall on a certain geometrical area, and we give the answer by giving two rates. That answer, then, is independent of the incident intensity, it gives the "rate of intensity scattered" in the same incident per second per meter. In other words, the rate

$$\frac{\text{total energy scattered per second}}{\text{energy incident per square meter per second}} \text{ is an area}$$

The significance of this area is that, (1) the area product is equal to that area we were to be quoted in cm^2 sometime. (2) that is the amount of energy that would have been by the area.

This area is called a cross section for scattering. The idea of a cross section is well established, when you write a minimum cross section proportional to the intensity of the beam. In such cases one always describes the amount of the absorption by saying what the effective area would have to be to pick up the amount of the beam. If there were no mass in any way that this resistance actually has such an area. If there were no mass present, but a mass which is shaking up and down, there would be no mass density associated with it, physically. It is merely a way of expressing the amount to a certain kind of problem; it tells us what area the equivalent beam would

have no air to scatter to account for the much energy scattering at. Thus, for our case,

$$\tau = \frac{8\pi^4}{3} \cdot \frac{\alpha^4}{(\omega^2 - \omega_0^2)^3} \quad (2.19)$$

The subscript is to "scattering".

Let's look at some numbers. First, if we go to a very low natural frequency ω_0 , or to completely unbound electrons, for which $\omega_0 = 0$, then the frequency is constant, and the wave function is a constant. This low-frequency term, or the first electron current density, is known as the Rayleigh scattering cross section. It has area whose dimensions are approximately 10^{-13} meter, times or less, on a side, i.e., 10^{-31} square meter, which is quite small.

On the other hand, if we take the case of light to be ω , we remember that for the excited frequencies of the oscillators are higher than the frequency of the light that we use. This means, for a fine approximation, we can disregard ω^2 in the denominator, etc. we find that the scattering is proportional to the fourth power of the frequency. That is to say, light which is of higher frequency by, e.g., a factor of $\omega_0 > 10^{10}$ times, more intensely scattered, which is a considerable difference. This means that the light which fluctuates twice the frequency of the incident end of the spectrum, is scattered as a far greater intensity than light which we look at the sky in only that glorious time that we see all the stars!

I have got several points to be stated about the atmosphere. One interesting question is why do we ever see the clouds? When in the clouds some friend Franklykilly knows it is the condensation of water vapor. But, of course, the water vapor is always in the atmosphere, however, condenses on why don't we see it, i.e.,? After it condenses it is perfectly obvious, it won't there, now it is clear that the mystery of where the clouds come from is not really such a difficult mystery as "Where does the water come from?" but has to be resolved.

We have just explained that every atom scatters light, and of course the water vapor will scatter light too. The trouble is, if you when the water is combined into clouds, does it scatter such a correspondingly greater amount of light?

Consider what would happen if, instead of a single atom, we had an aggregate of atoms, say two, very close together and spaced with the wavelength of the light. Recall that atoms is only an angstrom or so across, while the wavelength of light is, say, 500 angstroms, so when they form a dumbbell-like atoms together, they can be very close together compared with the wavelength of light. Then when the electric field is a sum of the two electric fields in phase, i.e., consider the amplitude that were ψ_1 with a single atom, and the energy which is proportional is the square of $|\psi_1|$ with one atom, it is with a single atom, not twice! So twice of atoms require no greater more energy than the single atom. Our argument, i.e., the pictures are independent is based on the assumption that there is a real and large difference in phase between any two atoms, which is true only if they are several wavelengths apart and randomly spaced, in moving. But, "they are right next to each other, they necessarily scatter in phase, and they have a coherent interference which gives us an increase in the scattering."

If we have N atoms in a line, which is a tiny droplet of water or other substance, it will be driven by the electric field in about the same way as before (the effect of one atom on the others is not important; it is just to get the idea anyway), and the amplitude of scattering from each one is the same, so the total field which is scattered is N -fold increased. The intensity of the light which is scattered is then the square, or N^2 -fold, increased. We would have imagined, if the atoms were spread out in space, only N times as much as intensity we get N^2 times as much as 1. That is to say, the scattering of water in terms of N molecules is not $\sim N$ times more intense than the scattering of the single atoms. Since however approaching the scattering increases, there is increase not different. Now, when does the analogy begin to fail? How many atoms are we put together before we cannot ignore the aggregate and consider it a dumbbell? When the water droplets are big, but still the size of the wavelength or so, then the atoms are no longer close

place because they will scatter light. So as we keep increasing the size of the droplets we get more and more scattering until we have about $10\text{ }\mu$ in diameter. At this size of a wave length, and then the scattering does not increase anywhere nearly as rapidly as the unperturbed light. Furthermore, the blue disappears, because the long wavelength the charge can be higher before this limit is reached, then they can be for short wavelengths. Although the short waves scatter more per atom than the long waves, there is a larger enhancement for the red end of the spectrum than for the blue end where all the charges are bigger than the wavelength, so the color is shifted from the blue toward the red.

Now we can make an experiment that demonstrates this. We can make particles that are very small at first, and then grow, if you like. We used a solution of sodium thiosulfate that was sulphuric acid, which precipitates very finely divided sulphur. As the sulphur precipitates the grains get continually smaller, and the scattering is a little clumpy. As it precipitates more it gets more clusters, and then will get sulphur crystals yet bigger. In addition, the light which goes straight through will have the blue taken out. That is why the sunsets are red, of course, because the light that comes through a lot of air to our eye has had a lot of blue taken out, and so is yellow-red.

Finally, there is one other important fact which really belongs in the next chapter, on polarization, but it is so interesting that we put it in now. This is the photoelectric effect of the scattered light which is a particle interaction. The electric field in the incoming light is oscillating in some way, and the driven oscillations of the atoms in the same direction, and if the atoms are scattered occur at right angles to the beam, we will see polarized light, that is to say, light in which the electric field is going only one way. In general, the atoms can vibrate in any direction at right angles to the beam, but if they are driven coherently toward or away from us, we do not see this. So if the incoming light has an electric field which changes and oscillates in any direction, which we call unpolarized light, then the light which is coming out at 90° to the beam will also be only one direction. (See Fig. 32-3.)

There is a substance called galena which has the property that when light goes through it, only one piece of the electric field which is along one particular axis can get through. We can use this to test for polarization, and indeed we find the light scattered by the hydrosolids to be a singly polarized.

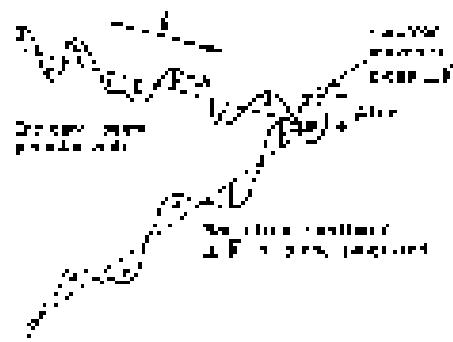

Fig. 32-3. Illustration of the origin of the polarization of scattered scattered straight engine to the medium beam.

Polarization

33-1 The electric vector of light

In this chapter we shall consider those phenomena which depend on the fact that the electric field E describes the light as a vector. In previous chapters we have not been concerned with the direction of oscillation of the electric field except to note that the electric vector E is always perpendicular to the direction of propagation. The particular direction in the plane does not concern us. We now consider those directions whose control factor ϵ_{xy} is the particular direction of oscillation of the electric field.

In ordinary monochromatic light, the electric field E oscillates at a definite frequency, but since the x-component and the y-component are not independently at a definite frequency, we must first consider the resultant effect produced by superposing two independent oscillations at right angles to each other. What kind of effect is this? It's much like that of a longitudinal and a transverse wave which oscillate in the same frequency. If one tends to an vibration along the x -axis and the y -vibration in the same phase, the result is a vibration in a new direction in the system. Figure 33-1 illustrates the superposition of different amplitudes for the x-vibration and the y-vibration. But the results shown in Fig. 33-1 are not the only possibilities; in all of these cases we have assumed that the x-vibration and the y-vibration are in phase, but this need not be the way. It could be that the x-vibration and the y-vibration are out of phase.

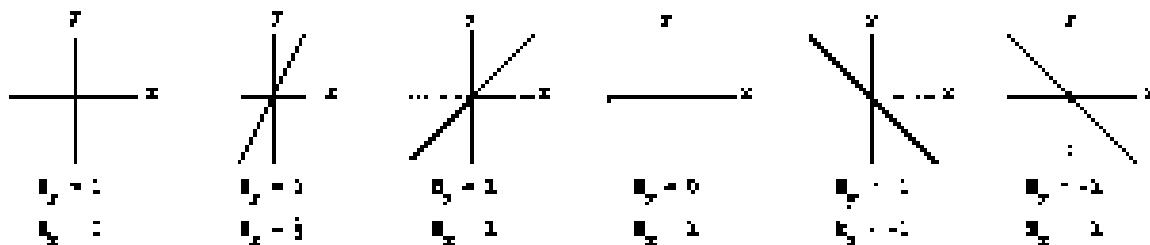

Fig. 33-1. Superposition of x-vibration and y-vibration in phase.

When the x-vibration and the y-vibration are out of phase, the electric field vector moves around in an ellipse, and we can illustrate this in a familiar way. If we hang a ball from a support by a long string, so that it can swing freely in a horizontal plane, it will execute "circular" oscillations. If we imagine horizontally x - and y -coordinates with their origin at the rest position of the ball, the ball will swing in either the x or y direction with the same fundamental frequency. By selecting the proper initial displacement and initial velocity v_0 , we can let the ball oscillate in straight paths, back and forth, or along any straight line in the xy -plane. These motions of the ball are analogous to the oscillations of the electric field shown illustrated in Fig. 33-1. In such line cases, since the x-vibration and the y-vibration both have constant frequency at the same time, the x and y oscillations are in phase. But we know that the actual motion of the ball is motion in an ellipse, which corresponds to oscillations in which the x - and y -oscillations are out of phase. The superposition of x and y vibrations which are not in phase is illustrated in Fig. 33-2. On a slightly elliptical orbit in the plane of the vibration are plotted two vibrations. The path of the ball is that the electric vector moves around in an ellipse. The motion is a straight line in a particular

34-1 Anomalous refraction

corresponding to a phase difference of zero (or an integral multiple of π); modulated electric waveforms have amplitudes with a phase difference of $\pi/2$ (or any odd integral multiple of $\pi/2$).

In Fig. 33-2 we have labeled the electric field vectors in the x - and y -directions with complex numbers, which is a common representation at higher frequencies. We project the real and imaginary components of the complex electric vector to this notation with the x - and y -components of the field. The x - and y -components plotted in Fig. 33-1 and Fig. 33-3 are actual electric fields that we can measure. The real and imaginary components of a complex electric field vector are only mathematical conveniences and have no physical significance.

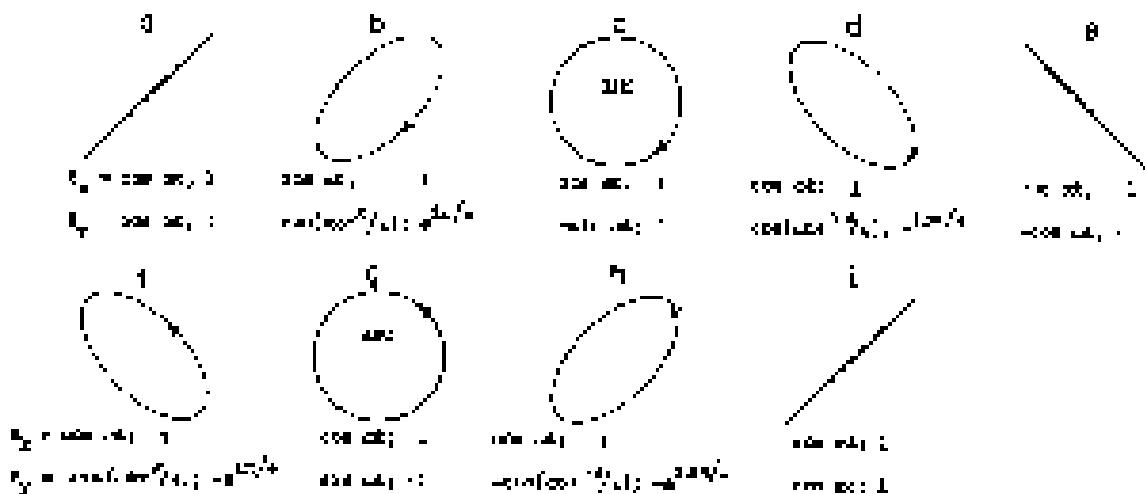

Fig. 33-2. Superposition of x and y vibrations with equal amplitude but vertical phase. The components E_x and E_y are expressed in both real and complex notation.

Now for some terminology. Light is linearly polarized (sometimes called plane polarized) when the electric field oscillates on a straight line. Fig. 33-1 illustrates linear polarization. When the end of the electric field vector revolves in an ellipse, the light is elliptically polarized. When the end of the electric field vector rotates around a circle the light is circular polarized. If the end of the vector is nearer when we look at it to the right, comes straight toward us goes around to the counterclockwise direction, we call it right-hand circular polarization. Figure 33-3(a) illustrates right-hand circular polarization, and Fig. 33-3(b) shows left-hand circular polarization. In both cases the light is coming out of the page. Our convention for labeling left-hand and right-hand circular polarizations is consistent with that which is used today for the outer electrons in atoms which exhibit polarization (e.g., electrons). However, in some books one finds the opposite convention is used, so one must be careful.

We have considered linearly, circularly, and elliptically polarized light which covers everything except for the case of unpolarized light. Now how can we light be unpolarized when we know that it must exhibit in one or another of these effects? If the light is not absolutely monochromatic, i.e., if the x - and y -phases are not kept perfectly together, or if the electric vector just vibrates in one direction, the polarization is constantly changing. Remember that one atom emits during 10^{-9} sec, and if a beam emits over air polarization, and then another atom emits light with a different polarization, the polarizations will change every 10^{-9} sec. If the polarization changes more rapidly than we can detect it, then we call the light unpolarized, because all the effects of polarization find average out. None of the few simple effects of polarization would show up with unpolarized light. But if we look from the definition, light is unpolarized only if we are unable to find out whether the light is polarized or not.

20-2 Polarization of scattered light

The first example of the polarization effect that we have already discussed is the scattering of light. Consider a beam of light, for example from the sun, passing through air. Electric field will produce oscillations of charges in the air, and motion of these charges will radiate light with its maximum intensity in a plane normal to the direction of vibration of the charges. The beam from the sun is unpolarized, so the direction of polarization changes randomly. If we consider light scattered at 90°, i.e. vibration of the charged particles relates to the observer only when the vibration is perpendicular to the characteristic line of sight, and then light will be polarized along the direction of vibration. So scattering is an example of one more of the many polarization effects.

20-3 Birefringence

Another interesting effect of polarization is the fact that there are substances for which the index of refraction is different for light linearly polarized in one direction and nearly polarized in another. Suppose that we had some medium which consisted of long, nonspinning molecules, longer than they are wide, and suppose that these molecules were arranged in the substance with their long axes parallel. Then what happens when the oscillating electric field passes through this substance? Suppose that because of the structure of the molecule, the vibration in the substance requires more energy to oscillate in the direction parallel to the axes of the molecules than they would require if the electric field tried to push them straight along the molecular axis. In this way we expect a different response for polarization in one direction from the polarization in other angles to that direction. Let us call the direction of the axes of the molecules the optic axis. When the polarization is in the direction of the optic axis the index of refraction is different than it would be if the direction of polarization were at right angles to it. Such a substance is called birefringent. It has two refractive indices, i.e. two indices of refraction depending on the direction of the polarization inside the substance. This kind of a substance can be calcite. In a birefringent substance there must be a certain amount of anisotropy, for one reason or another, in the medium itself. Our usual cubic crystal, which has the symmetry of a cube, cannot be birefringent. Our long needle-like crystals and rod-like molecules that are very metric, and one observes this effect very easily.

Let us see what effects we would expect if we were to shine polarized light through a plate of a birefringent substance. If the polarized wave is parallel to the optic axis the light will go through with one velocity; if the polarization is perpendicular to the axis, the light is transmitted with a different velocity. An interesting situation arises when, say, light is linearly polarized at 45° to the optic axis. Now the 45° polarization, we have already noticed, can be regarded as a superposition of the x- and the y-polarizations of equal amplitudes and in phase, as shown in Fig. 20-2(a). Since the x- and y-polarizations travel with different velocities, their phases change at a different rate as the light passes through the substance, but although the x- and y-polarizations are in phase, inside the material, the phase difference between x- and y-polarizations is proportional to the length of the substance. As the light proceeds through the material the polarization changes as shown in the series of diagrams in Fig. 20-2. If the thickness of the plate is just right to introduce $\pi/2$ phase shift between the x- and y-polarizations, as in Fig. 20-2(c), the light will come out elliptically polarized. Such a thickness is called a quarter-wavelength, because it introduces a quarter-cycle phase difference between the x- and the y-polarizations. If linearly polarized light is sent through two such thin plates, i.e. with some net plane polarization again, but at right angles to the original direction, as we can see from Fig. 20-2(d).

One can easily illustrate this phenomena with a piece of cellophane. Cellophane is made of long, fibrous molecules, and is not isotropic, since the fibers lie preferentially in a certain direction. To demonstrate this property we take a

is a linearly polarized light, and we can obtain it by sending unpolarized light through a sheet of polaroid. Polycryl, which we will discuss later in more detail, has the useful property that it transmits light that is linearly polarized parallel to the axis of the polaroid very well. Consequently, the light polarized in a direction perpendicular to the axis of the polaroid is strongly absorbed. When we pass unpolarized light through a sheet of polycryl, only one part of it emerges unchanged which is either (if parallel to the axis) or the polaroid goes through so that the transverse beam is identity polarized. This same property of polaroid is also useful in detecting the direction of polarization of a linearly polarized beam, or in determining whether a beam is linearly polarized or not. One simply passes the beam of light through the polaroid sheet and rotates the polaroid in the plane defined by the beam. If the light is not linearly polarized, it will not be transmitted through the sheet when the polaroid is turned in the direction of polarization. The transmission varies only slightly throughout when the axis of the polaroid sheet is rotated 1 through 90°. If the transmitted intensity is independent of the orientation of the system, the beam is not linearly polarized.

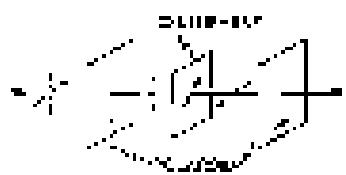

Fig. 30-3. An experimental observation of the birefringence of cellulose. The electric vectors in the light are indicated by the dotted lines. The axes of the polaroid sheets and their axes of the cellulose are indicated by arrows. The incident beam is unpolarized.

To demonstrate the birefringence of cellulose, we use two sheets of polaroid, as shown in Fig. 30-3. The first gives us a linearly polarized beam which we pass through the cellulose and then through the second polaroid sheet, which serves to detect any effect the cellulose may have had on the polarized light passing through it. If we first set the axes of the two polaroid sheets perpendicular to each other and rotate the cellulose sheet, we observe that in general the cellulose makes it possible for some light to pass through the second polaroid. However, there are two orientations of the cellulose sheet, at 45° angles to each other, which permit no light to pass through the second polaroid. These amounts given in which linearly polarized light is transmitted through the cellulose with no effect on the direction of polarization are those for the directions parallel and perpendicular to the optic axis of the cellulose sheet.

We suppose that the light passes through the cellulose with two different velocities to cause two different retardances, but this is not true without changing the directional retardation. When the cellulose is twisted halfway between these two orientations, as shown in Fig. 30-4, we see that the light transmitted through the second polaroid is bright.

It just happens that ordinary cellulose used in commercial packaging is very close to a half-wave thickness for most of the colors in white light. Such a sheet will turn the axis of linearly polarized light through 90° if the initial linear polarization is perpendicular to an angle of 45° with the optic axis, so that the beam emerging from the cellulose is propagating in the right direction to pass through the second polaroid sheet.

If we use white light in this form, rather than ordinary white, the cellulose sheet will be of the proper birefringent thickness only for a particular component of the white light, and the transmitted beam will have the color of this component. The color transmission depends on the thickness of the cellulose sheet, and we can vary the effective thickness of the cellulose by stretching it so that the light propagates through the cellulose at roughly one-and-a-half times longer path in the cellulose. As the sheet is stretched the transmissive color changes. With a thickness of 1.1 mm, the thickness can transmit blue light, still transmit yellow colors, the two polaroid sheets have their axes perpendicular, and the components of the light waves of the two polaroid sheets are parallel.

Another interesting application of aligned molecules is optical plastic. Certain plastics are composed of very long and complicated molecules which are joined together. When the plastic is crystallized, usually the molecules are all lined up in a more or less regular arrangement, many aligned in one direction or another, and so the plastic is not particularly transparent. Usually there are strains and stresses induced, and when the material is solidified, as the material is at first, there are

porous. However, if we apply tension to a piece of this plastic material, it is as if we were pulling a molecule of stress, and there will be more strings preferentially aligned parallel to the tension than in any other direction. So when a stress is applied to each plastic, they become birefringent, and one can see the effect of the birefringence by passing polarized light through the plastic. If we examine the transmitted light through a polaroid sheet, patterns of light and dark fringes will be observed (similar, if white light is used). The pattern of these fringes is applied to the sample, and by counting the fringes and seeing where most of them are, one can determine what the stress is. Engineers use this phenomenon as a way of finding the stresses in cylindrical pieces that are difficult to examine.

Another interesting example of a way of detecting birefringence is by means of a liquid substance. Consider a liquid composed of long, asymmetric molecules which carry a plus or minus charge near the ends of the molecule, so that the molecule is an electric dipole. In the collisions in the liquid the molecules will randomly bump into each other, with no net electric potential in one direction as a result. If we apply an electric field the molecules will tend to line up, and the moment they lose the dipole becomes extinguished. With two polaroid sheets and a trough containing such a polar liquid, we can devise an arrangement with the property that light is transmitted only when the electric field is applied. So we have an electric switch for light, which is called a Kerr cell. This effect, i.e., an electric field can produce birefringence in certain liquids, is called the Kerr effect.

13.4 Polarizers

So far we have considered substances in which the refractive index is different for light polarized in different directions. Of very great interest are the crystals and other substances in which not only the index, but also the coefficient of absorption, is different for light polarized in different directions. By the same arguments which I presented before of birefringence, it is understandable that a substance can vary with the direction in which the charges are forced to vibrate in an anisotropic substance. That's fine, so what example and example is another. Polaroid consists of a thin layer of small crystals of hemaphthite, or salt of iodine and quinone, all aligned with their axes parallel. These crystals absorb light when the oscillations are in one direction, and they do not absorb appreciably when the oscillations are in the other direction.

Suppose that we send light into a polaroid sheet polarized linearly at an angle θ to the passing direction. What intensity will come through? This incident light can be resolved into a component perpendicular to the pass direction which is proportional to $\sin \theta$, and a component along the pass direction which is proportional to $\cos \theta$. The amplitude which comes out of the polaroid is only the cosine of θ , since the sin θ component is absorbed. The amplitude which passes through the polaroid is smaller than the amplitude which entered, by a factor cos θ . The energy which passes through the polaroid, i.e., the intensity of the light is proportional to the square of cos θ . Use I_0 there, as the intensity transmitted when the light enters polarized at an angle θ to the pass direction. The absorbed intensity, of course, is $\sin^2 \theta$.

An interesting situation is presented by the following situation. We know that it is not possible to send a beam of light through two polaroid sheets with their axes crossed at right angles. But if we place a third polaroid sheet between the first two, with its axis tilted at 45° to the crossed axes, some light is transmitted. We know that polaroid reflects light, it does not do anything. Nevertheless, the addition of a third polaroid at the surface makes light to get through. The analysis of this phenomenon is left as an exercise for the student.

One of the most interesting examples of polarization is not in complicated crystals or difficult substances, but is one of the simplest and most familiar of situations: the reflection of light from a surface. Before it is lost, when light is reflected from a glass surface, it may be polarized, and the physical explanation of this is very simple. It was discovered empirically by Brewster that light reflected

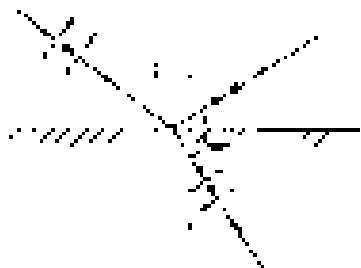

Fig. 33-4. Reduction of linearly polarized light at Brewster's angle. The polarization direction is indicated by dashed arrows; solid dots indicate polarization normal to the paper.

If a beam lies in a plane of polarization of the reflected beam, and the beam refracted into the mirror, form a right angle. The situation is illustrated in Fig. 33-4. If the incident beam is polarized in the plane of incidence, the beam will be reflected at all. Only if the incident beam is polarized normal to the plane of incidence will it be reflected. This reason is very easy to understand. If the reflecting material the light is polarized transversely, and we know that it is the motion of the charges in the material which generates the emergent beam, which we call the reflected beam. The source of this so-called reflected light is not simply that the incident beam is reflected; our deeper understanding of this phenomenon tells us that the incident beam drives an oscillation of the charges in the material, which in turn generates the reflected beam. From Fig. 33-4 it is clear that only the beam normal to the paper, i.e., radiating in the direction of reflection, and consequently the reflected beam will be polarized normal to the plane of incidence. If the incident beam is polarized in the plane of incidence, there will be no reflected light.

This phenomenon is readily demonstrated by reflecting a linearly polarized beam from a pane of glass. If the glass is turned to present different angles of incidence to the reflected beam, slight variation of the reflected intensity is observed when the angle of incidence passes through Brewster's angle. This variation is observed only if the plane of polarization lies in the plane of incidence. If the plane of polarization is normal to the plane of incidence, constant reflected intensity is observed at all angles.

33-5 Optical activity

Another most remarkable effect of polarization is observed in materials composed of molecules which do not have reflection symmetry: molecules shaped something like a dumbbell, or like a gloved hand, or any shape which, if viewed through a mirror, would be reversed in its sense (as, e.g., a left hand viewed inside as a right hand glove). Suppose all of the molecules in a substance are the same, i.e., none is a mirror image of any other. Such a substance may show an interesting effect called optical activity, whereby an initially polarized light passes through the substance, the direction of polarization rotates around the beam axis.

To inquire into the phenomenon of optical activity requires some calculation, but we can see qualitatively how it arises. Let's take a look, without actually carrying out the calculations. Consider an asymmetric molecule in the shape of a spiral, as shown in Fig. 33-5. Molecules need not actually be shaped like a corkscrew in order to exhibit optical activity, but this is a simple shape which we shall take as a typical example of those that do not have reflection symmetry. When a light beam linearly polarized along the y -direction falls on this molecule the electric field will drive charges up and down the helix, thereby generating a current in the helix; i.e., emitting an electric field, E , polarized in the y -direction. However, if the electrons are concentrated to move along the spiral, the spiral electrons will move in the x -direction to the x -axis, driving upward. When a current is flowing up the spiral, it is also flowing into the paper at $x = x_1$ and out of the paper at $x = x_2$. Let A be $\pi d^2/4$ the diameter of our molecular spiral. One might suppose that the current in the x -direction would produce no net field, since the currents are in opposite directions on opposite sides of the spiral. However, if we consider the contributions of the electric field to $x = x_1$ and $x = x_2$, we find that the field generated by the current at $x = x_1$ and $x = x_2$ are the field generated close to $x = x_1$ at time t and at $x = x_2$ separated in time by the distance d , and thus $\pi/2$ out of phase by $\pi/2$ radians. Since the phase difference is $\pi/2$, exactly $\pi/2$ between the fields due to the two ends, and because of the small x -component in the electric field generated by the motion of the electrons in the molecule, whereas the driving electric field has only a y -component. This small x -component, added to the large y -component, produces a resultant field that is tilted slightly with respect to the y -axis, the original direction of polarization. As the light moves through the molecule, the direction of polarization rotates about the beam axis. By carrying a few examples and calculating the correct effect will be set in motion by an accident.

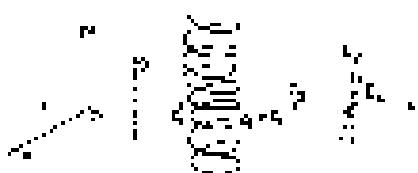

Fig. 33-5. A molecule with a shape that is not symmetric when reflected in a mirror. A beam of light, linearly polarized in the y -direction, falls on the molecule.

electric field, one can convince himself that the existence of optical activity and the sign of the rotation are independent of the orientation of the molecules.

Corn syrup is a common substance which possesses optical activity. The phenomenon is easily demonstrated with a polaroid sheet to produce a linearly polarized beam of transmission with an amplitude A , and a second polaroid used to detect the rotation of the direction of polarization as the light passes through a corn syrup.

31-6 The intensity of reflected light

Let us now consider quantitatively the reflection coefficient as a function of angle. Figure 31-6 illustrates a beam of light striking a glass surface, where it is partly reflected and partly refracted into the glass. Let us suppose that the incident wave has unit amplitude, is linearly polarized normal to the plane of the paper. Then we call the amplitude of the reflected wave b , and the amplitude of the refracted wave a . The refracted and reflected waves will, of course, be linearly polarized, and the electric field vectors of the incident, refracted, and reflected waves are all parallel to each other. Figure 31-6(a) shows the same situation but now we suppose that the incident wave, of unit amplitude, is polarized in the plane of the paper. Now let us call the amplitude of the reflected and refracted waves b and a , respectively.

We wish to calculate how strong the reflection is in the two situations illustrated in Fig. 31-6(a) and 31-6(b). We already know that when the angle θ is zero the reflected beam and refracted beam is a right angle. There will be no reflected wave in Fig. 31-6(a), but let us see if we cannot get a quantitative answer. Recall Eq. 30-1 for R which is a function of the angle of incidence, θ .

The principle that we must understand is as follows. The currents that are produced in the glass produce two waves. First, they produce the reflected wave. Moreover, we know that if there were no currents generated in the glass, the incident wave would continue straight in a straight line. Remember that all the sources in the world make the net field. The source of the incident light beam produces a field of unit amplitude which would move it to the glass along the dotted line in the figure. This field is not opposed, and therefore the currents generated in the glass must produce a field of amplitude -1 which moves along the dotted line. Using this fact, we will calculate the amplitudes of the reflected waves, b and a .

In Fig. 31-6(a) we see that the field of amplitude b is produced by the motion of the charges in the glass which are responding to a field coming in the glass, and that therefore b is proportional to v . We might suppose that since our two figures are exactly the same, except for the direction of polarization, the ratio b/a would be the same in both cases. This is not quite true, however, because in Fig. 31-6(a) the polarization directions are not all parallel to each other, as they are in Fig. 31-6(b). It is only the component of a which is perpendicular to B , A and i that is effective in producing B . The correct expression for the proportionality is then

$$\frac{b}{a} = \frac{\theta}{4 \pi n^2 (i + r)} \quad (31-1)$$

Now we can argue. We know that in both (a) and (b) of Fig. 31-6 the electric field in the glass must produce oscillations of the charges which generate a field of amplitude -1 , polarized parallel to the incident beam, and moving in the direction of the incident beam. But we see from part (b) of the figure that only one component of a that is normal to the original line has the right polarization to produce this field, whereas in Fig. 31-6(a) the amplitude is given in terms of the polarization of wave a to pass into the polarization of the wave of amplitude -1 . Therefore we can write

$$A \cos(i + r) = - \frac{a}{b} \quad (31-2)$$

since the two amplitudes on the left side of Eq. (31-2) each produce the wave of amplitude -1 .

Fig. 31-6 An incident wave of unit amplitude is reflected and refracted at a glass surface. In (a) the incident wave is linearly polarized normal to the plane of the paper. In (b) the incident wave is linearly polarized in the direction shown by the dotted electric vector.

Dividing Eq. (G1.1) by Eq. (G1.2) we obtain

$$\frac{S}{R} = \frac{\sin(\beta + \alpha)}{\sin(\beta - \alpha)}. \quad (G1.4)$$

a result which we can check against what we already know. If we take up Eq. (F2.2) it gives $S = 0$, as R never says it should be, so our results so far are at least not obviously wrong.

We have examined our amplitudes for the incident waves, so that $|S|^2/|R|^2$ is the reflection coefficient for waves polarized in the plane of incidence, and $|R|^2/|I|^2$ is the reflection coefficient for waves polarized normal to the plane of incidence.

The ratio of these two reflection coefficients is determined by Eq. (G1.4).

Now we can't just multiply our amplitude ratios together, but each oscillates $|S|^2/|R|^2$ and $|R|^2/|I|^2$ individually! We know from the conservation of energy that the energy in the reflected wave must be equal to the incident energy minus the energy in the reflected wave, $|I - R|^2$ in one case, $|S - R|^2$ in the other. Furthermore, the energy which passes into the glass in Fig. 32.6(b) is in the energy which goes into the glass in Fig. 32.6(a) as the sum of the square of the incident amplitudes, $|I|^2/|a|^2$. One might ask whether we really know how to compute the energy inside the glass, because, after all, there are energies of motion of the atoms in addition to the energy in the electric field. But $|I|^2$ is proportional to the various contributions to the total energy will be proportional to the square of the amplitude of the electric field. Therefore we can write

$$1 - |R|^2 = \frac{|I|^2}{|a|^2} = \frac{|S|^2}{|R|^2}. \quad (G1.5)$$

We now substitute Eq. (G1.5) into equation (G1.4) from the expression above, and express δ in terms of θ by means of Eq. (G2.3).

$$\frac{1 - \frac{|S|^2}{|R|^2}(1 + r)}{1 - |R|^2} = \frac{1}{\cos^2(\beta - \alpha)}. \quad (G1.6)$$

This equation contains the only one unknown amplitude, δ . Solving for δ^2 , we obtain

$$\delta^2 = \frac{\sin^2(\beta - \alpha)}{\sin^2(\beta + \alpha)} \quad (G1.7)$$

and, with the aid of (G1.1)

$$|R|^2 = \frac{\sin^2(\beta - \alpha)}{\sin^2(\beta + \alpha)}. \quad (G1.8)$$

so we have found the reflection coefficient $|R|^2$ for an incident wave polarized perpendicular to the plane of incidence, and so the reflection coefficient $|S|^2$ for an incident wave polarized in the plane of incidence!

It is possible to go on with arguments of this nature and deduce that R is real. To prove this, one must consider a case where light is coming from both sides of the glass at once in the same time, a situation not easy to arrange experimentally, but fun to analyze theoretically. I've never tried it in general case, so I can prove that R must be real, and therefore, in fact, that $\delta = \pm \sin(\beta - \alpha)/\sin(\beta + \alpha)$. It is even possible to determine the sign by considering the case of a very, very thin layer in which there is reflection from the front face from the back surface, and taking along how much light is reflected. The *sign* how much light should be reflected by that layer, because we know how much intensity is present, and we have been working out the fields produced by such structures.

One can show by these arguments that

$$R = \frac{\sin(\beta - \alpha)}{\sin(\beta + \alpha)}, \quad R = -\frac{\tan(\beta - \alpha)}{\tan(\beta + \alpha)}. \quad (G1.9)$$

These expressions for the reflection coefficients as a function of the angles of incidence and reflection are called Fresnel's reflection formulae.

If we consider the limit as β approaches $\pi/2$ and α goes to zero, we have, for the case of normal incidence, that $|S|^2 = |R|^2 = 1 - r^2/2(1 + r)^2$ for both polarizations.

since the angles are practically equal to the angles θ and ϕ in the diagram. But we know that $\sin \phi = \sin \theta$ when the angle of refraction $\phi = \theta = \pi$. It is thus clear that the coefficient of reflection for normal incidence is

$$R^2 = S^2 = \frac{1}{n} = \frac{D^2}{D^2 + D_0^2}.$$

It is interesting to find out how much light is reflected or normal incidence from the surface of water, for example. For water, $n = 1.33$, so that the reflection coefficient is $(1/1.33)^2 = 7\%$. A normal incidence only two percent of the light is reflected from the surface of water.

33-7 Anomalous refraction

The last polarization effect we shall consider was actually one of the first to be discovered: anomalous refraction. When viewing Iceland Spar back to the open sky (Fig. 33-7) which had the surprising property of not allowing anything over through the crystal appear divided, i.e., as two images. This came to the attention of Hippocrates, and played a important role in the discovery of polarization. As before, we note, the polarizations which are discovered first are the harder, if hardly, to analyze. It is only after we understand a physical concept long enough that we can carefully select those parameters which most easily and simply determine that concept.

Anomalous refraction is a particular case of the same kind of effect we considered earlier. Anomalous refraction occurs when the ray is optic, i.e., long axis of an optically uniaxial, or nonparallel to the surface of the crystal. In Fig. 33-7 are shown two pieces of birefringent material, with the optic axis as shown. In the upper figure, a incident beam falling on the material is refracted parallel to a direction perpendicular to the optic axis of the material. When this beam strikes the surface of the material, each point on the surface becomes source of a wave which travels along the crystal with velocity v_1 , the velocity of light in the crystal when the plane of polarization is normal to the optic axis. The wave front is not the envelope of dots of waves little spirals wavy, and the wave front moves straight through the crystal and out the other side. This is just the ordinary behavior we would expect, and the ray is called the ordinary ray.

In the lower figure, a linearly polarized light falling on the crystal has its direction of polarization passed through 90° , and at the surface lies in the plane of polarization. When we now consider the wave propagation at any point on the surface of the crystal, we see that they do not spread out in spherical waves but are travelling along the surface with velocity v_1 because the polarization is perpendicular to the optic axis, whereas the light travelling perpendicular to the optic axis travels with velocity v_2 because the polarization is parallel to the optic axis. This requires $v_2 < v_1$, and in the figure $v_2 < v_1$. A more complete analysis will show that the waves spread out on the surface of an ellipsoid, with foci on the major axis of the ellipsoid. The envelope of all the elliptical waves is the wavefront which spreads out roughly in a parabola in the direction shown. Again, at the back surface the beam will be detected just as it was at the front surface, as that the optic axis is parallel to the incident beam, but separated from it. Clearly, the beam does not scatter greatly here, but goes in the extraordinary direction. It is therefore called the extraordinary ray.

When an unpolarized beam strikes an uniaxially birefringent crystal, it is separated into an ordinary ray, which travels every through the material with the same velocity which is displaced as it passes through the crystal. These two emergent rays are linearly polarized at right angles to each other. This is true for linear polarization with a state of polarization to analyze the polarization of the emergent rays. We can also demonstrate by our interpretation of this phenomenon is correct by sending linearly polarized light into the crystal. By properly orienting the direction of polarization of the incident beam, we can make the light pass right through the crystal, or we can make it go through without splitting our wave a displacement.

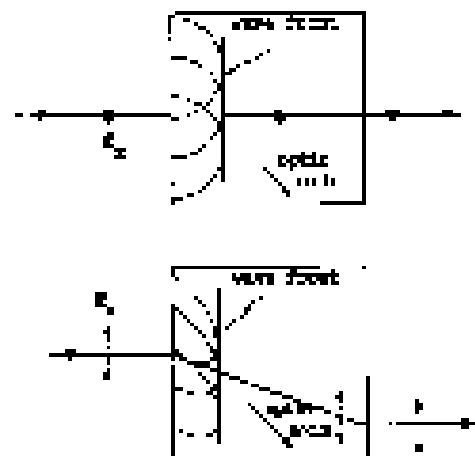

Fig. 33-7. Top diagram shows the path of the ordinary ray through a uniaxially birefringent crystal. The extraordinary ray is shown in the lower diagram. The optic axis lies in the plane of the paper.

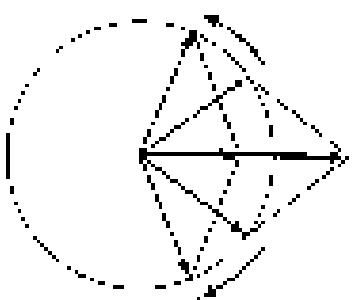

Fig. 33-5. Two oppositely rotating vectors of equal amplitude add to produce a vector in a fixed direction, but with an oscillating amplitude.

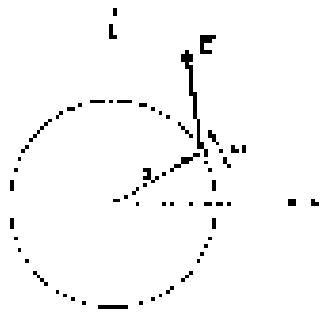

Fig. 33-6. A charge moving in a circle in response to circularly polarized light.

We have represented all the various extinction cases in Figs. 33-1 and 33-2 as superpositions of two fixed polarization states, namely x and y , in various amounts and phases. Other polarizations may we have been used. Polarization along any plane perpendicular to x and y is known to x and y as well as well [2]. For example, any polarization can be made up of superpositions of cases (a) or (c) of Fig. 33-2. It is interesting, however, that this can also occur for other cases [3]. For one spike, any linear polarization can be made up by superposing two while allowing suitable phases of light and left circular polarization (case (d)) are [3] (cf. Fig. 33-2'), since two equal waves collinear in opposite directions tend to give a single vector oscillating in a straight line (Fig. 33-3). If the phase of one is shifted relative to the other, the "line is helical." Thus all the pictures of Fig. 33-2 could be labeled "the superposition of equal amounts of right and left circular polarized light in various relative phases." As the left spike behind the right in phase, the direction of the linear path is reversed. The other possibly unique materials are in a sense, birefringent. Their nature has yet to be described by saying that they have different indexes for right- and left-hand circularly polarized light. Superposition of right and left circularly polarized light outside our interests produces elliptically polarized light.

Circular polarized light has another interesting property—it carries angular momentum (about the direction of propagation). To illustrate this, suppose that such light falls on an atom represented by a harmonic oscillator that can be displaced rapidly in any direction. In the plane of "Fig. 33-2" the x displacement of the electron will respond to the E_x component of the field, while the y -component responds, equally, to the zero- E_y component of the field but 90° behind it in phase. That is, the responding electron goes around in a circle with angular velocity ω in response to the rotating electric field of the light (Fig. 33-9). Depending on the direction and orientation of the response of the oscillator, the direction of the displacement of the electron, and the direction of the force q_E it need not be the same but they relate as follows: If q_E may have a component in right angles to E , the work done on the system and change in θ is zero. The work done per second is q_E . Over a period of time T the energy absorbed is $q_E T$, and $q_E T$ is the angular momentum delivered to the mass about the E axis. We see the effect that a beam of right circularly polarized light communicates a total energy $q_E T$ and angular momentum (work) $q_E T$ directed along the direction of propagation. For whom this beam is absorbed the angular momentum is delivered to the absorber. Left-hand circular light carries angular momentum of the opposite sign, $-q_E T$.

Relativistic Effects in Radiation

34-1 Moving sources

In the present chapter we shall describe a number of interesting effects in connection with radiation, and then we shall be finished with the classical theory of light propagation. In our analysis of light we have concentrated in great detail on only phenomena of very low speed associated with electro-magnetic radiation that we have not discussed is what happens if the speeds are increased to a few $\times 10^8$ cm/sec. Effectively, the size of the band being comparable to a wavelength — one to ten times slower than light itself. The phenomena of so-called radio waves and microwaves we shall discuss later; we shall first use another physical example: sound, and the next chapter will be on ultrasound. Except for this, the present chapter is a brief consideration of the classical theory of light.

Very soon we shall see the effects that we shall now discuss by performing test they have to do with the effects of moving sources. We no longer assume that the source is localized, with all its motion being at a relatively low speed near a fixed point.

We know that the fundamental laws of electro-dynamics say that, at large distances from a moving charge, the electric field is given by the formula

$$\mathbf{E} = \frac{q}{4\pi\epsilon_0 c^2} \frac{\mathbf{v}_S}{v_S^2 + c^2} \quad (34.1)$$

The second derivation of this first vector eqn. was given in the appendices to the notes, > the lecture notes on the electric field. This last vector does not point toward the present position of the charge, of course, but rather in the direction that the charge would seem to be, if the information traveled only at the finite speed c from the charge to the observer.

Associated with the electric field is a magnetic field, always at right angles to the electric field and at right angles to the apparent direction of the source, given by the formula

$$\mathbf{B} = -\mathbf{v}_S \times \mathbf{E} \quad (34.2)$$

Until now we have considered only the case in which motion is one-dimensional, at speed, so that there is no significant change in the direction of the source to be considered. Now we shall be more general and study the case where the motion is in x - y - z very arbitrary, and ask what effect this may be expected in those circumstances. We shall let the motion be an arbitrary speed, but of course we shall let it assume that the detector is very far from the source.

We already know from our discussion in Chapter 26 that the only thing that counts in $d\mathbf{v}_S/dt$ are the changes in the direction of \mathbf{v}_S . Let the position vector of the charge, $\mathbf{r}_S(t, x, y, z)$, with a measured along the direction of motion (Fig. 34-1). At a given moment in time say, $t = t_0$, the three components of the position are x_0 , y_0 , and z_0 . The distance R is very nearly equal to $(x_0^2 + y_0^2 + z_0^2)^{1/2}$. Now the direction of the vector \mathbf{v}_S depends mainly on x_0/R , but how you y_0/R and z_0/R . Now the three components of the unit vector are x/R and y/R , and when we differentiate these components we get things like x^2/R^2 in the denominators:

$$\frac{dx(R)}{dt} = \frac{dx/dt}{R} = \frac{dx}{dt} \frac{x}{R} \quad$$

34-2.6 The x, y, z four-vector

34-2.7 Aberration

34-2.8 The connection of light

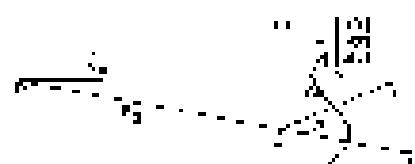

Fig. 34-1. The path of a moving source. The true position of the source is at t , but the retarded position, at $t + dt$, is used to find the apparent motion.

So when we are far enough away the only terms we have to worry about are the derivatives of x and y . Thus we take out the factors R_t and \dot{R}_t .

$$\begin{aligned} E_x &= -\frac{q}{4\pi\epsilon_0 R_t^2} \frac{\partial^2 x}{\partial t^2} \\ E_y &= -\frac{q}{4\pi\epsilon_0 R_t^2} \frac{\partial^2 y}{\partial t^2}. \end{aligned} \quad (34.8)$$

where R_t is the distance, measured to the origin of the coordinates (x, y, z) . Thus the electric field has a component anti-parallel to a very simple thing, the second derivatives of the x and y coordinates. (We could put it more mathematically by calling x and y the transverse components of the position vector r of the charge, but this would not add to the clarity.)

Of course we realize that the coordinates must be measured at the recorded time. Does we find that $\ddot{x}(t)$ does affect the calculation. Why? isn't the potential $V(t)$? If the time of observation is t , (the time of \ddot{x}) then the time τ to which this corresponds is $\tau = t - \Delta t$, but is delayed by the usual distance due the light having to go, divided by the speed of light, c , before approximation. This delay is R_t/c , a constant for uninteresting features, but in the next approximation we must include the effects of the position in the calculation of the time τ . Because it's a little further back, there is a little more retardation. This is an effect that we have neglected before, and it is the only change needed in order to make our results valid for all speeds.

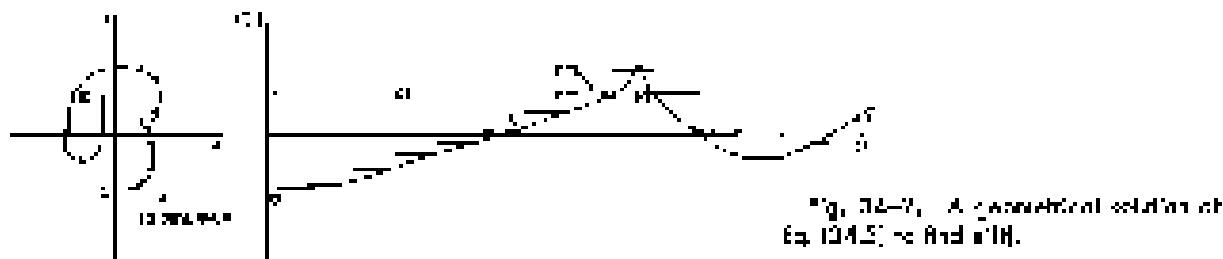

What we must now do is to choose a certain value of τ and calculate the value of \ddot{x} from it, and then find out where x and y are at τ . That is, given the recorded x and y , which we call x' and y' , where several derivatives determine the "tilt". This τ is determined by

$$\tau = t + \frac{R_t}{c} \div \frac{\dot{x}(t)}{c}$$

and

$$x'(t) = x(\tau), \quad y'(t) = y(\tau). \quad (34.9)$$

Now these are complicated equations, but it is easy enough to make a geometrical picture to describe their solution. This picture will give us a good qualitative feeling for how things work, but it still takes a lot of detailed mathematics to reduce the physical analysis of a complicated problem.

34-2 Finding the "apparent" motion

The above equation has an interesting simplification. If we disregard the time-varying component delay R_t/c , what we really did is just change the origin of τ by a constant. Then it says that

$$\ddot{x} = \alpha + \beta(t), \quad x' = x(t), \quad y' = y(t) \quad (34.10)$$

Now we need to find α and β as functions of t and τ , and we can do this in the following way: Eq. (34.9) says that we should take the recorded time and add a constant (the speed of light) times τ . What this comes out to mean is shown in Fig. 34-2. We take the actual motion of the charge (shown at 't') and imagine that it is going around it is being swept away from the point t at the speed c (there are no corrections for relativity or anything like that; this is just a mathematical addition of the τ). In this way we get a new motion, in which the line

of sight coordinate x , as shown at the right. (The figure shows the result for a rather complicated motion at a place, but of course the motion may not be to one point—it may be over some complicated curve motion in a plane.) The point is that the horizontal distance between the new x is no longer the old x , but is $x - ct$. And therefore is \vec{r} . Thus we have found a picture of the curve. A good argument! All we have to do is find the field is to look at the acceleration of the curve, i.e., to differentiate twice. So the final answer is: in order to find the electric field for a moving charge, take motion of the charge and calculate a book which speeds up "open it up." On the curve, so drawn, is a curve of the x and y positions of the function of t . The acceleration of this curve gives the electric field as a function of t . Or, if we like, we can say imagine that this whole "book" drove away forward at the speed c . I wish the plane of sight, so that the point of intersection with the plane of sight has coordinates x and y . The acceleration of this point makes the electric field. This solution is just as correct as the formula we started with—simply a geometrical representation.

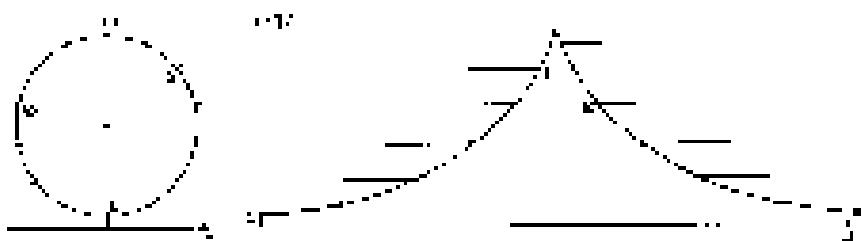

Fig. 24-3. The field curve for a particle moving at constant speed $v = 0.9cc$, a circle.

If the motion is relatively slow, so, for instance if we were in reality as just going up and down slowly, then when we went that much away at the speed of light, we would just of course, a simple engine curve, and that gives a formula we have been making out for a long time, it was the field produced by an accelerating charge. A more interesting example is an electron moving, exactly, very nearly at the speed of light, i.e., a circle. If we look in the plane of the circle, the retarded field appears as shown in Fig. 24-3. What is this curve? It is the y -axis given a radius vector from the center of the circle to the charge, and if we extend this vector by a little bit past the charge, just a shade if it is going fast, then we come to a point on the line that goes to the speed of light. The line, which we consider the motion back to the speed of light, can correspond to having a "wind" with a charge on it rolling backward (without slipping) at the speed c ; this is not a curve which is very close to a cycloid—it is called a hyperboloid. If the charge is going very nearly at the speed of light the "wings" are very sharp indeed; if it were actually the speed of light they would be almost exactly infinitely sharp. "Ininitely sharp" is interesting; it means that near c the slope of the curve is enormous. That is, in each cycle there is a sharp pulse of electric field. This is not at all what we would get from a nonrelativistic motion, where each time the charge goes around there is a uniform field at all other times ("strength") E the time. Instead, there are very sharp pulses of electric field spaced at time intervals $1/T$, equal where T is the period of revolution. The strong electric fields are caused in a sense due to the direction of motion of the charge. When the charge is moving away from us, there is very little resistance and there is very little radiation field in the direction of P .

24-3 Radiation radiation

We have very frequently seen moving in circular paths in the synchrotron; they move exactly at very nearly the speed c , and the point of interest above occurred as you might expect. Let's discuss this in more detail.

In the synchrotron we have electrons which go round in circles in a uniform magnetic field. First let us see why they go in circles. From Eq. (12.10), we know that the force on a particle in a magnetic field is given by

$$\vec{F} = q\vec{v} \times \vec{B}, \quad (24.1)$$

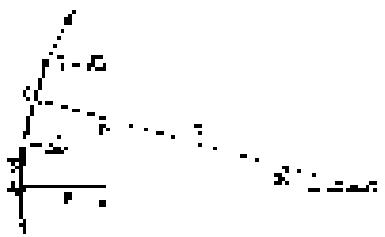

Fig. 34-6. A charged particle moves in a circle by radial path in a uniform magnetic field.

and v is at right angles both to the field and to the velocity. As usual, the force is equal to the rate of change of momentum with time. If the field is directed upward out of the paper, the weight $m g$ of the particle and the force on it are as shown in Fig. 34-4. Since F is perpendicular to the velocity, the kinetic energy and therefore the speed remain constant. All the magnetic field does is to change the direction of motion. In a short time Δt , the momentum vector changes at right angles to itself by an amount $B p = B m v$, and therefore p turns through an angle $\Delta\theta = B p \Delta t / m v = q B \Delta t / m$, since $p = m v$. But in this same time the particle has gone a distance $d = v \Delta t$. But only the two lines 1.8 and 2.0 mi intersect at a point O such that $O A = O B = R$ where $R = v \Delta t$. Comparing this with the previous expression, we find $R = v \Delta t = q B \Delta t / m$, from which we find

$$v = q B R \quad (34-7)$$

and

$$R = q B / m. \quad (34-8)$$

Since this argument can be applied during the next instant, the next, and so on, we conclude that the particle must move, in a cycle of radius R , with angular velocity ω .

The result that the momentum of the particle is equal to $q B R$ times the radius times the magnetic field is a very important law that is used a great deal. It is important for practical purposes because if we have extremely particles which all have the same charge, and we observe them in a magnetic field, we can measure the ratio of currents of their orbits and, knowing the magnetic field, thus determine the momenta of the particles. If we multiply both sides of Eq. (34-7) by q , and express $q m$ in terms of the electron charge, we can measure the momentum in units of the electron volt. In these units our formula is

$$p e(v) = 1.8 \times 10^9 (q/m) B R, \quad (34-9)$$

where B , R , and the speed of light are all expressed in C.G.S. system, the latter being 1.8×10^9 , numerically.

The value of magnetic field is called a gauss per square meter. This is an older unit which is still in use today, called a gauss. One gauss m^{-2} is equal to 10^4 oersted. To give an idea of how big a magnetic field is, one of the strongest magnets made thus far can usually make an intensity of about 1.1×10^4 gauss, beyond that the advantage of using iron disappears. Today, electric currents around wire superconducting at the melting temperature produce fields of over 10^6 gauss strength, that is, 10 kilogauss. The field of the sun is a few tenths of a gauss at the equator.

Returning to Eq. (34-9), we can imagine the synchrotron running a billion electron volts beam with 10^9 per billion electron volt. (We shall come back to the energy in just a moment.) Then, if we had a B corresponding to one 1000 gauss, which is a 10^4 oersted field, our R would be 10^9 cm, or 10 km. It would have to be 2.3 meters. The polar radius of the California synchrotron is 2.7 miles, the field is a little bigger, and the energy is 1.5 billion, but it is the same idea. So now we know a feeling for why the cyclotron has to stay at low E .

We have calculated the momentum. We also know that the total energy including the rest energy, is given by $E = \sqrt{p^2 c^2 + m^2 c^4}$, and for an electron the rest energy corresponding to $m c^2$ is 0.511×10^6 ev, or when p is 10^9 ev we neglect $m c^2$, and as for all practical purposes the p is small, the speed is relativistic. It is practically the same as say the energy of an electron in a billion electron volts as in eq. 34-9, numerically (that is, a billion-electron-volt $E^2/2P = 10^9$ ev), it is easy to show that the speed C is less than the speed of light by less than one millionth.

We shall now let the particle emitted by such a particle. A particle having 20.0 miles of curves 1.5 meters in 20 meters circumference, since around must be roughly the time it takes light to go 20 meters. So the wavelength λ would be emitted by such a particle would be 20 miles in the x-ray wave region. But because of the filling up effect that we have been calculating (Fig. 34-5), and because the distance by which we may extend the radius to reduce the speed is 24-4

only one part of each Miller of the radius. The steps of the hyperbolas are conveniently sharp compared with the distance between them. The acceleration, which increases toward the positive side, is equal to $(m/e)E$, where E is the voltage, for $m/e = 2 \times 10^8$ becomes, on the scale, a value of eight million times the acceleration of the electrons. Thus we might say that effective space would be made shorter, to the extent of 64 times by 10^8 if the electrons had been confined to the γ -ray region. Actually, the step size is not the only determining factor, since there also influence is the region where the step. The change in frequency is determined of the source, but it is also a consequence of the motion. Thus, even though a slowly moving electron would have more time between radiations, the frequency of the wave it is emitting is so much that we can ignore it. Now, the light should be accelerated with constant frequency parallel to the direction of motion.

It further appears that we would also be supposed that we could make such light no sharply enough because the source is so far apart from us, we can just take one reflector and direct it under a different angle, so that it is at 90° to scattering wires. After the pulse leaves away from the grating, what does it do? (We should see it again, but in glass of course, it would not light at all.) Well, as we see? The pulses strike the glass surface and all the oscillations of the grating, being here no electric field, need not add their rays shown again, but cancel. They have source shown in ω form, ω is shown in Fig. 34-5. Let the point P be at the end of the grating arm in the ω direction, ω and ω' . The field is held away from wind A , now from B , and so on; finally, the pulse from reflector surface. It goes to one of the reflectors, all the successive waves cancel out. In Fig. 34-5(a), the electric field with its successive pulses and the very like a long wave whose wavelength is the distance between the pulses just as would be the wave going out of the slit along the ω axis. So we get shorter light all right. But, ω in some amount will be too great. Then another kind of a "pulse" like supposed to be made up of such two other waves or wave and of the scattered waves together generated by a small angle between them. This is seen. Then we see that the field would not shorten it to a very short length, because each pulse does not carry much of the wave function, scattered pulses.

The electric magnetic radiation emitted by a radio is called radio waves. Induction in a magnetic field is called magnetism. It is to name the activities of man, but, almost, nothing specifically to synthetic ones, or even man's natural properties. This is the main reason that it also occurs in nature.

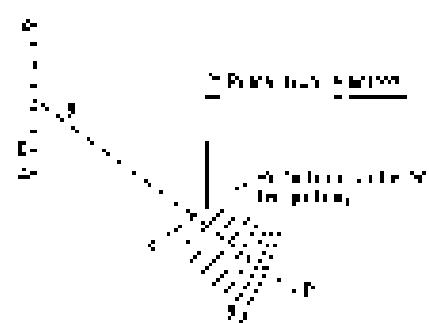

Fig. 34-5. The light after striking a grating at a large angle ω from ω' will have a certain reflection angle at different colors.

Fig. 34-6. The electric field E is the same as in Fig. 34-5, but the radio wave has a much larger amplitude.

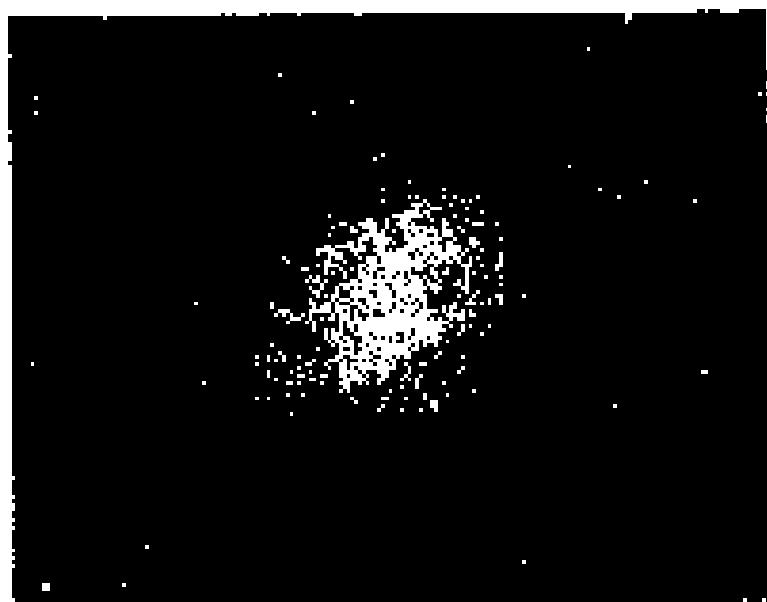

Fig. 34-7. The multi-colored pattern on a color filter.

34-4 Cosmic gamma-ray radiation

In the year 1054 the Chinese and Japanese citizens were watching the most brilliant display of fireworks in the entire universe, and they recorded, more or less graphically, an explosive bright star that year. (It is interesting to note that the European monks, writing in the books of the middle ages, even bothered to write in Latin especially for the sky, but they did not.) Today we may take a picture of that star, and what we see is shown in Fig. 34-7. On the outside is a big mass of red filaments which are produced by the stars of the hot gas "boiling" at the surface. In practice this means a bright line spectrum with different frequencies in it. The red component is the one to be due to nitrogen. On the other hand, in the central region is a magnetized, very point of light in a continuous distribution of frequency, i.e., there are no special frequencies associated with particular resonance. This is not dust "blown up" by nuclear stars, which is one way by which one can get a continuous spectrum. We can see stars through it, so it is transparent, but it is glowing light.

In Fig. 34-8 we look at the same object, using light in a region of the spectrum which has no bright spectral lines, so that we examine the central region. When the two solar polarizers have been put on the telescope, and the two views correspond to two orientations SIP and T. We see that the pictures are different. This is due to the light polarization. The reason, presumably, is that there is a large magnetic field, and many very energetic electrons are going around in that magnetic field.

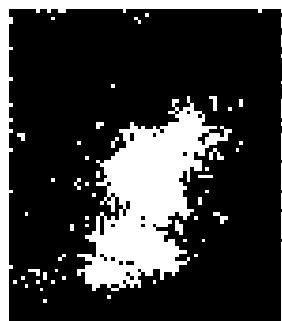

We have just illustrated that the electrons could go around the field in a circle. We'd add to this statement say uniform motion in the direction of the field, since the force $(qv) \times B$, has no component in this direction and, as we have already realized, the stimulated radiation is evidently polarized in a direction at right angles to the projection of the magnetic field onto the plane of sight.

Putting these two facts together, we see that, in a region where one picture is bright and the other one is black, the light in the first is clearly field-compared polarized in one direction. This means that there is a magnetic field at right angles to this direction, while in other regions where there is no strong emission in the center picture, the magnetic field runs in the other way. If we look carefully at Fig. 34-4, we may notice that there is, roughly speaking, a general set of "lines" but one way in one picture and at right angles to this in the other. The pictures correspond to those directions. Presumably the magnetic field lines will tend to extend indefinitely long distances in their own direction, and so, presumably, the two long regions of magnetic field will all be running spiraling one way, while in another region the field is the other way and the electrons are also spiraling that way.

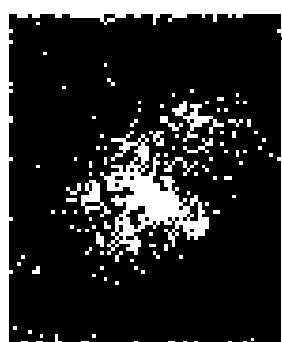

What keeps the electron energy so large for so long a time? At least it is 1000 years since the explosion. How can they keep going so fast? How they maintain their energy and how this whole thing keeps going is still not thoroughly understood.

34-5 Decelerating

We can now remark briefly on one other interesting effect of a very fast-moving particle that requires energy. The idea is very similar to the one we have just discussed. Suppose that there is an uncharged particle in a piece of paper and a very fast electron, say coming by (Fig. 34-9). Then, because of the electric field around the electric charges, the electron is pulled, accelerated, so that the curve of its motion has a slight kink or bend in it. If the electron is travelling at very nearly the speed of light, what is the electric field caused in the direction of? Remember our rule: we take the electric field from translation (not velocity) if speed v , and that's exactly where things measure the electric field. It was moving toward us at the speed v , so the field must run with the whole picture compressed into a small distance in proportion as $v = c$ is smaller than c . So, $E = \infty$? There is a very sharp and rapid decrease of E , and when we take the second derivative of that we get a very high field in the direction of the motion. So when very energetic electrons move through matter they spit radiation in a longitudinal direction. This is called decelerating. As a matter of fact, they don't

[a]

[b]

Fig. 34-7. The same object is seen through a blue filter and a polaroid. [a] Magnetic vector vertical. [b] Electric vector horizontal.

Fig. 34-9. A fast electron moving near a massive nucleus energy in the direction of its motion.

we would have to go to higher-energy electrons (actually if we could get them out of the machine more conveniently we could just say this) so to make very energetic photons—gamma rays. By passing the energetic electrons through a field larger than $\frac{1}{2} m_e c^2$ one letting them radiate, photons from this bremsstrahlung effect.

34-6 The Doppler effect

Now we go on to consider some other examples of the effects of moving sources. Let us suppose that the source is a stationary atom which is oscillating at one of its natural frequencies ω_0 . Then we know that the frequency of the light we would observe is ω_0 . But now let us take another example, at which we have a simple oscillator with length a with a frequency ω_0 , and at the same time the source moves, the whole oscillator, is moving along it's direction toward the observer at velocity v . Then the actual motion of source is as shown in Fig. 34-10(a). Now we play our usual game we add v ; that is to say, we calculate the wave curve between and beyond the source, as in Fig. 34-10(b). In a given amount of time t , when the oscillator would have gone a distance a , on the x - y coordinate it has a displacement $= -vt$. So all the oscillations of frequency ω_0 in the last $2a$ are now found in the interval $2a - (-vt)$ and $2a$; they are equivalent to $\omega_0 t$, and appear to us since $v \gg a$ speed c , now with a light of a higher frequency, higher by just the compression factor $(1 - v/c)$. This we observe:

$$\omega = \frac{\omega_0}{\sqrt{1 - v/c}}. \quad (34-10)$$

We can, of course, analyze it's situation in various ways. Suppose that the source were emitting instead of continuous, a series of pulses, pip-pip-pip-pip at a certain frequency ω_0 . At what frequency would they be received by us? The first one that arrives would be in full, but the next one is delayed because it's traveling the extra distance due to the receiver. Therefore, the time between successive pulses, instead of the interval t was analysis the geometry of the situation, we find that the frequency of the pipe is increased by the factor $1/\sqrt{1 - v/c}$.

If $v = \omega_0/c(1 - v/c)$, then, the frequency that would be observed if we took an ordinary atom, which had a natural frequency ω_0 , and caused it to move the source at speed v , the source with $v/c < 1$, the altered frequency ω_1 of a uniform atom is not the same as that measured when $v \gg a$ and $v/c \ll 1$, because of the relativistic addition in the rate of passage of time. That is, we're the $1/(1 - v/c)^{1/2}$ frequency, i.e., the endothermic frequency, would be

$$\omega_1 = \omega_0 \sqrt{1 - v/c}. \quad (34-11)$$

Therefore the observed frequency is

$$\omega = \frac{\omega_0 \sqrt{1 - v/c}}{1 - v/c}. \quad (34-12)$$

The shift in frequency observed in the above situation is called the Doppler effect. If something moves toward the light it emits appears more violet, and if it moves away it appears more red.

We shall now give an analysis of this same interesting and important result. Suppose, now, that the source is also doing still another motion, at frequency ω_0 , while the observer is moving with speed v toward the source. After a total period of time t , the source will have moved to a new position, a distance $v t$ from where it was at $t = 0$. How many radians of phase $\omega_0 t$ is there now? At a certain number, say, went past any given point, and in addition to that it has kept past some more by his own motion, carrying a number $v t$, the number of cycles is $\omega_0 t + v t$ times the cycles per sec. So the total number of radians in the time t , or the observed frequency, would be $\omega_0 + v \omega_0$. We have made this analysis from the point of view of a inertial rest. We would like to know how it would look to the man who is moving. Then we have to worry again about the difference in clock rate for the two observers, and this time the results that we have to multiply v/c by ω_0 . So if ω_0 is the source's number of cycles

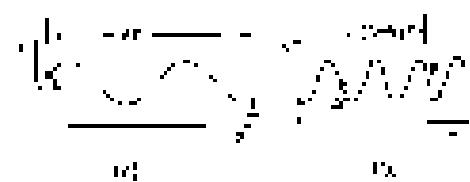

Fig. 34-10. The $x = x$ and $x' = t$ curves of a moving oscillator.

the vector is the direction of motion, and ω_0 is the frequency, then the observed frequency for a moving man is

$$\nu = \frac{\omega_0}{\sqrt{1 - v^2/c^2}} \quad (34.13)$$

For the case of light, we know each $\lambda_0 = \lambda/c$, so, in this particular problem, the equation $\nu = \lambda/c$ read

$$\nu = \frac{\omega_0(1 - v/c)}{\sqrt{1 - v^2/c^2}}, \quad (34.14)$$

which looks completely unlike formula (34.12)! The frequency that we would observe if we never moved a source different than the frequency that we would see if the source moved toward us? Of course not! The theory of relativity says that v/c must be zero by definition. If we don't want strange mathematical results we would naturally recognize this. These two measurement frequencies are exactly equal. In fact, the *observed* equality of the two frequencies is one of the ways by which some people like to demonstrate the *realistic* requirement of time dilation, because if v/c did not fit these square-root factors in, they would no longer be equal.

Since we know about relativity, let us analyze it in full & think why, while they appear to differ, there *are* general. It is really the same thing since it makes no difference how we do it! According to the relativity theory there is a relationship between position and time as observed by one man and another, and time as seen by another who is moving relative to him. We will show these relationships long ago (Chapter 18). This is the Lorentz transformation and its inverse:

$$\begin{aligned} t' &= \frac{t - vx}{\sqrt{1 - v^2/c^2}}, & r' &= \frac{r - vc}{\sqrt{1 - v^2/c^2}}, \\ r' &= \frac{1 + v/c}{\sqrt{1 - v^2/c^2}}, & t &= \frac{t' + v/c}{\sqrt{1 - v^2/c^2}}. \end{aligned} \quad (34.15)$$

If we were standing still on the ground, the term r/v would be constant. And so if the reader and author and audience would follow that term. But what can a man do now, especially the non-physical ones, well? Well, if the field is zero, the positions of all the readers are the same (within the field is zero, everyone measures the field is zero); that is a relativistic invariant. So the term is the sum of the x 's, and we expect that we will transform it into the form of reference

$$\cos(\omega t - kx) = \cos\left[\omega \frac{t - v/c}{\sqrt{1 - v^2/c^2}} - k \frac{r - vc}{\sqrt{1 - v^2/c^2}}\right].$$

If we expand the terms inside the brackets, we get

$$\begin{aligned} \cos(\omega t - kx) &= \cos\left[\frac{\omega - k\omega}{\sqrt{1 - v^2/c^2}} t - \frac{v - \omega/c^2}{\sqrt{1 - v^2/c^2}} x\right] \\ &= \cos\left[\omega t - \omega - \frac{v - \omega/c^2}{\sqrt{1 - v^2/c^2}} x\right]. \end{aligned} \quad (34.16)$$

This is $\omega' + \omega/c^2$, a wave, in which there is a certain frequency ω' , a wave number k' , and some other constant, ω/c^2 , multiplying ω . We call ω' the wave number or the number of waves per meter, for the other man. Therefore the other man will see a new frequency and a new wave number given by

$$\omega' = \frac{\omega + kv}{\sqrt{1 - v^2/c^2}}, \quad (34.17)$$

$$k' = \frac{k - \omega/c^2}{\sqrt{1 - v^2/c^2}}. \quad (34.18)$$

If we look at (34.14), we see that ν is the same for rule (34.18), then we obtained by a more physical argument

34-7 The ω , k four-vector

The relationships indicated in Eqs. (34.17) and (34.18) are very interesting, because they say that the new frequency ω' is a combination of the old frequency ω and the old wave number k , and that the new wave number is a combination of the old wave number and frequency. Now the wave number is the rate of change of phase with distance, and the frequency is the rate of change of phase with time, and in these two equations we see a close analogy with the Lorentz transformation, in which the time coordinate t is divided by c and the space coordinate x is divided by c . Then the new ω' will be like ω , and the new k' will be like k/c^2 . That is to say, because the Fourier transformation would transform the wave number k in exactly the same way as it transforms the frequency ω , when a quantity has four components transforming like time and space, it is a four-vector. Everything about ω is right. But, except for one little thing: ω and k as four-vectors have to have four components: where are the other two components? We have seen that wave k in the time and space is the \hat{x} -axis direction, but ω is in all directions, and so we must solve fully the problem of the propagation of light in three space dimensions, not just in one dimension, or we have been doing up idealism.

Suppose that we have a coordinate system $x, y, z, \text{and } t$ with x is travelling along and whose variation axes are shown in Fig. 34-1. The wavelength of the wave is λ , but the direction of motion of the wave does not happen to be \pm the direction of one of the axes. What is the formula for such a wave? The wavevector already has $(\omega - kx)$, where $k = k_x \hat{x}$ and x is my distance along the direction of motion of the wave—the component of the spatial position in the direction of motion. Let us put it this way: if $x > 0$ the vector position of a point in space, \mathbf{r} , is $\mathbf{r} = \hat{x}x$, where \hat{x} is a unit vector in the direction of motion. That is, x is just $\cos(\theta, \hat{x})$, the component of \mathbf{r} in the direction of motion. Then the wavevector is $\omega - k_x \hat{x} - k_y \hat{y} - k_z \hat{z}$.

Now it turns out to be very convenient to define a vector \mathbf{k} , which is called the ω , k vector, which has a magnitude equal to the wave number, Eq. 34.16, and is pointed in the direction of propagation of the wave:

$$\mathbf{k} = 2\pi\mathbf{v}/\lambda = \mathbf{v}\hat{\omega} \quad (34.19)$$

Using this vector, our wave can be written as $\cos(\omega t - \mathbf{k} \cdot \mathbf{r})$, or as $\cos(\omega t + \hat{\omega}_x x - \hat{\omega}_y y - \hat{\omega}_z z)$. What is the significance of a component $\hat{\omega}_x$? $\hat{\omega}_x$ is $\omega \sin \alpha$. Clearly, $\hat{\omega}$ is the rate of change of phase with respect to x . Referring to Fig. 34-11, we see that the phase changes as we change x , just as if there were a wave along a fan of a large-wavelength. The “wavefronts” in the x -direction“ \rightarrow longer than a natural, free wavelength by the secant of the angle α between the actual direction of propagation and the x -axis.

$$\hat{\omega}_x = \omega/\cos \alpha \quad (34.20)$$

Because the rate of change of phase, which is proportional to the reciprocal of λ_ω , is smaller by the factor $\cos \alpha$, that is just how k_x would vary if we took the magnitude of \mathbf{k} times the cosine of the angle between \mathbf{k} and the x -axis!

There, then, is the nature of the wave vector (and we use to represent a wave in three dimensions). The four quantities ω , $\hat{\omega}_x$, k_x , $\hat{\omega}_y$, k_y , $\hat{\omega}_z$, k_z transform in analogy as a four-vector, where ω corresponds to the time, and $\hat{\omega}_x$, $\hat{\omega}_y$, $\hat{\omega}_z$, k_x , k_y , k_z correspond to the x , y , z , and t components of the four-vector.

In our previous discussion of gravitational relativity (Chapter 17), we learned that there are ways of taking dot-products with four-vectors. If we take the position vector \mathbf{r}_ω , where ω stands for the four components (time and three space ones), and if we call the wave vector \mathbf{k}_ω , with ω the time, \mathbf{k}_ω has four space components, time and three space ones, then the dot product of \mathbf{r}_ω and \mathbf{k}_ω is written $\Sigma k_\omega \epsilon_{\omega i}$ (see Chapter 17). This last relation is an invariant, independent of the coordinate system: what is it equal to? By the definition of a dot product for four-vectors, it is

$$\Sigma k_\omega \epsilon_{\omega i} = \omega - \hat{\omega}_x x - \hat{\omega}_y y - \hat{\omega}_z z \quad (34.21)$$

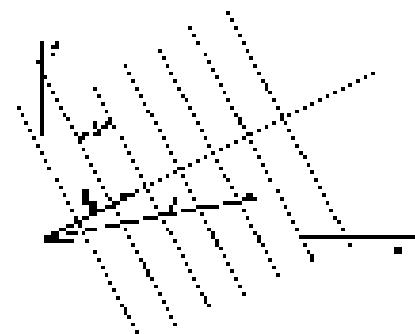

Fig. 34-11. A plane wave traveling in one direction.

We know from our study of vectors that $\nabla \cdot \vec{v}_r$ is invariant under the Lorentz transformation, since \vec{v}_r is a four-vector. But this quantity is precisely what appears inside the braces for a point vector, and it ought to be invariant under a Lorentz transformation. We connect this to a formula with something like a "charge inside the braces," since we know that the place of having connected charge with we change the coordinate system.

24-8 aberration

In deriving Eqs. (24.7) and (24.13), we have taken a simple example where it happened to be a direction of motion, but, of course, we can generalize to other cases also. For example, suppose there is a source sending out light in a general direction but at a point of view of $\vec{v}_r = 0$, at rest, but we are moving along on the earth, as in Fig. 24-12. From which direction does the light appear to come? To find this, we will need to write down the four components of \vec{v}_r and apply the Lorentz transformation. The answer, however, can be found by the following argument: we have to point our telescope at an angle to see the light. Why? Because the light is coming down at the speed c , and we are moving sideways at the speed v , so the telescope has to be tilted forward so that the light comes down at an angle, slower than the rate. It is very easy to see that the horizontal distance is given when the vertical distance y is given; therefore, x is the hypotenuse, and $\theta = \pi/2 - \phi$. However! How nice, indeed, even for such a thing! If θ is the angle at which we would have seen the telescope relative to the earth, because we made our telescope. The point of view is a "fixed" observer. When we stand the horizontal distance is up, the angle of the earth would have been a different θ . Determining θ measured with a "spinning" robot, informs us that because of that centrifugal effect,

$$\tan \theta = \frac{v/c}{\sqrt{1 - v^2/c^2}}$$
 (24.14)

which is equivalent to

$$\sin \theta = \gamma \phi. \quad (24.15)$$

It will be the reader's for the student to derive the result using the Lorentz transformation.

This effect, the telescope has to be tilted, is called aberration, and it has been observed. Now can we observe it? What may occur where a given star should be? Suppose we do have a fault in our wrong calculation in such a way, however, we know it is a wrong correction? Decrease the earth's speed all the same. Today we have to point the telescope one way; six months later we have to tilt the telescope the other way. But is it so we can tell that there is such an effect?

24-9 The aberration of light

Now we turn to a different topic. We have never, in all our discussion of the previous chapters, said anything about the effects of the magnetic field and its associated with light. Ordinarily, the effects of the magnetic field are very small, but there is one interesting and important effect which is a consequence of the magnetic field. Suppose that \vec{v}_r is $v \hat{i}$, and there is a current i passing all a charge, and driving that charge q , and down. We will suppose that the charge moves in the x direction, i.e., the motion of the charge is also in the x direction; it has a position r and a velocity \vec{v}_r , as shown, in Fig. 24-13. The magnetic field is at right angles to the electric field. Now as the electric field acts on the charge and makes it go up and down, what does the magnetic field do? The magnetic field acts on the charge (say an electron) only if the it is moving in the electric field direction, it is driven by the electric field, so the two of them work together. While the thing is going to the left, v has a velocity $v \hat{i}$, there is a force on it. It has a $v \times \vec{B}$; but in which direction is this force? It has the direction of the polarization of light. Therefore, when $v \hat{i}$, v is going at a charge and it is oscillating in a perpendicular \hat{j} -direction.

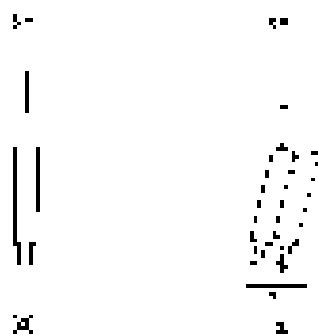

Fig. 24-12. A telescope on Earth is viewed by (a) stationary telescope and (b) a leisurely moving telescope.

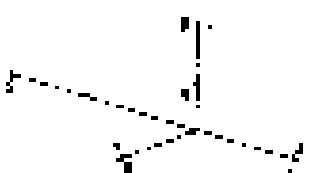

Fig. 24-13. Electromagnetic forces on a charge which is driven by the electric field and by the direction of the light beam.

charge there is a driving force in the direction of the light beam. This is called radiation pressure or light pressure.

Let us determine how strong the radiation pressure is. Once again it is $F = qE$, where q is the charge. If everything is oscillating, it is the time average of this. From (24.2), the energy E of the magnetic field is the same as the sum of the electric field squared by c , so we need to find the average of the electric field, times wave velocity, times the charge. This is $1/c$. ($F = qE/c^2$). But the charge q times the field E is the electric current on a charge, and this sum over the charge gives the radiation pressure for a single atom on the charge! Therefore the force, the "pushing momentum," that is delivered per second by the light is equal to $1/c$ times the energy absorbed from the light per second! That is a general rule, since we did not say how strong the oscillator was, or whether some of the charges varied more. In our circumstances stars light is being diminished above a percent. The momentum that the light delivers is always equal to the energy that is absorbed, divided by c :

$$F = \frac{dE/dt}{c}. \quad (24.24)$$

That light carries energy we already know. We now understand that it also carries momentum and hence, that the momentum is equal to $1/c$ times the energy.

When light is emitted from a source there is a recoil effect. The something is reverse. It can alone is carrying an energy E in some direction, then there is a recoil momentum $p = E/c$. If light is reflected normally from a mirror we get twice the force.

This is as far as we shall go using the classical theory of light. Of course we know that there is a quantum theory, and that in it light represents light acts like a particle. The energy of a light-particle is a constant times the frequency:

$$E = h\nu = pc. \quad (24.25)$$

We now express the fact that light also carries a momentum equal to the energy divided by c in another way. Let the effect be γ per photon. Then γ is momentum

$$\gamma = E/c = h\nu/c = p. \quad (24.26)$$

The direction of the momentum is, of course, the direction of propagation of the photon. γ is just p in vector form,

$$\gamma = \gamma_x \hat{i} + \gamma_y \hat{j} + \gamma_z \hat{k}. \quad (24.27)$$

We now show, of course, that the energy and momentum of a particle that forms a wavelet. We have just observed that ω and k form our vector. Therefore it is a good thing that (24.27) has the same form in both cases; it means that the quantum theory and the theory of relativity are morally consistent.

Equation (24.27) can be written more elegantly as $\gamma = \hbar k$, if we replace ν by ω , for a particle associated with a wave. Although we have discussed this only for photons, for which \hbar (the magnitude of \hbar) equals one and $\nu = \omega/c$, the relation is much more general. In quantum mechanics all particles, not only photons, exhibit wavelike properties, but the frequency and wave number of the wave is related to the energy and momentum of particle by (24.27) (called the deBroglie relation) even when \hbar is not equal to \hbar_{Planck} .

In the last chapter we saw that a beam of right or left circularly polarized light can carry angular momentum in an amount proportional to the energy E of the beam. In the (ν, ω, k) picture, a beam of circularly polarized light is represented as a screw of photons, each carrying an angular momentum $\pm \hbar$ along the direction of propagation. That is what the axes of polarization in the complex plane of ν —the previous ω —carry angular momentum, as spinning electrons do. But this "bullet" picture is really incomplete in the "wave" picture, and we shall have to discuss these ideas more fully in a later chapter on Quantum Relativity.

Color Vision

35-1 The Human Eye

The perception of colors depends partly on the physical world. We discuss the colors of light and what is being produced by interference. But then, obviously, it depends on the eye, or what happens behind the eye, in the brain. These characteristics of light that enter the eye, but also that our sensations are the result of physiological and psychological processes.

There are many interesting phenomena associated with vision which involve a mixture of physical phenomena and physiological processes, and the full appreciation of natural phenomena as we see them must go beyond physics to the social sciences. We make no apologies for making these excursions into other fields, since the separation of fields, as we have anticipated, is merely a human convenience, and an unnatural thing. Nature is not interested in our convenience; hence, and many of the interesting phenomena bridge the gaps between fields.

In Chapter 1 we have already discussed the relation of physics to the other sciences in general terms, but now we are going to look in considerably more specific field in which physics and other sciences are very, very closely interrelated. That one is vision. In geometry, "visual" effects refer to the present of light. At the present of light, we shall discuss mainly the observable phenomena of human vision, and in the next chapter we shall consider the physiological bases of vision, both in man and in other animals.

It all begins with the eye; so, in order to understand what phenomena we see, some knowledge of the eye is required. In the next chapter we shall discuss in some detail how the various parts of the eye work, and how they relate to the connection with the nervous system. For the present, we shall describe only briefly how the eye functions (Fig. 35-1).

Light enters the eye through the cornea; you have already learned how it is bent and is focused on the retina, called the "bottom" of the lens of the eye, so that different parts of the retina receive light from different parts of the visual field outside. The result is not necessarily uniform; there is a "fovea," a spot, in the center of our field of view which we can see. You can prove this yourself carefully, and of which we have the greatest clarity of vision if we call it the *foveal macula*. This is deep in the eye, so we can immediately appreciate from our experience in looking at things, why we are able to see best in seeing. That is in the center of the eye. There is also a spot in the fovea where the nerves are trying all the information out front; that is a blind spot. There is no sensitive part of the retina here, and it is possible to demonstrate this. You take a key, hold it up and look straight at something, and then move a finger or another small object slowly out of the field of vision, suddenly disappears, vanishes. This is just what would happen if that part of the eye were like a photographic negative, because quite a fellow, in the court of a king of France by painting his coat of arms, in the boring sessions that he was with his courtiers, the king could amuse himself by "cutting off their heads" by breaking at one and separating another head disappear.

Figure 35-2 shows a magnified view of the inside of the retina in somewhat schematic form. In different parts of the retina, the nerve fibers and optic nerves. The objects that occur more densely near the periphery of the retina are rod cells. Close to the fovea, we find, besides these rod cells, also cone cells. They are, I suppose, the receptors of the rods. As we get closer to the fovea, the number of cones increases, etc. In the fovea itself there are (in fact, nothing but) cone cells, packed very tightly, so (which fits), the cone cells are substituted, a narrower

35-5 The chromaticity diagram

35-6 The mechanics of color vision

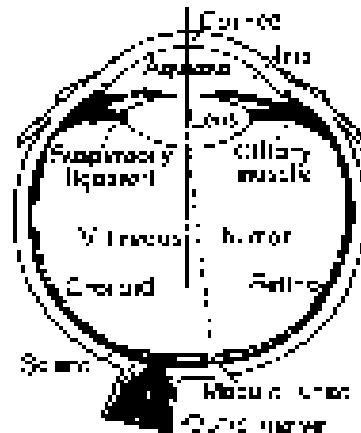

Fig. 35-1. The eye.

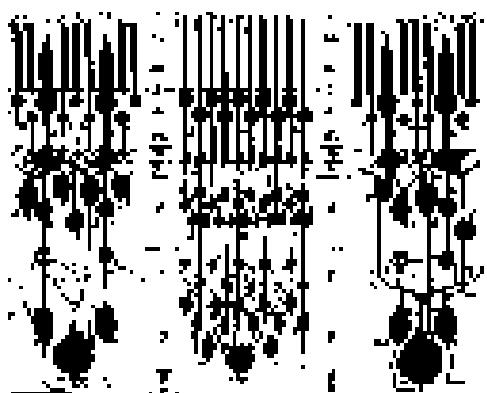

Fig. 35-2. The structure of the retina (light rays have been added).

Now there is something else. You must appreciate that we see with the cones right in the middle of the field of view, but as we go to the periphery we have: the rod cells, the rods. Now the interesting thing is: That is the part's each of the cells which is sensitive to light is not connected by a fiber directly to the optic nerve, but is connected to many other cells, which are the other members of the cone system. There are several kinds of cells; there are rods that carry the information toward the optic nerve. In other words, there are rods that are actually interconnected. "Locally." There are essentially two kinds of cells. The overall organization details are: The main thing we emphasize is: the "the light signal is already being 'thought about.'" To put it simply, the information from the various rods does not immediately go to the optic, spot for spot, but it is carried as a certain amount of the information has already been "thought" by a combining of the information from several visual receptors. It is important to understand that some brain-function processes occur in the eye itself.

35-2 Color depends on luminosity

One of the most striking phenomena of vision is the dark adaptation of the eye. If we pass into the dark from a brightly lit room, we cannot see very well. We're white, but gradually things become more and more discernible, and eventually we can see something where we could see nothing before. If the intensity of the light is very low, the things that we see have no color. It is known that this dark-adapted vision is almost entirely due to the rods, while the vision in bright light is due to the cones. As a result, there are a number of phenomena that we can easily appreciate because of this transfer of attention from the cones and rods that first engaged our eye.

There are many situations in which, if the light intensity were stronger, we would see colors, and we would find these things quite beautiful. One example is the through a telescope we usually always see "black and white" images of these nebulae, but W. C. Miller of the Mt. Wilson and Palomar Observatories had the permission to do color pictures of some of these objects. Naturally he could really see these colors with the eye, but they cannot be taken because it is merely that the light intensity is not strong enough for the cones in our eye to see them. As long as the main spectrum of such objects are the same nebula and the Cepheids. The former shows a definite blue color at night, bright red color during the day, and red-orange during the day, punctuated by bright red-orange flares.

In the bright light, apparently, the rods are at very low sensitivity - but in the dark, as time goes on they pick up their ability to see light. The variations in light sensitivity here which one can observe is over a million to one. Nature does not do all this with just one kind of cell, but she gives her job from bright-light-sensing cells, the cone-sensing cells, the cones, to low-intensity, dark-adapted cells, the rods. Again, the interesting consequence of this shift is this: first, that there is inversion, and second, that there is a difference in the relative brightness of sufficiently colored objects. It is to note that the rods are never trying the sun than the cones do, and the inversion can, for example, keep light while the rods find the color fully impossible to see. So what's black at first is the color now normal. For two pieces of colored paper, say this and that, in which the red might be even brighter than the human eye, will, in the dark, appear completely reversed. It is a very striking effect. If we are in a dark room and we find a magazine or something that has only a red, before we know for sure what the colors are, we judge the place and darker areas, and if we then take the magazine into the light, we may see this very remarkable shift in color which was the brightest color and which was red. This phenomenon is called the Purkinje effect.

In Fig. 35-3, the dashed curve represents the sensitivity of the eye in the dark, i.e., using the rods while the solid curve represents it in the light. We see that the peak sensitivity of the rods is in the green region, and that of the cones is more in the yellow region. If there is a red-colored page, (say a red nothing) we can see it if it is brightly lighted, but in the dark it is almost invisible.

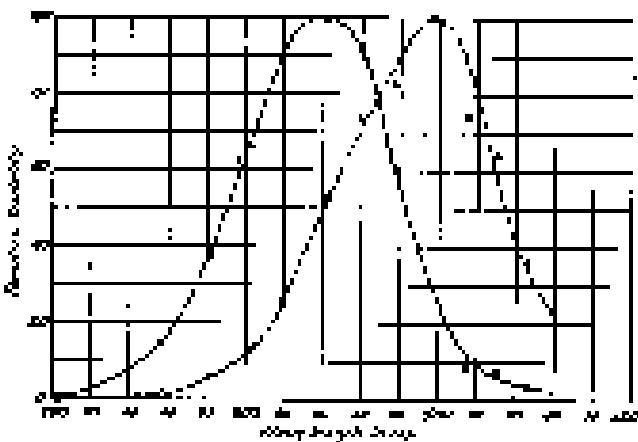

Fig. 35-9. The spectral sensitivity of the eye. Dashed curve, received & review.

Another effect of the Sun that only lasts over at the dusk, and then there are no clouds in the future, is that when we look straight at something in the dark, our vision is not quite as acute as when we look to one side. A faint star or nebula can sometimes be seen better by turning a little to one side than directly at it. However we do not have sensitive rods at the middle of the fovea.

Another interesting effect of the Sun is that the number of cones decreases as we go further out. The edge of the field of view is the last, even in a bright light, cover disappears as the object goes far enough away. The way to test that is to look in some particular field direction. Let a friend walk in from one side with colored cards, and try to decide what color they are before they are right in front of you. One hand can be seen out at the earliest distance, long before he can determine the color. When doing this, it is sufficient to come up from the side again, a few steps, since as it is converging rather easily to almost see the color, then does not see anything, then to see the color again.

Another interesting phenomenon is that the periphery of the retina is very sensitive to motion. Although we cannot see very well from the center of our eye, if a little bug comes and we do not expect anything to be moving over there we are immediately sensitive to it. We are all "wired up" to look for something jiggling to the side of the field.

35-3 Measuring the color stimulus

Now we pass from the more refined, to the brighter vision, and we come to the question which is most characteristic of wave vision, and the *color*. As we know, white light can be split by a prism into a whole spectrum of wavelengths which appear to us in many different colors; that is what colors are, of course, appearances. Any source of light can be analyzed by a grating or a prism, and one can determine the spectral distribution, that is, the "amount" of each wavelength. A certain light may have a lot of blue, considerable red, very little yellow, and so on. That is all very precise at the sense of vision, but the question is, what color will it appear to us? It is evident that the different colors depend somehow upon the spectral distribution of the light, but the problem is to find what characteristic of the spectral distribution produces the various colors. For example, what do we have to do to get a green color? We all know that we can simply take a glass of incandescent light which is green. But is that the only way to get green, or orange, or any other color?

In the course I am one spectral distribution which produces the same apparent visual effect. I hope answers a, definitely yes. There is a very limited number of your effects, in fact, just a three-dimensional manifold of them, as we shall shortly see, but there is an infinite number of different curves that we can draw to the light the colors from different sources. Now the question we have to discuss is, under what conditions the distributions of light appear as exactly the same color to the eye?

The true power of psychophysical technique in color judgment is to use the eye as a *unit instrument*. And so we do not try to find in which conditions a given sensation is to measure its whatness or what it gives us back because it turns out that this is not easily accomplishable. Instead, we study the conditions under which two stimuli are indistinguishable. Then we do not have to decide whether two people see the same coloration in different circumstances; h. only whether, if two people two sensations are the same. They can also decide for another. We do not have to decide whether, when one sees something green, what it feels like outside is the same as when he looks like inside someone else when he sees something green, we do not know anything about that.

To illustrate the possibilities, we may use a series of four projectors upon which have filters on them, and whose brightness are continuously adjustable over a wide range: one has a red filter and makes a spot of red light on the screen, the next one has a green filter and makes a green spot, the third one has a blue filter, and the fourth one is a white circle with a black spot at the middle of it. Now if we look on colored light, and not on a pure monochrom, we see that it is the case of overlap it produces a sensation which is not what we call reddish green, but a new color, yellow in this particular case. By changing the proportions of the red and the green, we can go through various shades of reddish green. But if we have an R, G, B, and a yellow, we can also obtain that same yellow not by mixing these two colors but by mixing some other ones, perhaps a yellow filter with some "green," or something like that, to get the same sensation. In this way, it is possible to make various colors by using the same way by mixing the lights from various filters.

What we have just discovered may be expressed symbolically as follows. A particular color, say, for example, can be represented by a certain symbol R which is the "sum" of certain amounts of red, green, light filtered, and colored light (G). By using determinate values and G , to describe how bright the R, and G are, we can write a formula for this yellow:

$$Y = cR + cG \quad (1)$$

The question is, can we make all the different colors by adding together two or three lights of different fixed colors? Let us see what can be done in real connection. We certainly cannot get all the different colors by mixing only red and green, because, for instance, the orange appears in such a mixture. However, if you try to make blue the central region, where all the lights overlap, may be made to appear a very fairly "ice white." By mixing the various colors and keeping at this center region, we find the *whole* possible visible range of colors in this region by changing the proportions, and so it is not impossible that all the colors can be made by mixing these three colored lights. We shall discuss this point. This is true; it is in fact, very likely correct and we shall shortly see how to confirm the proposition better.

In order to illustrate our point, we move the spots on the screen so that they all fall on top of each other and then we try to make a particular color which appears in the overlapping shade by the fourth lamp. What we find though, is that "orange" coming from the first, it always appears yellowish. One may try to match this by adjusting the red and green one. But as far as we can see a kind of error and error, and we find that we can approach rather closely this particular shade of "orange" color. So it is very hard to believe that we can't make the color. We can try to make yellow in a moment, but before we do that, there is no doubt that orange is very hard to make. People who give lectures on colorimetry, the "colorist" unless, but they never make brown, and it is hard to recall ever having seen brown light. As a matter of fact, this color is never used for any stage effects, nor never seen a yellow with brown light, so we think it might be impossible to make brown. In order to find out whether it is possible to make brown, we point out that brown light is mostly something that we are not used to seeing without its background. As a matter of fact, we can make it by mixing red and yellow. To prove that we are looking at brown light, we merely increase the brightness of the peculiar

superposed against which we see the very same light, and we see that that b. is full white, we call it yellow! Brown is always a dark color due to a lighter background. We can easily change the coloring of the brown— for example, if we have some green, and we get a reddish brown, apparently a chocolate reddish brown, and if we put some green to it, in proportion, we get the beautiful color which all the uniforms of the Army are made of, for the light from that color is not so sensible by itself as the yellowish green, but seen against a light background.

Now we put a yellow glass in front of the sun, to filter and try to see whether the intensity must be exactly as before the range of the various lights; we cannot make something which is too bright, because we do not have enough power to hold up. But we can make the yellow; without a green and no mixture, and you add a touch of blue to make it even more perfect. Perhaps we are ready to believe that, under good conditions, we can make a perfect mixture of any given colors.

Now let us discuss the laws of color mixing. In the first place, we find that different spectral distributions etc., produce the same color. Next, we saw that "why" could not be made by taking twelve these spectral colors, not if we had just one. The most interesting feature of color mixing is that if we have a certain light, which we may call X , and if it appears indistinguishable from Z to the eye (it may be a different spectral distribution, but it agrees with probabilities), we call them colors "equal." In the sense that the eye sees them as equal, we write

$$X = Y \quad (35.2)$$

Here is one of the great laws of color. If two spectral distributions are indistinguishable, and we add them to a certain light, say Z , of intensity $X - Z$, this means that we shine both lights on the same patch, and then we take X and add the same amount of the tinted or light Z , the two colors are also indistinguishable.

$$X + Z = X + Z \quad (35.3)$$

We have not mentioned the yellow; if we now shine pink light on the white China, it will still match. Shining any other light to the pink or light, we're a match. In other words, we can summarize all these exact relationships by saying, and once we have said it, the same two colored lights, say X and Z to each other in the same circumstances, then this makes X red, and one light can be substituted for the other light in any other color mixing situation. In fact, it turns out, and it is very important, and interesting, that this mixing of the colors of lights is not dependent upon the characteristics of the eye at the moment of observation; we know that, if we look at a bright red surface in a bright red light, and then look at a white paper, it looks grayish, and other colors are also changed by our seeing looked so long at the bright red. If we now have a match between, say, two surfaces, and we look at them and make the match, then we look at a bright red surface for a long time, and then turn back to the yellow, it may not look very red; but when what color it will look, and it will not look yellow. Now unless the surface and wall look washed, and we, as the eye, adapt to various ranges of intensity, the color match X works with the absolute exception of when we go into the region where the intensity of the light goes down, then we have shifted from one to the other, then the color match is no longer a color match, because we are using a different system.

The second principle of color mixing, of lights is this, any color of all can be made from three different colors, the primary, red, green and blue lights. By suitable mixing the three regresses we can create anything at all, as we demonstrated with our own examples. Furthermore, there are very interesting mutual relations. Let's see what are interested in the two halves of one thing, it turns out as follows. Suppose that we have our three colors which were red, green, and blue, but label them A , B , and C , and call them our primary colors. Then any color can be made by certain amounts of these three; say an amount x of color A an amount y of color B , and z amount of color C makes X .

$$X = ax + by + cz \quad (35.4)$$

Now suppose we have color Z & make from the same three colors:

$$Z = \sigma X + \tau Y + \rho Z' \quad (35.2)$$

This is just $\text{out } Z'$, the mixture of the original X, Y & Z & one of the components of the base that we have already previously obtained by taking the sum of the components of X, Y & Z :

$$Z = X + Y - (1 - \sigma)X - (\bar{\sigma} - \delta)Y + (\rho + \varepsilon)Z' \quad (35.3)$$

It is just like the mechanics of the addition of vectors when (α, β, γ) are the components of one vector and (x, y, z) are those of another vector, and the new light Z is just the "sum" of the vectors. This subject has always appealed to physiologists and mathematicians. In fact, Spinoza's wrote a wonderful paper on color vision¹ which he developed his theory of vector analysis as applied to the mixing of colors.

Now a question is, what are the correct primary colors in \mathbb{R}^3 ? There is no such thing as "the" normal primary colors for the mixing of lights. There may be, for practical purposes, some prims that are more useful than others. By putting a palette of colored pigments, but we can see differentiating them now day from differently colored lights & moreover can always be mixed in the correct proportion to produce any other color at it. Can we assume we have found our four? Instead of using red, green, and blue, let us use red, blue, and yellow in our projector. Can we use red, blue, and yellow to make, say, green?

By mixing these three colors in various proportions, we get quite an array of different colors, ranging from white to gray. But as a matter of course, after a lot of trial and error, we find that certain sets look like green. The question is, are we *sure* about it? The answer is, *now*², by projecting now red & blue the green, then we can make a match with a certain mixture of yellow and blue! So we have *two* blues there, except that we had to cheat by putting the red on the other side. But since we have two in the red-yellow location, we can approach it this way. We *only* showed was not that *any* colors always be made, say, of red, blue, and yellow, but by putting colored on the other side we found that red plus X could be made out of blue & yellow. That is, without loss of generality, we can interpret X as a negative number, so it *can* still allow that the coefficients in equation (35.4) can be both positive and negative, and if we interpret negative amounts to mean the colors would have to subtract out, then any color can be produced by any mix, and there is no such thing as "the" fundamental primaries.

We must ask whether there are three colors, i.e., some only with positive amounts for all its digits. The answer is no. Every set of three primaries requires negative amounts for some colors, and therefore there is no such as red, green, & blue a primary. In elementary books they insist it is red, green, and blue, but this is merely because with these a wider range of colors is available without minus signs for some of the coefficients.

35-4 The chromaticity diagram

Now let us discuss the combinations of colors or, in mathematical language, geometrical group addition. If any one vector is represented by Eq. (35.4), we can plot it as a vector in space by starting from the origin O , in a line a , and then a certain vector is a point. If a color vector is (σ, τ, ρ) , the color is σ red, τ green, ρ blue. In general however, as we know, the color which comes from adding these as vectors. We can simplify the diagram and reduce everything to a plane by the following observation: If we had a beam of color light, and merely multiplied it and to itself, then, if we make them all stronger in the same ratio, it is the same color, but brighter. So, if we project everything to the same light intensity, then we can project every thing into a plane and the we have there in Fig. 35-1, it follows that any color obtained by adding a given red & some pro-

¹ Except, of course, if one of the bases can be matched by mixing the other two.

position λ . This is where the mixing law "between the two points." For instance, a 50-50 mixture would appear halfway between them, and 1/3 of one and 2/3 of the other would appear 1/3 of the way from one point to the other, and so on. However, this is a *pure* color, not a mix, because the light doesn't have the same make-up; positive coefficients are needed, the active triangle, which contains "inside" of the colors that we can see, because all the colors that we can see are contained in the solid triangle bounded by the sides. Where is this zero come from? That turns out to mark a very special mixture of the colors, but we can see against it, or spectral pure. But we do not have to check all colors that we can see, we only have to check the pure spectrals. Because of the spectrum, any light can be considered as a sum of various positive amounts of various pure spectral colors, just like the physical wave point. A given light will have a certain amount of red, yellow, blue and even—greenish colors. So if we know how much of each of our three chosen primaries is needed to make each of these pure components, we can calculate the total amount of each to make our given color. So, if we add up what the color coefficients are, the spectral colors sum for any given color are my colors, then we can work out the whole color mixing rule.

An example of such experimental results for mixing three lights together is given in Fig. 33-4. This figure shows the amount of each of three different primary primaries red, green and blue, which is required to make each of the spectral colors. Notice at the left end of the spectrum, yellow is next to violet, and the two are close. Notice that at some places minus signs are necessary. It is from such data that it is possible to write the proportion of all of the colors in a chart where the x - and y -coordinates are relative to the sum of the different proportions that are used. That is the way that the curved boundary $\Delta\alpha\beta$ has been found. It is because of the pure spectral relations. Every spectral color can be made by adding spectral pure, of course, and so on, but then anything that can be produced by connecting one part of the curve to another is a color that is visible in nature. The straight line connects the end of the spectrum with the extreme mixture. This is because of the purple. Inside the triangle you can see that can be made with lights, and outside it are colors that cannot be made with lights, and nobody has ever seen them except possibly in after-images.

33-5 The mechanism of color vision

Now the next aspect of color vision, in the question, why do colors behave in this way? The simplest theory, proposed by Young and Helmholtz, suggests that in the eye there are three different regions which receive the light and that these three different regions absorb light at different places strongly, say, in the middle, either they have mostly in the blue, another absorbs in the green. And when we shine a light on them we will get different amounts of energy lost in the three regions, and these three pieces of information are somehow transmitted to the brain and in the brain it's converted to decide what the color is. It is easy to convince that all of the rules of color mixing would be a consequence of this proposition. There has been a considerable debate about the thing because the next problem, of course, is to find the share of absorption by each of the three pigments. It turns out, unfortunately, that because we can transform the color coordinates in a *very* manner we want to, we can only find *certain* kinds of linear combinations of absorption curves by the orthogonality experiments, but not the curves for the individual pigments. People have tried all various ways to obtain specific ones which also describe some particular physical properties of the eye (though not in a very satisfactory way), something like in Fig. 33-5. In this figure are two curves, one for eyes in the dark, the other for eyes in the light; and here is the cone being measured. This is measured by finding what is the smallest amount of colored light we need to add to the white to just see it. This measures how sensitive the eye is to different spectral regions. Eyes are very interesting way to measure this. If we take two colors and make them appear in unison by flickering back and forth from one to the other, we see a flicker if the frequency is too low. However, as the frequency increases,

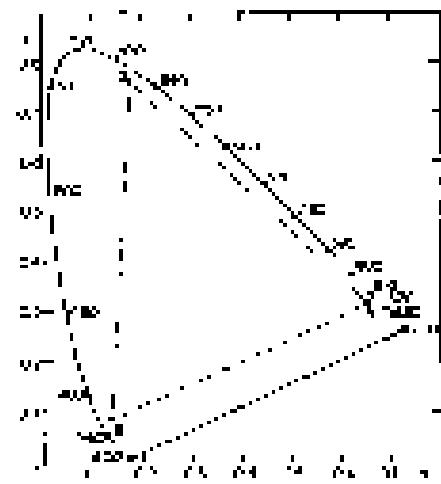

Fig. 33-4. The standard chromaticity diagram.

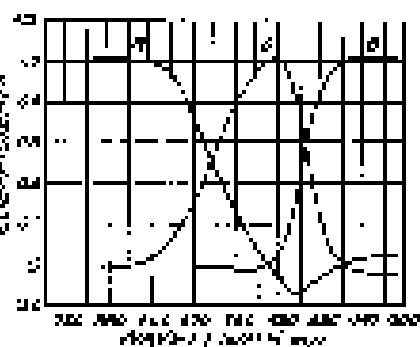

Fig. 33-5. The color coefficients of pure spectra values in terms of a cone in one of standard primary colors.

The color will change slightly depending on a certain frequency that depends on the brightness of the light. If we try to see repetitions per second, now if we adjust the brightness of the stimulus so one color cannot be seen, there comes an intensity where the flicker of the colors disappears. To see flicker with the brightness so adjusted, we have to go to a much lower frequency in order to see a flicker of the colors. So, we get what we call a flicker of the brightness at a higher frequency and, it is known that there is a flicker of the colors. It is possible to match two colors for "equal brightness" by this frequency technique. The results are almost, but not exactly, the same as those obtained by measuring the threshold sensitivity of the eye for seeing weak light by the cones. Most workers use the Flicker system as a definition of the brightness curve.

Now, if there are three other sensitive pigments in the eye, the problem is to determine the shape of the absorption spectrum of each one. Now,¹ we know there are people who are color blind—eight percent of the male population and one-half of one percent of the female population. Most of the people who are color blind are abnormal in either one has a different degree of sensitivity. There others may see some of colors but they still need three colors to match. However, there are some who are called dichromats, for whom the color can be matched by only two primary colors. These are called anomalous trichromats. They are missing one of the three pigments. If we can find three kinds of color-blind dichromats who use different sensitivity rules, one kind should be missing the red sensitive pigment, and another the blue sensitive pigment. By measuring all these types we can determine the three curves. It turns out that there are three types of dichromats and three types. There are two anomalous types and a third very rare type and from these three it is then possible to deduce the spectrum absorption spectra.

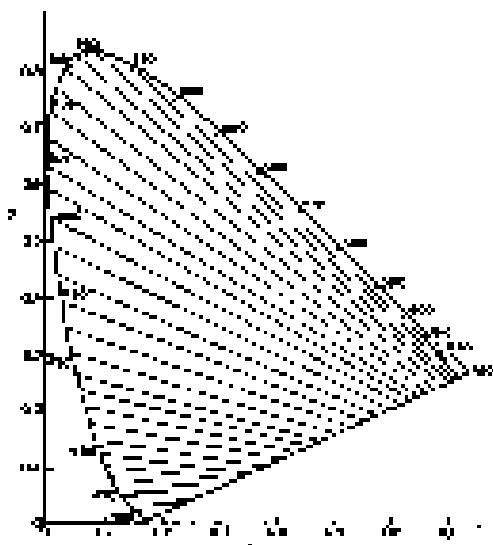

Fig. 25-6. Loss of color caused by dichromats.

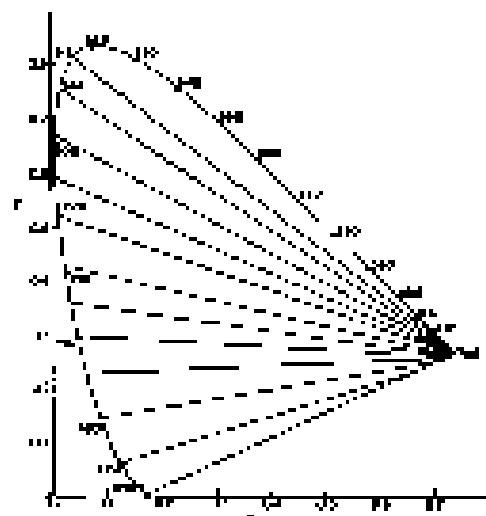

Fig. 25-7. Loss of color caused by protanopes.

Figure 25 follows the color missing of a particular type of color-blind person called a dichromat. For him, the set of curves above are not quite the certain lines, along each of which the color appears to him to be the same. If the theory that he is missing one of the three colors is confirmed, it might well be that all the lines should intersect at a point. If we carefully measure on the graph, they do intersect perfectly. Obviously, therefore, this has been made by a mathematical calculation and does not represent real data. And in fact, if we look at the lined paper with real data, it turns out this in the graph of Fig. 25-6, the point of intersection of all the curves is not exactly at the right place. Using the lines as in the above figure, we can find a reasonable spectrum; we need negative and positive absorptions in different regions. In using the new sets of curves, it turns out that each of the absorption curves is everywhere positive.

Figure 35-7 shows a different kind of color blindness, that of the protopigment, which has a peak near the red end of the incoming curve. You can just approach the same position in this case. Using the same color-matching curves of color blindness, the three-pigment response curves have fully been determined, and are shown in Fig. 35-8. *Really?* Perhaps there is a question as to whether the three-pigment idea is right. We know color blindness results from loss of one pigment, and even whether the following data are color blindesses are right. Different workers get different results. This field is still very much under development.

35-6 Physiochemistry of color vision

Now, what about checking these curves against real pigments in the eye? The pigment then can be obtained from a retina consisting mainly of a pigment cell (retinoblastoma). The most remarkable feature of this are, first, that it is the eye of almost every vertebrate animal, and second, that its response curve fits beautifully with the sensitivity of the eye, as seen in Fig. 35-9, in which we plotted on the same graph the absorption of visual purple and the sensitivity of the dark-adapted eye. This pigment is evidently the pigment that we see with it; the dark-adapted eye. This pigment is evidently the pigment that we see with it; the dark-adapted eye. This fact was discovered in 1877. From today it can be said that the other pigments of the cones have never been obtained in a live eye. In 1938 it could be said that the other pigments had never been seen at all. But since that time, two of them have been discovered by techniques by a very simple and beautiful technique.

The trouble is, presumably, that since the eye is so weakly sensitive to bright light compared with light of low intensity, it needs a lot of visual purple *as pigment*, but not much of the other pigments for seeing colors. Reddish's idea is to have the pigment in the eye, and measure it anyway. What he does is this. The eye is instrumented with an ophthalmoscope for sending light into the eye through the lens and even focusing the light that comes back out. With a photogate measure how much is reflected. So one measures the reflectance coefficient of light that has passed once through the pigment (reflected by a back layer in the eyeball, and coming out through the pigment) reflected by a back layer in the eyeball, and coming out through the pigment of the cone again. Nature is not always so beautifully designed. The cones are interestingly designed so that the light that comes into the cone bounces around and works its way down into the light-sensitive points of the eyes. The light goes right down to the sensitive point, bounces to the bottom, and comes back out again, having lost only a considerable amount of the intervening pigment; also, by lossless reflection, where the cone membrane is not exercised by visual purple. But the color of the retina has been seen a long time ago: it is sort of orangy pink; then there are all the blood vessels and the color of the muscle of the back, and so on. How do we know when we are looking at the pigment? Answer: First we take a color-blind person, who can never distinguish between it is therefore easily to make the analysis. Second, the various pigments, like visual purple, have an intensity excess when they are bleached by light; that is, when light on them they change their composition. So, while looking at the absorption spectrum of the eye, R. takes pulsed beam in the whole eye, which changes the contrast ratio of the pigment, and he measured the change in the spectrum, and the difference of course has nothing to do with the amount of blood or the color of the intervening layers, and so on. Just only the pigment, and at this measurement obtained a curve for the pigment of the photoreceptor, which is given in Fig. 35-10.

The second curve in Fig. 35-10 is actually obtained with a normal eye. It is obtained by taking a normal eye and, having already determined what one pigment was, bleaching the other one in the red where the last one is insensitive. Red light has no effect on the photopigment eye. In this is the normal eye, and thus one can obtain the curve for the missing pigment. The shape of one can fit perfectly with Yoshida's green curve, but the red curve is only fit displaced. So you know we are getting at the right track. Or perhaps not—the latest work with spectrometers does not show any definite pigment missing.

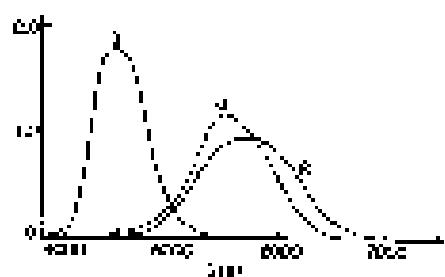

Fig. 35-8. The spectral intensity curves of three normal trichromatic receptors.

Fig. 35-9. The sensitivity curve of the dark-adapted eye compared with the absorption curve of visual purple.

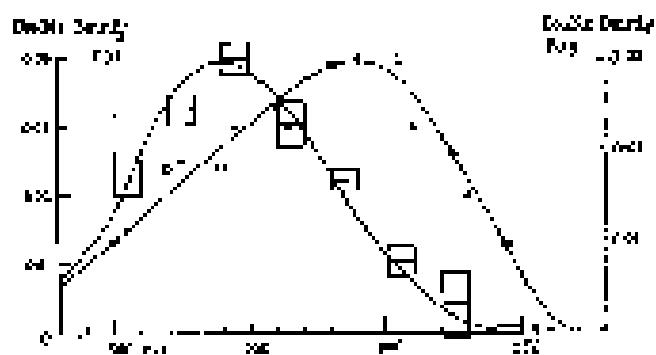

Fig. 15-10. Absorption spectrum of the color pigment of a person with anomalous trichromacy and a normal eye pigment.

Color vision, as one of the products of the life of the individual, is a common, and not unusual, function in different living organisms. For instance, if we have a pink light, made by superimposing crossing beams of white light and red light full spectrum, made with white and red incandescent lamps, we may observe that white light may appear pink. If we place an object in the beam, it casts its shadow, one illuminated by the white light alone and the other by the red. But most people see "white" shadow of an object, like blue, but, if we keep superimposing this shadow until it covers the entire screen, we see that it suddenly appears white, not blue! We can get other effects of these combinations by using red, yellow, and white light. Red, yellow, and white light can produce only orange, yellow, and so on. See if we mix red lights roughly equally, we get only orange light. Now, since, by mixing 3 different kinds of colors in the light, we have some coverage of colors, one gets quite a series of beautiful colors, which are not in the light themselves (that is only a concept, but in our sensations). We clearly see many colors and colors that are quite unlike the "physic" ones in the beam. It is very important to appreciate that a retina is already "thinking" about the light, it is comparing a color it sees in one region with what it sees in another, although not consciously. What we know of how it does this is the subject of the next chapter.

Mechanisms of Seeing

26-1 The sensation of color

In discussing the sense of sight, we have to realize that function of a gallery of modern art! succeeds not so much in space of colors or space of light. When we look at art, what we see is not always the thing; in other words, the artist interferes when we want. How it does this, no one knows, and it does it, of course, at a very high level. Actually we evidently learn to recognize what the man knows after much experience, this and a number of features to vision which are more clever are not which are in the combining information from different parts of what we see. To help us a diagram shows we can be an integrator of all sorts of images. It is not so difficult to study the earlier stages of the cutting together of information from the different visual cells. In the present chapter we do "experiments" with the aspect of vision, although we shall also mention a number of theories as we go along.

An example of the fact that we have an accommodation, at a very elementary level, of information from several parts of the eye at the same time, beyond the voluntary control of auditory to learn, was that the shadow which was produced by white light when both white light and were shining on the same screen. The other is, how interestingly, that the background of the screen is white enough, when we are looking at the blue shadow, i. e. only "white" light coming into a particular cell in the eye; nevertheless, years of information have been put into it. The more complete and familiar the context is, the more the eye will make corrections for peculiarities. In fact, Land has shown that if we mix that equal blue and the red in various proportions, by using two photographic transparencies with a stopper in front of the red and a slide in different proportions, it can be made to receive a real scene, with no attempt to keep it fully. This is because, a lot of information to apparent colors too, analogous to what we do, if you're mixing red and blue green; it seems to be a blue + magenta sort of color, but if we look very hard at them, they are not very good. Then so, it is surprising how much can be obtained from just red and blue. To make the white looks like a real silverman, the more one is able to see patient. In the first, total the light is actually decreasing, but think

Another example is the appearance of "colorless" like black and white rotating disc, whose black and white rings are as shown in Fig. 26-1. When the disc is rotated, the sensations of light and dark for any one cell are exactly the same; it is only the background that is different for the two kinds of "colorless". You see all the "rings" appear colored with one color, and the other with another.¹ You may yet understand the reason for these colors, but it is clear that attention is being put together at a very elementary level, in the eye itself, most likely.

Although presenting these kind of color vision, that is not mixing discs in fact. But the way you're segments in the cases of the eye and the, it is the spectral absorption in these three pigments that functionally produces the color sense. But the total sensation that is associated with the absorbed chromatic is less than the three segments acting together is not necessarily the sum of the individual sensations. We all agree that yellow and green seem to be reddishness; but that though this is somewhat surprising to most people to discover that light is, in fact, a mixture of colors, because presumably the spectrum of light

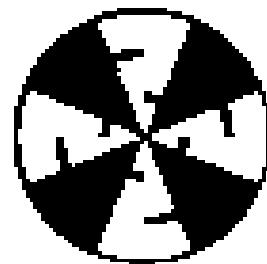

Fig. 26-1. When a disc like above is spun, colors appear in only one of the two outer "rings". If the spin direction is reversed, the colors appear in the other ring.

¹ The colors depend on speed of rotation, on the magnitude of illumination, and the size of the white bands at the central line in order to occur in them.

is due to some other process than a single neuron like a chord in muscle, where two other notes are there at the same time and if we listen hard we can hear them individually. We cannot look hard and see the red and the green.

The earlier responses of Valen said that there are three pigments and three kinds of cones, each kind containing one pigment; each a different form with cones in the brain, so that the three pieces of information are carried to the brain; and this is the brain, anything can happen. This, of course, is an incomplete idea; it does not seem to discover that the information is carried along the eye to nerve to the brain, however we have not even started to solve this problem. We must ask more basic questions: Does it make any difference where the information is put together? Is it simpler, but it is carried right up into the brain in the optic nerve, or think the retina do some analysis first? We have given a picture of the retina as an extremely complicated thing with lots of interconnections (Fig. 33-2) and it might take some analysis.

As a matter of fact, people who study anatomy and the development of the eye have known that the retina is in fact the brain; in the development of the embryo a piece of the brain comes out at birth, and long fibers grow from the retina to the brain. The retina is organized in just the way the brain is organized and, as someone has beautifully put it, "The brain has developed a way to look out upon the world." The eye is a piece of brain that is catching light, so in effect, it is already. So it is, at all unlikely that some analysis of the color has already been carried by the retina.

This gives us a very interesting opportunity. None of the other senses involves such a large amount of calculation as happens before the visual gets to the brain. One can make measurements on the calculations for all the rest of the senses mostly happen in the brain itself, which is very difficult to get at specifically, or to be measurements, because there are so many interconnections. But, with the visual sense, we have the optic nerve with lots of cells making calculations, and the results of the calculations being transmitted through the optic nerve. So we have the first chance to observe physiologically how, perhaps, the last layers of the brain work in their test steps. It is this sort of thinking which, too, simply furnishes the vision, but interesting in the whole problem of physiology.

The fact that there are three pigments does not mean that there are the three kinds of sensations. One of the other theories of color vision has it that there are really opposite color schemes (Fig. 33-3). That is, one of the nerve fibers carries a lot of impulses if there is yellow being seen, and less if it is not for that. Another nerve fiber carries green and red impulses, but in the same way, and, moreover, red to red black. In other words, in this theory someone has already started to make a connection in the system to sorting the sensations of calculation.

The problem we are trying to solve by posing in these first calculations, are questions about the sensations we report are seen on a pink background, when happens when things are adapted to different colors, and about the sorts of psychological phenomena. The psychological phenomena sort of the nature, for instance, that white does not "feel" blue and yellow and blue, and this has been well known. Because the psychologists say that there are four apparent pure colors: "There are four colors which have a nervous tendency to evoke sensations, namely, simple blue, yellow, green and red blue respectively. Unlike the magenta, purple, or mixtures of the circumlocutable colors, these simple blue are reported in the same time, these particles of the nature of the other; specifically, blue is not yellowish, and blue, in greenish, and so on; these are psychologically-primary hues." That is a psychological term, so-called. To find out from what evidence this psychological fact was deduced, we must search very hard indeed through all the literature. In the modern literature, all we find on the subject is a remark of the author of the book, or of one by a famous psychologist who was one of his professors Leonardo da Vinci, who, of course, we all know was a great artist. He says, "Even in the design there were two colors." Then, looking still further we find in a still older book, the evidence for the subject. The book systematically like this, "Purple is reddishblue, orange is reddish-yellow, but can not be seen as, purpleish-orange? And not red yellowish-green, inquiry that purple is strong?" The average person, asked to state which

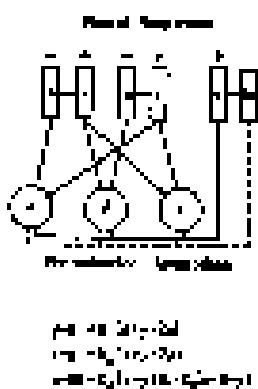

Fig. 33-2. Neural connections according to the "opponent" theory of color vision.

values are ordinary, or red, yellow, and blue, there's blue, and some others are also a faint green. Psychologists are accustomed to accept this form of "value" sense." So that is the situation in the psychological analysis of color vision; if everybody says, because three, and somebody says there are four, and they want it to be four, it will be four. That shows the difficulty with psychologists, resembles. It is clear that we're research findings, but it is very difficult to obtain more information about them.

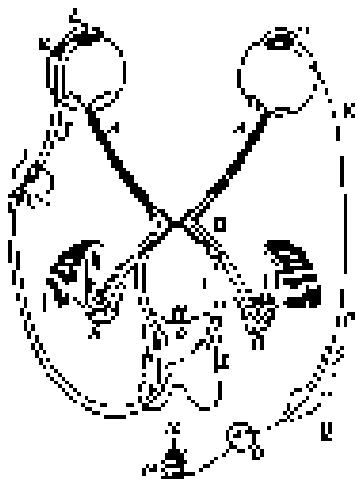

So the other direction we go is the physiological direction, to find out experimentally what actually happens in the brain, the eye, the retina, & whatever and perhaps to discover that same combinations of impulses from various cells travel along certain nerve fibers. Additionally, primary pigments do not have to be the separable cells, one can have cells in which are substances of the secondary pigments, cells with the red and the green pigments, & it's well known that in formation of colors in the white infant, long before birth. There are many ways of looking at the system so you have to find one other way before this ends. It would be no use, necessarily, that after we make out the physiological connections we will have a little bit of understanding of some of those aspects of the psychology, so we look in that direction.

36.2 The physiology of the eye

We begin by talking not only about color vision, but about vision in general, just to remind ourselves. First, the information comes in the retina, shown in Fig. 36.2. The retina is really like the surface of the brain. Although the actual picture through a microscope is a little more complicated looking than the anatomical schematic drawing, by careful analysis one can see all these interconnections. This is in practice the main part of the surface of the retina is connected to other parts, and that the information doesn't go out on the long axons, which generate the axonettes, or ramifications of it between them many cells. There are three layers of cells in the succession of crossover there are retinal cells, which are thinner than the bipolar cells, an intermediate cell which takes information from a single or a few retinal cells and gives it out again to several cells in a third layer of cells and connects it to the brain. There are all kinds of mechanisms in these cells in the layers.

We now can discuss aspects of the structure and performance of the eye (Fig. 36.3). The focusing of the light is done principally by the cornea by the fact that it has a curved surface which "bends" the light. This is why we cannot see clearly under water, because we then get a very large difference between the index of the cornea, which is 1.33, and the of water, which is 1.33. Because the cornea is water, principally with an index of 1.33, and beyond that is air, which has a very interesting structure; it is a series of layers. We can ignore except that it is all transparent and its refractive index is 1.00 in the middle and 1.00 at the outside. It would be nice if we could make optical glass in which we could adjust the "bend" throughout, but then we would not have a curve it so much as we do when we have a uniform index. Furthermore, the shape of the cornea is not that of a sphere. A spherical lens has a certain amount of spherical aberration. This aberration is "haloed" at the outside, it is a halo in in just such a manner that the spherical aberration is less far below than it would be if we put a spherical lens instead. The eye is focused by the curved lens system, onto the retina. As we focus on things that are closer and further away, the lens tightens and loosens and changes the focus to adjust for the different distances. To adjust for the total amount of light the iris may vary, which is what we call the pupil of the eye, it grows or bars, depending on what it is, as the amount of light increases and decreases, the iris moves around.

Let us now look at the neural mechanism. In controlling the accommodation of the lens, the motion of the eye, the muscles which move the eye in the socket, and the visual conduction, ideally in Fig. 36.3. Of all the information that comes out of the optic nerve at the great majority is divided into one of two bundles (which we will talk about later) and comes to the brain. But there are a few fibers, of

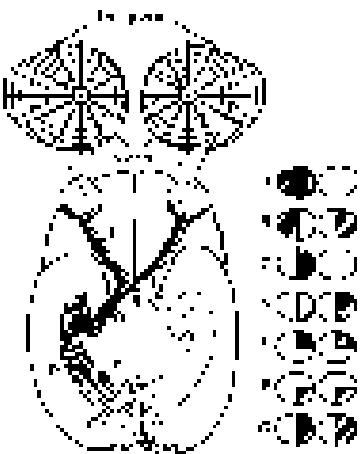

Fig. 26-4. The visual connections from the eyes to the visual cortex.

intense to us now; what do not immediately go to the visual cortex of the brain? These are the fibers which move to the storage spot and make adjustment for the images. If the image loses focus, they try to correct the lenses, if there's a double image, they try to adjust the eye for binocular vision. At any rate, they go through the pretectal area and feed back into the eye. At first the muscles which can be accommodated by the lens are not at all effective, then more is occurring. The orb has two muscle systems. One is extensor muscle, which, when it is active, pulls in and causes diverging motions very easily, and the result is it may connect from the brain through short axons into them. The opposite muscles are called "constrictors," etc., etc. The things you care about the skeletal muscle fibers, here would include you, too. There are however, in many places in the body, a pair of muscles which work in opposite directions, are in almost every spot like the nervous system which consists of two, so it is very delicately regulated that when one goes one way it is tightened, others are automatically and it follows the other. The iris is a peculiar exception, the muscle which moves the iris connects to the cones we have already described, but the nerves which make the iris expand and contract come from nearby where, go down to the spinal cord back of the chest into the thoracic sections out of the spinal nerve, up through the neck to place, and all the way up and back up into the brain in order to run the afferent of the iris. In Fig. 26-4, the optic nerve through a remarkably sufficient nervous system, not the central nervous system at all, but the sympathetic nervous system, so it is a very simple way of making things go.

We have already emphasized another strange thing about the eye, that the optic nerve comes from the wrong side, so that the right eye -- goes through several layers of other cells before it gets to the receptor -- it is quite sure and. Some of the features are very useful and some are apparently stupid.

Figure 26-5 shows the connections of the eye to the part of the brain which is most directly concerned with the visual process. The optic nerve fibers from both eyes pass just beyond D, called the lateral geniculate, whatever you like, and then to a portion of the brain called the optic cortex. Notice the fibers from each eye are sent over to the side of the brain, so the picture formed is incomplete. The optic nerves from either side of the left eye are sent to the right optic chiasm, & while the ones on the left side of the left eye come around and go off some way to the right side of the brain across all the interpeduncular commissure from the left side of the eyeball of each eye, i.e., on the right side of the right optic, while the right side of the brain sees the left side of the visual field. This is the connection in which the information from each of the two eyes is put together. In order to tell how far away things are, this is the system of binocular vision.

The connections between the retina and the visual cortex are interesting. If a spot in the retina is excited or destroyed in any way, even the whole lens will do, and we can thereby find out where it is connected. It turns out that necessarily, the connections are one to one, for each spot in the retina there is one spot in the visual cortex, and each spot and every other together in the retina are very close together in the visual cortex. So the spot which represents the spatial arrangement of the rods and cones, is, of course, much dissected. Those which are in the center of the field, which occupy a very small part of the retina, are represented over many, many cells in the visual cortex. It is clear that it is useful to know things which are originally close together, still close together. The most remarkable aspect of the matter, however, is the following. The point where one would think it would be most important to have things close together would be right in the center of the visual field. Because if or not, the spot above line is your visual field as we have it concerning a certain animal. But the information from all the points on the right side of that line is going into the left side of the brain, and vice versa. From the point on the left side is going into the right side of the brain, and the way this is made, there is a cut right down through the middle, so that the things that are very close together right in the middle are very far apart in the brain. Some of the information has to go to the outside of the brain to do this through some other standards, which is quite surprising.

The question of how the nervous system gets "wired" together is very interesting. The problem of how man is able to walk and move such a learned from childhood. It is not like I thought long ago, that perhaps it does not have to learn, since carefully it is not, it is only just properly interconnected, and then, by experience, the young child learns that what it finds is "out there" it contains some stimulus, in the left eye, it can also tell us who, the young child "knows," but how does one know what a child finds at the age of one? The child, at the age of one, supposedly sees that an object is "out there," gets a certain association, and learns to touch "there," however when he touches "there," it does not work. The approach probably is not correct, because we already see that in many cases there are these special direct interconnections. My illustration is the same that now I think requires them, with a salamander. (Incidentally, with the salamander there is a direct crossover connection, without the optic chiasm, because the eyes are on each side of the head and have no common area. Reptiles do not have binocular vision.) The experiment is this: When one optic nerve to a salamander has been cut, will give out binocular eyes again. Thousands and thousands of cell lines will thus be established. However, now, in the optic nerve, the first feature is a salamander's eye, otherwise it looks a good, slippery multi telephone cable, all the fibers twisting and turning, but when it goes to the brain they are flattened out again. When we cut the eye nerves of the salamander, the interesting question is, will it ever get right again? The answer is remarkable; yes. If we cut the optic nerve of the salamander, and it grows back, the salamander has good binocular sight again. However, if we cut the optic nerve and you see eye suddenly and let it grow back again, it is good visual acuity, of sight, but it has a terrible error, when the salamander sees a fly "up here," it appears it "down there"; and vice versa. Therefore, there is some mysterious way by which the thousands and thousands of fibers find their right place in the brain.

The problem of how much is wired in, and how much is not, is an important problem in the theory of the development of creatures. The answer is not known, but is being studied intensively.

The same eyes in man, in the case of a painful operation, there is a terrible loss like a great star or complication, in the optic nerve where we cut it, but in spite of it, it is the fine axons back to vision again, placed in the brain.

Let's consider this, we may grow into the odd channels of the optic nerve they must make several decisions about the direction in which they should grow. How do they do this? There are in the brain channels that different fibers respond to differently. Pairs of the common nerves of growing fibers, each of which is an individual, I believe, in some way, has its neighbors, in responding to whatever the chemical stimulus, it depends in a unique, unambiguous way to find its proper place for ultimate connection in the brain. This is an interesting—a framework—of some of the quite recently discovered phenomena of biology, and is undoubtedly connected to many other biological problems of growth, organization, and development of organisms, and particularly of embryos.

One of the interesting phenomena is to do with the motion of the eye. The system of the eyes in order to be the two images coincide in different circumstances. These motions are of different kinds: one is to follow something, which requires the left eye to move in one particular direction, right or left, and the other is to swing them toward the same place at varying distances away, which requires that they move, and oppositely. The nerves going to the muscles of the eye are already wound up for just such purposes. There is a set of nerves which will pull the muscles on the inside of one eye and the outside of the other—and others, the opposite muscles, so that the two eyes move together. There is another center where one will know to set the eyes around in a coordinate-like form parallel. Both eyes can be turned out to the exterior, the other eye never leaves the nose, but it is a peculiarly remarkable to move slightly to turn both eyes out at the same time, not however from one to another, but has to be binocularly, so as to align to turn both eyes out, unless we have had an accident or there is something the matter, for instance, if a nerve has been cut. Although the muscles of one eye can certainly steer that eye about, not over, a Yogi is able to move both eyes out freely

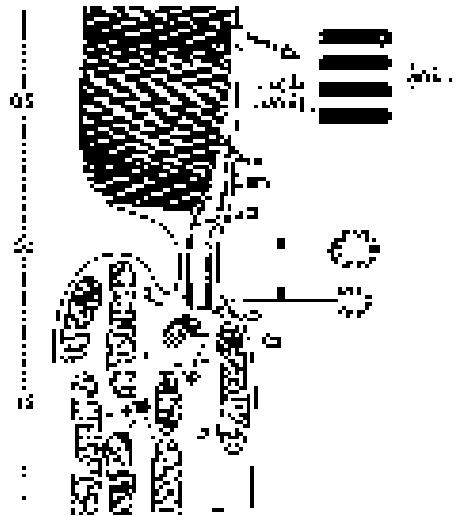

Fig. 26-5. Electron micrograph of a rod cell.

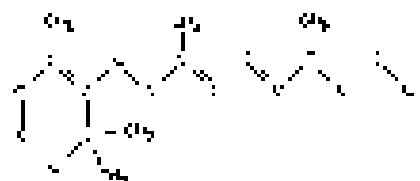

Fig. 26-6. The structure of retinene.

makes it difficult to see, so there does not seem to be any way to do it. We are almost given to a certain point, because most of the earlier books on vision, *y* and conductivity, and so on, the eye apparatus or do not emphasize the fact that we are so amazingly well prepared—they say that everything is just perfect.

26-3. The rod cells

Let us now examine in more detail what happens in the rod cells. Figure 26-5 shows an electron micrograph of the nucleus of a rod cell (the rod cell sleeps going up out of the field). There are layers after layers of plate-like structures, shown here, tilted at the right, which contain the substance rhodopsin (rhodo purple), the eye pigment which produces the effects of vision in the dark. The rhodopsin, which is the pigment, is a big protein which contains a special greenish-yellow retinene, which can be taken out the protein, and which is undoubtedly, the main reason of the absorption of light. We can not measure all the energy that is absorbed, but it is very likely that the best reason for getting all the rhodopsin molecules excited. The chemistry of the retina has been worked out to a large extent, but there might be some physics to it. It may be that it will be measured very accurately in some day of a new century when others measure the extent which is generated, yes, may not all the way down to one-tenth of a volt if it is designed, or something like that. The voltage is very important, and having homogeneous electric fields throughout both bioceramics and solid state physics or something like it, will ultimately be used.

This kind of a structure with layers appears in other circumstances where light is important, for example in higher-order problems, where the light causes photosynthesis. If we magnify those, we find the same thing with almost the same kind of layers, but there we have of "roughly" of course instead of smooth. The chemical form of rhodopsin is shown in Fig. 26-6. It has a series of alternating double bonds along the side chain, which is characteristic of such all strongly absorbing organic substances. I recall, methyl, Ethyl, Propyl, Butyl, and so on. These kinds of acids are impossible for human hair to absorb in their complete—*we have to eat it*. So we eat all the fat of a special substance, which is exactly the same as retinene except that there is a hydrogen tie on the right end; *so called dimethyl*, and if we do not eat enough of it, we do not get a supply of retinene, and the eye becomes blind, we call *night blindness*, because there is *not* enough pigment in the rhodopsin to eat with the rods at night.

The reason why such a series of double bonds absorbs light very strongly is also simple. We have just given a bit: The alternating series of double bonds is called conjugated, which means that there is an extra electron there, and this extra electron is easily shifted to the right or left. When light strikes the electron of each double bond it is shifted over by one step. All the electrons in the whole chain shift, just a single electron moving over, and though each one moves only a little distance we would expect that, in a single atom, we would move the electron only a little distance. The effect is the same as though the right end was moved over to the other end! It is the same as though one electron were to go from the left end to the right end, in this manner, we get much stronger absorption under the influence of the electric field, than if we move only *one* electron a distance which is associated with one atom. So, since it is easy to move the electron back and forth, it must absorb light very strongly; that is the machinery of the physical chemistry of our eye.

26-4. The compound (insect) eye

Let us now return to biology. The human eye is not the only kind of eye. In the invertebrates, almost all eyes are essentially like the human eye. However, in the lower animals there are many other kinds of eyes, especially various eye spots, and other less sensitive things which we have not mentioned yet. But there is one often highly developed eye among the invertebrates, the compound eye of the insect. Most insects living on the ground eyes also have various additional similar eyes usually. A fly's eye is one which has been studied very carefully. It is

only very slightly the properties of vision of bees because they are unadapted to beauty, and we can make experiments in which we identify the honey by putting it on blue paper or red paper, and see which one they come to. By this method some very interesting things have been discovered about the vision of the bee.

In my first glass, in trying to measure how acutely bees can see the violet light area between two pieces of "white" paper, and it was found that they were not very good, and others found they were considerably good. Even if the two pieces of white paper were almost exactly the same, the bees could still tell the difference. The experimenters used true white for one piece of paper and had others for the other, and although these look exactly the same to us, the bee could easily distinguish them, because they reflect a different amount of the ultraviolet. In this way it was discovered that the bee's eye is sensitive over a wide range of the spectrum. Far is it from 3000 Angstroms to 4300 Angstroms, from red to violet, but the bee can see down to 2800 Angstroms into the ultraviolet. This is also the number of different interesting effects. In the first place, bees can distinguish between many flowers which we look alike. Of course, we must realize that the colors of flowers are not designed for our eyes but for the bees' eyes and they train the bees to a specific flower. We all know that there are many white flowers. And only white is not very interesting to the bees, because it turns out that all of the white flowers have different proportions of reflection in the ultraviolet. They do not reflect one hundred percent at the ultraviolet as would a true white. If the light is not coming back, the ultraviolet is missing and that is a color, just as, for me, if the sun is missing, it comes out yellow. So, if the flowers are colored for the bees. However, we also know that red cannot be seen by bees. This might surprise you, but it does not look how to the bee. Instead, a careful study of red flowers shows, first, that even with our own eyes we can see the red, because red flowers have a little edge because they are actually reflecting ultraviolet spectrum in the blue, which is the part that the bees see. Furthermore, experiments also show that flowers vary in their reflection of the ultraviolet and different parts of the public variation. So if we put two flowers together they would be quite more attractive than the full

It has been shown, however, that there are a few red flowers which do not reflect in the blue or in the ultraviolet, and would therefore appear black to the bee. This was of course not known to the people who worry about this matter, because those eyes are not like ours, so they do not know what is hard to tell from a early childhood. It actually turns out that these flowers were chosen by bees, those are the flowers that we should be growing today, and summing up, can say now?

Another interesting aspect of the vision of the bee is that bees can apparently tell the direction of the sun by looking at a patch of bright sky without using the sun itself. We cannot easily do this. If we look outside windows at the sky and see that it is blue, in which the sun is the sun.[†] The bee can tell, because the bee is quite sensitive to the polarization of light, and the general light of the sky is polarized.[‡] There is a million calculations how this sensitivity operates. Whether it is because the receptors of the eye are different in different circumstances, or the bee's eye is actually sensitive, is not yet known.[†]

If you look at the television screen flicker up to 300 oscillations per second, while we see it only up to 20. The motion of bees in the house is very quick, the bee moves with the wind, etc., but it is very hard for us to see these motions with our eye; however, if we could see more rapidly, we would be able to see the motion. It is probably very important to the bee that its eye has such a rapid response.

[†] The wings of the bee have a slight sensitivity to the polarization of light, and this will help to tell the position of the sun. This phenomenon can be described best as called Ruffing's effect, which is a form of break among certain patterns due to the state of the visual field when one looks at a fixed, featureless surface using polarizing glasses. It can also occur in the blue sky when wearing glasses that reduce the field of view and affect the visual system.

[‡] Professor Sherratt's work, which has been given indicates that the eye is directly sensitive.

Fig. 36-7. The structure of an ommatidium (a single "eye" of a compound eye).

Now let us discuss the visual acuity we could expect from the bee. The eye of a bee is a compound eye, and it is made of a large number of special cells called *ommatidia*, which are arranged radially on the surface of a sphere (except for) on the outside of the bee's head. Figure 36-7 shows a picture of one such ommatidium at the top. This is a longitudinal section kind of thing. But actually it is more like a filter or light pipe or something going down along the "anterior fiber," which is where the absorption presumably occurs. Out of the center cell it comes the *optic fiber*. The central fiber is surrounded on its sides by six cells which, in fact, have absorbed the light. That is enough explanation for our purposes; the point is that it is a vertical ring of cells, each next to each other all over the surface of the eye of the bee.

Now let us discuss the resolution of the eye of the bee. If you draw lines (Fig. 36-8) from every ommatidium on the surface, which we suppose is a sphere of radius r , the bee actually receives here with each ommatidium a very small bit of air, and assuming that resolution is as clever as we are! If we have a very large assumption, we can see how much resolution. That is, one cell gets a piece of information from one direction, and the next cell gets a piece of information from another direction, and so on, and the bee cannot see things from too many well, but the angle subtended by each unit in the eye will surely correspond to an angle, the angle of the end of the ommatidium — relative to the center of curvature of the eye. (The eye cells, of course, exist only at the surface of the sphere; incident light is the bead of rays etc.) This angle, from our assumption to the best, is, of course, the diameter of the cone-like device by the ratio of $\lambda/\pi r^2$.

$$\theta_0 = \frac{\lambda}{\pi r^2}.$$

(36.1)

So, we may say, "The lines we make the θ_0 we meet the visual reality. So why doesn't the bee just use very very fine ommatidia?" Answer. We know enough physics to realize that if we are trying to get θ_0 down into a cone like that, we cannot do it really in a given direction because of the diffraction effect. The light that comes from every cone has an interference due to diffraction, **so will** get light coming in at angle $\Delta\theta$ such that

$$\Delta\theta = \lambda/r.$$

(36.2)

Now we see the "If we make the θ_0 too small, then each ommatidium does not look in only one direction, because of diffraction!" If we make them too big, each one looks in a different direction, but there are not enough of them to get a good view of the scene. So we find the best resolution to make minimum the total angle of these two. If we add these two together, and find the place where the sum has a minimum (Fig. 36-9), we find that

$$\frac{\Delta\theta_0 + \Delta\theta_D}{r} = 0 = \frac{1}{r} - \frac{\lambda}{r^2},$$

which gives us a distance

$$r = \sqrt{\lambda r}.$$

(36.3)

If we know that r is about 7 millimeters, since the light that the bee sees is 1000 wavelengths, we put the two together and take the square root, we find

$$r = (7 \times 10^{-3} \times 1 \times 10^7)^{1/2} \text{ m} \\ 7.0 \times 10^{-2} \text{ m} = 7.0 \mu.$$

(36.4)

The book says the diameter of the eye of the bee is about 1 mm, so, apparently it really works, and we can understand what determines the size of the bee's eye. It is also easy to you can observe that hawk which had 20 times greater the visual acuity is 100 angstrom resolution; it is very poor relative to man, who. We can see things the same thirty times smaller in apparent size, i.e., how the bee has a rather sharp out-of-focus image; this is what we call *see*. Nevertheless it is still right, and it is the best they can do. The important why the bees do not develop

be like eye like our own, with a lens and so on. There are several interesting reasons. In the first place, the bee is very small; if it had our eye like ours, but in 10⁻³ scale, the eye-ball would be about 20 cm in size and ditto the eye would be as important there as would not be able to see very well anyway. The eye is not good if it is so small. Secondly, if it were as big as he was itself, then the eye would occupy the whole body of the bee. The beauty of the compound eye then is that up to species, it is just a very thin layer on the surface of the bee. & when we argue that they didn't have done it our way, we need remember the "They had their own systems."

34-5. Other eyes

Besides the bees, many other animals can see color. Fish, butterflies, birds, and insects can see color, but it is believed that the mammals cannot. The primates can see color. The birds certainly see color, and that means a lot for the colors in birds. There would be no point in having such ordinary colored males if the females could not notice it. That is, the evolution of the sexual "show-off" is that the body color is a result of the female being able to see males. So, for example we have all these peacock feathers, think of what a brilliant display of colors it is and how beautiful the colors are, and what a wonderful aesthetic sense it takes to appreciate all that. But, we should not compliment the peacock, but should compliment the vision, sensory, and aesthetic sense of the peacock, because that is what has generated the beautiful scene.

All vertebrates have poorly developed eyes or compound eyes, but all the vertebrates have eyes very similar to man's eyes, with one exception. If we consider the higher form of animal, we usually say "the eye is not," but if we take a less prejudicial point of view and reflect causatives to the invertebrates, we find we cannot ignore insects, and ask what is the highest invertebrate animal? Most zoologists agree that the octopus is the highest in animal. It is very interesting then, besides the development of the brain and its reactions and so on, which is certainly good for an invertebrate, it has a well-developed, independent, a different eye. It is not a compound eye or an eye spot—it has a retina, it has lens, it has iris, it has pupil, it has a region of walls, it has a lens capsule. It is extremely like ours as the eye of the vertebrates. It is a remarkable example of a coincidence in evolution where we have twice discovered the same solution to a problem, with one slight improvement. In the octopus it is larger, and, consequently, that the retina is a piece of the brain that has come out in the same way in its embryo, it develops right from the start very early on, but the interesting thing which is different is the cells which are sensitive to light are on the inside and the cells which do the processing are on the back of them, rather than "face on," as in our eye. So we see, perhaps, that there is no general reason for us being upside out, the other invertebrates much like us are straightforward (Fig. 34-10). The largest eyes in the world are those of the giant squid. They have been found to be 8 inches in dia. (80 cm).

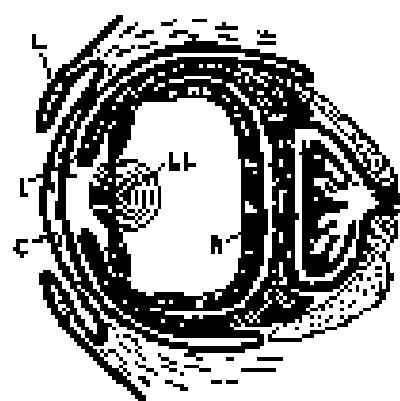

Fig. 34-10. The eye of an octopus.

34-6. Neurology of vision

One of the main points of our subject is the transmission of information from one part of the eye to the other. Let us consider the compound eye of the housefly, on which considerable experimental work has been done. First of all, we must appreciate what kind of information it conveys to consciousness. As we know, it is a kind of disturbance which has an electrical effect, that is easy to detect, a kind of wave-like vibration that which can flow, the nerve and processes can affect at the other end: a long piece of the nerve cell, called the axon, carries the message. You always, as I have said, kind of surprise, called a "spike," you know if it is excited or not and when one spike goes along the nerve, another comes immediately follow. All the spikes are of the same size, so it is not that we get bigger spikes when the thing is more strongly excited, but that we get more spikes per second. The sort of energy is determined by the "PSP". It is important to understand this in order to see what happens next.

Fig. 36-11. The compound eye of the horseshoe crab. (a) Normal eye. (b) Crushed eye.

(from Dr. G. H. D. T. Gray, Duke University Marine Laboratory, Beaufort, North Carolina, with permission.)

Figure 36-11(a) shows the compound eye of the horseshoe crab; it is just as much of an eye as has only skin as transverse commissure. Figure 36-11(b) is a crushed compound eye system; one can see the commissure, which however does not run across them and go into the brain. But note that even in a horseshoe crab there are little transverse lines. They are much less elaborate than in the human eye, and it is worth while to study a simpler example.

Let us now look at the experiments which have been done by cutting the electrodes in the simple nerves of the horseshoe crab and stimulating one or more of the commissures, which is easy to do with Lucas. If we turn a light on, it stimulates α_2 , and because the other ion channels will come out, we find that there is a spike, followed by three or four series of discharges which gradually slow down to a uniform rate, as shown in Fig. 36-12(a). When the light goes off, the discharge stops. Now, it is very interesting that if, while our stimulus is still on in the same nerve fiber we shine light on a different commissure nothing happens; no signal.

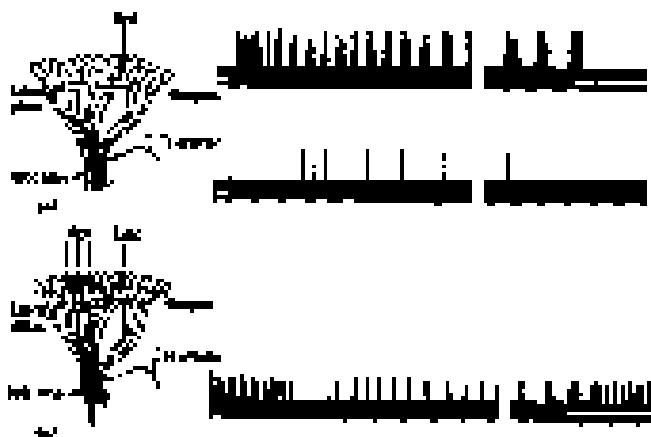

Fig. 36-12. The response in light of the nerve fibers of the eye of the horseshoe crab.

Now we do another experiment, as shown in the figure on the original commissure and get the same response, but if we now turn light on and the time as they as well, the pulses are in different spikes and then come a much slower rate (Fig. 36-12b). The case of rest is inhibited by the impulses which are coming out of the other. In some ways each nerve fiber carries the information from one commissure, but is stronger than it is inhibited by the signals from the other. So, for example, if the whole eye is uniformly or nonuniformly illuminated, the inhibition coming from any one commissure will be relatively weak because it is balanced by so many. In fact the inhibition is enhanced if we shine light on several nearby commissures the inhibition is very great. The inhibition is weaker when you stimulate one fiber and if the stimulated fiber is enough away from one another, inhibition is practically zero. So it is not dependent on the distance, there is a first example of inhibition from different parts of the existing commissure in the eye itself. We can see, perhaps, that link also in a vertebrate, that has to do due to inhibition occurring at the edges of retinula, because if part of the retina is light and a part is black, then the inhibition in the liquid and you impulsive nature

inhibited by all the other lights in the neighborhood, so it is relatively weak. On the other hand, an *occluding* edge, the boundary which is given a "dark" impulse is also inhibited by others in the neighborhood, but there are not as many of them, since some are exactly in the right place, so it therefore strengthens. The result would be a curve something like that of Fig. 26-11. The crab will see an enhancement of the concave.

The fact that there is an enhanced *out-of-concave* boundary has been known; it fact it is a remarkable thing that has been commented on by psychologists many times. In order to view an object, we have only to close our eyes. How does one get an enhanced picture than is merely the outline? What is the answer? The solution is only the edge difference between light and dark in one corner and another. It is not even *strongly* defined. In other words, it is not that every object has one arcuate in. There is no such line. It is only in our own psychological make-up that we do this; we are beginning to understand the reason why the "line" is enough of a cue to go the whole thing. Presumably our own eye works in a similar manner, much more complicated, but similar.

Finally, we can briefly describe one more elaborate work, the beautiful, elaborate work that has been done on the frog. Doing corresponding experiments on a frog, by pulling very fine, beautifully-woven woodlike strips over the eye, one can obtain the signals, but > a living thing, one will pull over and over again, just as in the case of the horseshoe crab, we find that the information does not depend on just one spot in the eye, but is a sum of information over several spots.

The most recent paper¹ of the operation of the frog's eye is the following. One can find four different kinds of optic nerve fibers, in the sense that there are four different kinds of responses. These experiments were undertaken by Stimberg and *et al.* in 1958 of the frog, because that is not *that* a frog does. A frog just sits there and his eyes never move, unless the fly just flies around, and he turns, and in that case his eyes will like just right so that the image stays just. He uses *not* both his eyes, if anything moves in his field of vision, like a little bug flies by, while in the something small moving in the field backs, needs to turn so that there are four of the kinds of fibers which carry the visual properties are summarized at Table 26-1. Sustained edge detection... interesting, means that if we bring an object with a *edge* into the field of view of the frog, then there are a lot of impulses in this particular fiber while the object is moving in. If you suddenly let a *sharp* edge impulse just experience suddenly as the edge is there, even if it is standing still, then you can see the light, the impulses stop. If we turn it on again, while the edge is still in view, they start again. They are *reversible*. Another kind of fiber is very similar, except that if the edge is straight, it does not work. It may be convex only with its back side. How conspicuous must be the edge and how small is the number of the edges the frog is forced to pay attention to in order to notice what has moved in! Furthermore, if through this fiber does sustain temporal, if there are sustained impulses along the center, and if we turn the fiber around, it immediately goes back up again. It depends on the *rocking* of the nerve.

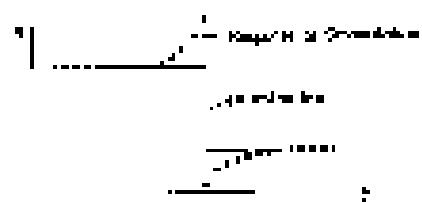

Fig. 26-10. The net response of an omniotic crab omniotic eye to three concaves in Horseshoe.

Table 26-1
Types of responses to optic nerve fibers of a frog

Type	Size	Angular field
1. Steepest edge detector (concave)	0.1 mm radius	1°
2. Convex edge detector (convex)	0.5 mm	2-3°
3. Convex detector	1.2 mm	10-15°
4. Dynamic detection	Up to 2 m, sec.	Up to 10°
5. Vertical detector	1	Very large

surface. The eye sees it come in and announces that it is there, but if we merely turn out the light for a moment, it simply forgets it and no longer sees it.

Another example is change-in-intensity detection. If there is an ugly moving it, we feel there are pulses, but if the thing stands still there are no pulses at all.

Then there is a third detection. If the light intensity is uniformly decreased it creates pulses, but if it goes down or goes up, the response depends on the source where the pulse is coming.

Then, finally, there comes the third which is dark detection. A most amazing thing they are all the same! If we increase the light, they fire less rapidly than all the time. If we decrease the light, they fire more rapidly than ever. In the dark they are like mad, perpetually saying "It is dark! I is fired! I is it!"

Now these responses seem to be rather complicated to classify, and we might wonder whether perhaps the sensations are better distinguished. But it is very interesting that these same classes are very clearly separated in the anatomy of the frog. By this measurement, after these responses had been classified by observation, the next step is to about 1000. It was discovered that the visual system of the different fibers there was not too simple, so there was another, independent way to check what kind of a fiber we have found.

Another interesting question is from how big an area is one particular fiber making its contributions? The answer is different for the different classes.

Figure 24-14 shows the surface of the so-called optic tectum of a frog, where the nerves come into the brain from the eye is shown. All the nerve fibers coming in from the optic nerve make numerous anastomosing layers of the tectum. This typical structure is analogous to the retina. To large, by which we know that the brain and retina are very similar. Now, by taking an electron microscope it does not succeed in finding the fibers, we can find out which kinds of optic nerves end where. And the beautiful and remarkable result is that the different kinds of fibers end at different layers. The first ones end in number 1 type, the second in number 2. The third and fourth end in the same place, and deeper of all is number four (which is remarkable, they put the number eleven in the right place! No, that is not true, they numbered them that way, and the paper had the numbers in a different order!)

We may easily summarize what we have just learned this way. There are three types, presumably. There may be many different kinds of receptor cells containing the three pigments in different proportions, but these are ready cross connections which may permit utilization of some colors in much detail and discrimination in the nervous system. So before we really understand color vision, we will have to understand the final connection. This subject is still to be done, but these researches with electron microscopy and so on will perhaps ultimately give us more information which we see each.

Quantum Mechanics

37-1 Atomic mechanics

In the last few chapters we have treated the essential ideas necessary for an understanding of most of the important physical and optical effects in electromagnetism in general. We have left some specific topics for later years. Specifically, the role of the idea of wave materials had been somewhat neglected. What we now do with it is called the "kinetic theory" of electric waves, which turns out to be a extremely elegant description of motion for a very number of effects. We have not had to worry so about the fact that light energy comes in lumps or "photon."

We would like to take up as our first subject the problem of the behavior of matter in very small pieces of matter, both mechanical and thermal properties, for instance. In studying these, we will find that the "kinetic" (or "classical") theory of matter is inadequate, because matter is really made up of wave-like particles. So, you will deal only with "kinetic" particle theory, i.e., in the style of R.F. Landau, we can understand using the classical mechanics we have been learning. But, we can't make very successful. We shall find out in the case of matter, unlike the case of light, we shall have difficulties, definitely even. We could, of course, even entirely skirt away from the atomic effects, but we shall instead face here a short discussion of what we will describe the basic ideas of the quantum properties of matter, i.e., the quantum theory of atomic physics, so that you will have some feeling for what it is we are leaving out. Let us will now review and sum up important subjects that we are not using, coming down to.

So, we will give now the representative to be object of quantum mechanics, but we will be able actually to get into the subject much much later.

"Quantum mechanics" is the description of the behavior of matter in all its detail and, in particular, of the happenings at the atomic scale. This is not *easy*, we believe. No, nothing that you can see directly exceeds above. They do not behave like waves, they do not behave like particles. They do not be like clouds, or billiard balls, or weights on springs, or like anything that you have ever seen.

Everyone thought that light was a corpuscular effect, but that was discovered, as we have seen here, that it behaves like a wave. Later, however, (at the beginning of the twentieth century), we found that light did indeed sometimes behave like a particle. Historically, the electron, for example, was thought to behave like a particle and then it was found that it more closely behaved like a wave. So, clearly behaved like neither. Now we have given up. We say, "It is the *activity*."

This is not only better, however, electrons behave just like light. The system exhibits a "wave effect" when one passes between screens, and when it is too coarse-grained, they are a "particle effect," or vice versa you will not call them. So, while we can, abstractly speaking, electrons (which we shall do for our example) will apply to both "particles," including photons of light.

The general conclusion of information that almost all one could be having about the fine quarks of this creature, which gave some indications about how *tiny* things we cannot produced in the using equipment which was finally developed in 1926 and 1927 by Schrödinger, Dirac, Heisenberg and Pauli. They finally obtained a description description of the behavior of matter on a small scale. We take up the main features of their derivation in this chapter.

Because atomic behavior is so unlike ordinary experience, it is very difficult to get used to and it appears paradoxical and mysterious to every new book to the

music and to the experimental physicist. But the experts do not understand it in any way they would like to, and it is probably conceivable that they wouldn't because all of our human experience and of human intuition applies to large objects. We know how large objects will act but things on a small scale just do not act that way. So we have to learn about them in a sort of abstract or mathematical fashion & don't have connection with our direct experience.

In the chapter we shall locate immediately the basic element of the mysterious behavior in its most strange form. We shall see a situation of polarization which is impossible physically impossible to explain in any classical way, and which lies in the heart of quantum mechanics. In reality, it contains the only mystery. We cannot explain the mystery in the name of "probability" how it works. We will tell you how it works. In telling you how it works we will not tell you about the probabilities of all quantum mechanics.

37-1 An experiment with bullets

To try to understand the quantum behavior of electrons, we do something similar and contrast their behavior at a particular experiments setup, with the more familiar behavior of particles like bullets. We want the behavior of bullets like the other waves. We consider first the behavior of bullets in a experiments setup shown diagrammatically in Fig. 37-1. We have a machine gun that shoots a stream of bullets. It is not a very good gun, in that it sprays the bullets randomly over a fairly large angular spread, as indicated in the figure. In front of the gun we have a wall (made of dense, plated lead bricks) in our house just about big enough to let a bullet through. Beyond the wall is a backstop made of thick wall which will "absorb" the bullet when they hit it. In front of these we have an object which we shall call a "detector" of bullets. It might be a box containing sand. And, finally, that's the detector will be stopped and accumulated. When we wish we can empty the box and count the number of bullets that have been caught. The detector can be moved back and forth so when we will collect a direction. With this apparatus we can find out experimentally the answer to the question "What is the probability that a bullet which passes through the hole in the wall will arrive at the backstop at the distance x from the center?" First, you should realize that we should talk about probability, because we cannot say definitely where any particular bullet will go. A bullet which happens to hit one of the holes may become at the edges of the hole, red over and over again in a wall. By "probability" we mean the chance that the bullet will arrive at the distance x , which we can measure by counting the number which arrive at the detector at a certain time and then taking the ratio of the number to the maximum that will hit the backstop during that time. Or, if we assume that the gun always shoots at the same rate during the measurement so the probability we want is just proportional to the number of bullets which the detector is some standard time interval.

For our present purposes we would like to imagine a somewhat idealized experiment in which the bullet are not real bullets, but are mathematical bullets they cannot break in half. In our experiment we find that bullets always come in jumps, and when we find something in the detector, it is always one whole bullet. At the instant which the machine gun fires a bullet, say how, we find that any given moment either nothing arrives at our sand box, or exactly one—exactly one—bullet arrives at the backstop. Then, the size of the jump certainly does not depend on the rate of firing of the gun. We shall say: "Bullets also wear their identical jumps." What we mean is that our detector is the probability of arrival of a jump. And we measure the probability as a function of x . The result of such measurements with the apparatus for have not yet done the experiment, we are really imagining, is seen in Fig. 37-2 and plotted in the graph shown a part of Fig. 37-3. In the graph we plot the probability in the right and x vertically, so that the x scale fits the diagram of Fig. 37-1. We call the probability P_x because the bullets may pass completely through hole 1 or through hole 2. You will not be surprised that P_1 is large near the middle of the graph and gets small if x is very large. You may wonder, however, why P_2 has its minimum value at $x = 0$. We can understand

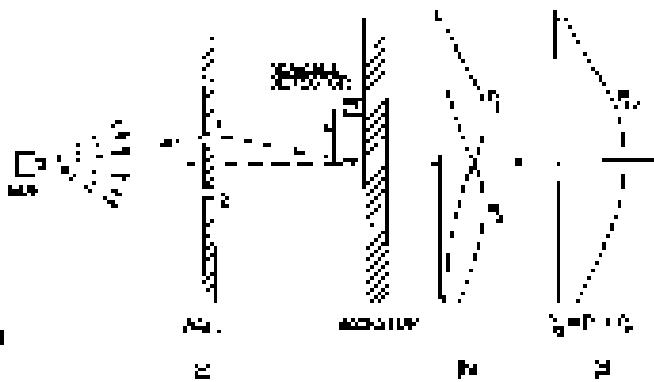

Fig. 27-1. Interference experiment with bullets

to see if we do not expect to get after covering up hole 1, and once more while covering up hole 2. When hole 2 is covered, bullets can pass only through hole 1, and we get the curve marked P_1 in part (a) of the figure. As you would expect, the maximum of P_1 occurs at the value of x which is on a straight line with the gun and hole 1. When hole 1 is closed, we get the symmetric curve P_2 drawn in the figure. P_2 is the probability distribution for bullet positions through hole 2. Comparing part (a) and (c) of Fig. 27-1, we find no surprise there:

$$P_{12} = P_1 + P_2 \quad (27-1)$$

The probabilities just add together. One bullet will be found either in the sum of the paths with each hole open alone. We shall call this result an instance of "no interference" for a reason that you will see later. So much for bullets. They come in lumps, and their probability of arrival does not interfere.

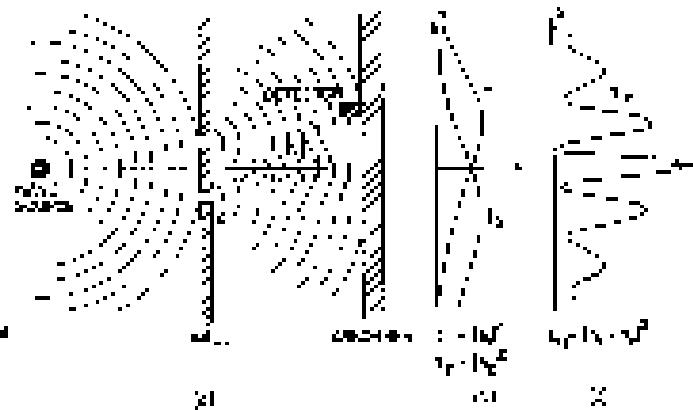

Fig. 27-2. Interference experiment with water waves

Now we wish to consider an experiment with water waves. The apparatus is shown diagrammatically in Fig. 27-2. We have a shallow trough of water. A small object labeled the "wave source" is jiggled up and down by a motor and makes circular waves. To the right of the source we have again a wall, with two holes, and beyond that is a second wall, which, to keep things simple, is an "absorber," so that there is no reflection of the waves that arrive there. This can be done by putting a padded board "back" in front of the second wall. The detector is now a device which measures the "Intensity" of the wave motion. You can imagine a gauge which measures the height of the wave motion, but whose scale is calibrated in proportion to the square of the wave height, so that the reading is proportional to the intensity of the wave. Our detector reads, then, a proportionality to the energy being carried by the waves—*i.e.* either the rate at which energy is carried to the detector.

With our wave apparatus the first thing to notice is that we *excessively* do not have any size. If the gun just makes a very small sound, then there is just a little bit of wave motion at the detector. When there is more twanging, however,

there is some intensity at the detector. The intensity of the wave can have any value at all. We would not say that there was one "component" in the wave, unless it is.

Now let us measure the wave intensity for various values of θ (keeping the wave source operating always in the same way). We get the interesting looking curve recorded in the portion of the figure.

We have already worked out how such patterns can come about; when we studied the interference of electric waves. In this case we would observe that the original wave is diffracted at the holes, and two similar waves expand out from each hole. If we cover one hole at a time and measure the intensity distribution at the detector we find the rather simple intensity curves shown in part (c) of the figure. I_1 is the intensity of the wave from hole 1 (which we find by measuring when hole 2 is "blocked" or open). I_2 is the intensity of the wave from hole 2 (seed when hole 1 is blocked).

The intensity I_3 observed when both holes are open is obviously not the sum of I_1 and I_2 . We say that there is "interference" of the two waves. At some places where the curve I_3 has no maximum the waves are "in phase" and the wave peaks add together to give a large amplitude, therefore a large intensity. We say that the two waves are "constructively interfere" in such places. There will be such constructive interference whenever the distance from the detector to one hole is a whole number of wavelengths larger than the distance from the other hole to the detector.

At those places where the two waves interfere destructively, the distance of θ (where they are "out of phase") just regulating wave motion at the detector will be the difference of the two amplitudes. The waves "interfere destructively," and we get a low value for the wave intensity. We repeat our law values whenever the distance between hole 1 and the detector is different from the distance between hole 2 and the detector by an even number of half-wavelengths. The low values of I_3 in Fig. 32.2 are, according to this principle, due to destructive interference.

You will notice that the square law relationship between I_1 , I_2 , and I_3 can be expressed in the following way: The instantaneous height of the water wave at the detector for the wave from hole 1 can be written as $(\delta_1 + \delta_2)$, where the "amplitude" δ_1 is, in general, a complex number. The intensity is proportional to the mean squared height, when we use the complex numbers as $|\delta_1|^2$. Similarly, for hole 2 the height is δ_2 and the intensity is proportional to $|\delta_2|^2$. When both holes are open, the wave heights add to give the height $(\delta_1 + \delta_2)^2$ and the intensity $|I_3| = |\delta_3|^2$. On this the equations of proportionality for all present purposes can serve as follows for anything waves are:

$$I_1 = |\delta_1|^2, \quad I_2 = |\delta_2|^2, \quad I_3 = |\delta_3|^2. \quad (32.2)$$

You will notice that the intensities of waves from the different holes follow (Eq. 32.1). If we expand $|\delta_3|^2$ we see that

$$|\delta_3|^2 = |\delta_1|^2 + |\delta_2|^2 + 2[\delta_1 \delta_2 \cos \theta], \quad (32.3)$$

where θ is the phase difference between δ_1 and δ_2 . In terms of the intensities, we could write

$$I_{12} = I_1 + I_2 + 2\sqrt{I_1 I_2} \cos \theta. \quad (32.4)$$

The last term in Eq. 32.4 is the "interference term." We may for most waves. The intensity can have any value, and it always is, when

32.4 An experiment with electrons

Now we propose a similar experiment with electrons. It is shown diagrammatically in Fig. 32.3. We make an electron gun which consists of a tungsten wire heated by an electric current, and a cathode ray tube, a metal box with a hole in it. If the wire is at a negative voltage with respect to the box, electrons emitted by the wire will be repelled and cannot hit the wire and some will pass through the hole. All the electrons which come out of the gun will after (just like) the water waves in front of the sun is seen as a wall (just a thin misty pattern with maxima and minima) if

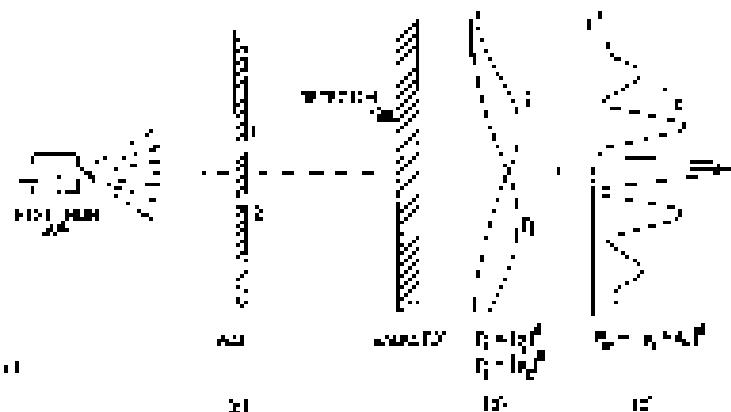

FIG. 37-2. Interference experiment with electrons.

Before we do another glove which will serve to cover up the front of the backstop we place a more elaborate detector. This detector consists of a paper tape counter, perhaps followed by an electrical integrator, which is connected to a loudspeaker.

We should say right away that we should not try to set up this experiment (as you could have done with the one we have already described). Our experiment has never been done in just this way. It remains to be seen if the apparatus would ever in fact be made or if it possibly would fail to show the effects which we expect. We are doing a "thought experiment," which we have chosen because it is easy to think about. We know the results that would obtain because there are many similar ones that have been done, in which the scale and the proportion have been chosen to give the effects we shall describe.

The first thing we notice with our electron experiment is that we hear sharp "clicks" from the detector (that is, from the loudspeaker). And all "clicks" are the same. There are no "half-clicks."

We would also notice that the "clicks" come very erratically. Something like click . . . click click . . . click . . . click click . . . click . . . etc., just as you have no doubt heard a radio timer operating. If we count the clicks which arrive in a sufficiently long time—say for many minutes—and then count again for another equal period, we find that the two numbers are very nearly the same. So we can speak of the average rate at which the clicks are heard (say, about many clicks per minute at the end of a day).

As we move the detector around, the instant at which the clicks appear is fast or slow; but the overall character of each click is always the same. If we lower the temperature of the gun or the gun tube, or of the detector, it goes down, but still each click sounds the same. We would notice also that if we put separate detectors at the backstop, say 8 inches apart, we still click, but never both at once. (Even if this does not occur in a while, if there were two clicks very far apart in time, you might not notice the separation.) We conclude, therefore, that whatever arrives at the backstop comes in "umps." All the "umps" are the same size, only while "umps" arrive, and they arrive one at a time at the backstop. We shall say "electrons always arrive in individual lumps."

Just as in our experience with bullets, we can now proceed to "feel experimentally" the answer to the question: "What is roughly the probability that an electron 'ump' will arrive from the backstop various distances from the center?" As before, we calculate a relative probability by measuring the rate of clicks within a given range of position. The probability that humps will arrive in a particular place is proportional to the average rate of clicks at that place.

The result of our experiment is the interesting curve marked $I_0 e^{-x^2/l^2}$ in Fig. 37-2. See this is the way electrons go.

37-5. The interference of electron waves

Now let us try to analyze the curve of Fig. 37-2 to see whether we can understand the behavior of the electrons. Let us first bring in what may be called "electron wave columns," each lump which we may as well call an electron, has an "electron wave column" through hole 2. Let us write this in the form of a "Proposition":

Proposition A: Both electrons enter goes through hole 1 or it goes through hole 2.

Assuming Proposition A, > electrons road arrive at the backplane can be divided in two classes: 1) those that come through hole 1, and 2) those that come through hole 2. So our observed curve would be the sum of two effects of the electrons which come 1. In hole 1 see the electrons whilst come through hole 2. This includes interference by experiment. First, we will make a measurement for those electrons that come through hole 1. We knock off hole 2 and count our counts of the electrons from the detector. From the counting rate, we get P_1 . The result of the measurement is shown by the curve marked P_1 in part (b) of Fig. 3-3. The result seems quite reasonable. In a similar way, we measure P_2 , the probability distribution for the electrons that come through hole 2. The result of this measurement is also shown in the figure.

The result $P_{1,2}$ obtained with both holes open is clearly not the sum of P_1 and P_2 , the probabilities for each hole alone. In analogy with our water-wave experiment, we say: "There is Interference."

$$\text{For interference: } P_{1,2} \neq P_1 + P_2. \quad (37.5)$$

How can such an interference come about? Perhaps we should say: "Well, but course, probability, too, it is not true that the things go either through hole 1 or hole 2, because if they did, the probability would be 1. Perhaps they go in a more complicated way. They split in half and . . ." But no! They cannot they always arrive in lumps . . . "Well, perhaps some of them go through . . . and then may go around through 2, and then around a few more turns, or by some other complicated path . . . then by closing hole 1, we changed the chance that an electron that was going out through hole 1 would finally get to the backplane . . ." But notice. There are some situations which we know very well when both holes are open, but which leaves many electrons if we close one hole, so closing one hole removed the number from the other. But this however, just in the center to the pattern, $P_{1,2}$ is more than which gives $P_1 + P_2$. It is as though closing one hole decreased the number of electrons which come through the other hole. It seems here to explain this effect by regarding the the electrons travel in complicated paths.

"I'm afraid my ideas. And the more you look at it, the more mysterious it seems. Many ideas have been suggested to try to explain the curves for $P_{1,2}$ to terms of individual electrons going around in complicated ways through the holes. None of them has succeeded. None of them can get the right curve for $P_{1,2}$ in terms of P_1 and P_2 .

Yet we mightly suspect, the requirement for relating P_1 and P_2 to $P_{1,2}$ is extremely simple. For $P_{1,2}$ is just like the curve $S_{1,2}$ of Fig. 37-2, and that was simple. What is going on at the backplane, he described by two complex numbers that we will call δ_1 and δ_2 (they are functions of x , of course). The contribution of δ_1 gives the other you only have to add. That is, $P_1 = |\delta_1|^2$. The other were only hole 2 been to given by δ_2 in the same way. That is, $P_2 = |\delta_2|^2$. And the combined effect of the two holes is just $P_{1,2} = |\delta_1 + \delta_2|^2$. The conclusion is the same as one we had for the water waves. (It is hard to see how one could get such a simple result from complicated paths of electrons going back and forth through the hole on some strange trajectory.)

We conclude the following: The electrons arrive in lumps, not particles, and the probability of finding n these lumps is distributed like the distribution of intensity of a wave. It is in this sense that an electron behaves "sometimes like a particle and sometimes like a wave."

Incidentally, when we were working your classical waves we defined the intensity as the trace over time of the square of the wave amplitude, and we used complex numbers as a mathematical trick to simplify the analysis. When quantum mechanics it comes in, that the amplitudes must be represented by complex numbers. The real parts alone will not do. This is a technical point for the moment, because we'll consider back just the same

Since the probability to arrive here of both holes is given as simple addition it is not equal to $(P_1 + P_2)$, that is really to say. But there is a large number of况sories involved in the fact that nature does work this way. We would like to illustrate some of these subtleties for you now. First, since the number that arrives at a particular point is not equal to the number that arrives through 1 plus the number that arrives through 2, as we would have concluded from Proposition A, undoubtedly we should conclude that Proposition A is false. It is not true that the electrons go either through hole 1 or hole 2. But this conclusion can be tested by another experiment.

37-6 Watching the electrons

We do this by the following experiment. To our electron apparatus we add a very strong light source: glass! Behind the wall and between the two holes, as shown in Fig. 37-4. The glass and electric arcs give rather light. So when an electron passes through a glass pane, owing to the reverb., it will scatter some light to our eye, and we can see where the electron goes. If, for instance, an electron were to take the path via hole 2 that is indicated in Fig. 37-4, we should see a band of light coming from the vicinity of the place marked A in the figure. If an electron passes through hole 1 we would expect to see a band B in the vicinity of the upper hole. If it should happen that we get light from both places at the same time, because the electron divides in half... (i.e. we do the experiment!!)

Fig. 37-4. A different electron experiment.

Here is what we see: every time that we hit a "click" from our electron detector δ , the backs up we also see a flash of light either near hole 1 or near hole 2, but never both at once! And we observe the same results no matter where we put the detector. From this observation we conclude that when we think of the electrons we find that the electron goes either through one hole or the other. Ergo immediately, Proposition A is necessarily true.

What, then, is wrong with our argument against Proposition A? Why isn't Proposition A right in Fig. 37-4? Back in experiment 1 let us stop most of the electrons and find out what they are doing. For each position (or location) of x in $y = x$ we will count the electrons that arrive and also keep track of which hole they went through, by watching for the flashes. We can keep track of things, for why, whenever we hear a "click" we will turn a counter in Column 1 if we see the flash near hole 1, and if we see the flash near hole 2, we will turn a counter in Column 2. Every electron which arrives is counted in one of two classes: those which come through 1 and those which come through 2. From the numbers recorded in Column 1 we get the probability P_1 that an electron will arrive at the detector via hole 1, and from the numbers recorded in Column 2 we get P_2 , the probability that an electron will arrive at the detector via hole 2. If we now repeat and a measurement for many values of x , we get the curves for P_1 and P_2 shown in part (a) of Fig. 37-4.

We find that this is certainly surprising. We get the something quite similar to what we got before for P_1 by blocking off hole 2 and P_2 is similar to what we got by blocking hole 1. So there is an very unexpected business like going through both holes. When we watch now, the electrons come through just as we could

move there to come through. Whether the holes are closed or open, those which we see come through hole 1 are distributed in the same way whether hole 2 is open or closed.

But wait! What do we know for the total probability, the probability that an electron will survive all the detectors by any route? We already have that information. We just pointed that we can record a single light flashes, and we keep track of the detector clicks which we have recorded into the two columns. We know, in fact, the numbers. For the probability that an electron will survive the two holes by passing through either hole, we've had $P_{1,2} = P_1 + P_2$. That is, although we succeeded in *writing out* how one electron could pass through, we no longer get the old probabilities $P_{1,2}$ or P_1 , but a new one, $P_{1,2}$, *causing no interference*. It's our fault that $P_{1,2}$ is restored.

We now can think that when we look at the electrons the distribution of them in the screen is coherent with what we saw on each. Perhaps it is something in our light source that causes this? It might be that the electrons are very electric, and the light, when it captures all the electrons, gives them a jolt that changes their motion. We know that the electric field of the light source can change will went a photon on it. So perhaps we should expect the motion to be changed. Anyway, the light exerts a big influence on the electrons. By trying to "watch" the electrons we have changed their motion. That is, by just going to the place on where the photon is considered to be, we try to change the electron's motion enough so that it it might have gone somewhere else. If it was a mass point, it will instead travel where it was a remnant; that is why we no longer see the wave interference effects.

You may be thinking: "Don't use such a big 'gun'—turn the brightness down! The light waves will then be weaker and we can measure the electrons much more surely, by seeing the light dimmer and dimmer, eventually the wave will be weak enough that it will have a negligible effect." It is. Let's say it. The last thing we observe is that the *coherent* light measured from the electrons as they pass by does not get weaker. It always has constant Bush. The only thing that happens as the light is made dimmer is that sometimes we hear a "click" from the detector but see no Bush at all. This situation has gone along with increasing $P_{1,2}$. When we are decreasing is the light also acts like electrons, we know that it is as " $P_{1,2}$," but now we find that it is also " $P_{1,2}$," it always arrives in a scattered—in truth, that we call "photon." As we turn down the intensity of the light source we do not change the ϕ of the photons, only the rate at which they are emitted. This explains why, when we turn our dim, some electrons go by without being seen. They did not happen to be a photon and not in the range the electron went through.

This is all a bit disconcerting. It is because whenever we "see" the electron we see the normalized Bush, i.e., how many times we see are above the detector noise. Let us try the electrons from our own light sources. Now whenever we hear a click in the detector we can keep a count. i.e., how many times in Column 1; those that were seen by hole 1. In Column 2, those electrons seen by hole 2, and in Column 3, those electrons not seen at all. When we work up everything (computing the probabilities) we find these results. These "seen by hole 1" have a distribution like $P_{1,2}$; but the "seen by hole 2" have a distribution like $P_{1,2}$; and those "not seen at all" have a "heavy" distribution just like $P_{1,2}$ of Fig. 10-2. If the electrons are not seen, no more surprises!

That is understandable. When we do see an electron, no photon can be in, and when we do see it, a photon has disturbed it. There is always the same amount of disturbance from the light photons; all photons are registered effects and the effect of the previous being scattered is enough to smear out any interference effects.

Is there not some way we can see the electrons without disturbing them? We learned in an earlier chapter that the momentum carried by a "photon" is linearly proportional to its wavelength by $= \lambda/2\pi$. Considering the job given to the electrons when the photon is scattered, would our eye depend on the momentum that photon carried? And if we want to detect the electrons only

Energy we could not have known! The intensity of the light we should have known if its frequency rose with as increasing its wave length. That is, the light of a greater color. We could have the infrared light, or even waves like radar, and "heat" where the electrons went to form, help of some energy given. But can "heat" light of these higher wave lengths. It is the "geometric" light propagation we will be discussing the electrons so much.

Let us try the experiment with larger waves. We shall keep repeating our experiment with the small light of a longer wavelength. At first nothing seems to change. The results are the same. Then a terrible thing happens. You remember that when we discussed the microscope we pointed you to, due to the wave nature of the light, how a limited number above two spots can be had or can be seen as two separated spots. This distance is of course of the wavelength of light. So now, when we make the wavelength longer than the distance between our holes we see a big fuzzy flash when the light is scattered by the electrons. You can no longer tell which hole the electron went through. We just don't want to see it! And it is just as I light of the radar that we find that the jets grow as the jets are strong enough so that they begin to look like P_1 , that we begin to get some interference pattern. And it is only for wavelengths longer than the separation of the two holes ($\lambda > d$) that we get at all scattering where there is no result that the distance d , i.e., the light goes sufficiently small that we again get the curve P_1 shown in Fig. 31-3.

In our experiment we find that it is impossible to change the light in such a way that we can tell which hole the electron went through and yet the wave still not change. Let me tell. It was suggested by Heisenberg that the "new laws of mechanics" only by connection with the wave mechanics can be experimental possibilities and previous theoretical. He proposed, as a general principle, his uncertainty principle, which we can verify in our experiment as follows: "It is impossible to design an apparatus to find out which hole the electron passes through, but still not to decrease time during which hole the electron goes through. It cannot be so ruled out, if it does not disturb the pattern in an essential way. No one has ever found (or even thought of) a way around the uncertainty principle. So we must assume that it describes a basic structure of nature.

The complete theory of quantum mechanics which we now have is that the charge and, in fact, the matter depend on the interpretation of the uncertainty principle. Since quantum mechanics is such a proceeding theory, you believe in the uncertainty principle is reinforced. But the way in "heat" the uncertainty principle were ever discussed, quantum mechanics would give inconsistent results and you would never discussed it as a valid theory of atoms.

"Well," you say, "What about Proposition A? Is it true, or is it not true? If the electron does pass through hole 1 or it goes through hole 2?" The only answer we can be given is that we have found from experiment that there is a certain special way that we have a third possibility that we do not get in a meaningful ratio. What we can say is avoid taking wrong position and to do the following. If one looks at the detector, then one asks, also, if one has a piece of apparatus which is capable of detecting whether the electron goes through hole 1 or hole 2, then one can say that it is possible through hole 1 or hole 2, but when one does not try to tell which wave the electron goes, when there is nothing in the experiment to disturb the electrons then one may not say that an electron goes either through hole 1 or hole 2. If one does say it, and starts to make any deductions from the statement, he will have errors in the analysis. This is the logical tightrope on which we must walk if we wish to deduce nature successfully.

To the notion of "heat" as well as electrons—must be described in terms of waves, what would we have in our first experiment? Why didn't we see 62 different reprints in there? It turns out that the bullet-like wavelengths were too tiny that no interference pattern became visible. So however fast the wave may

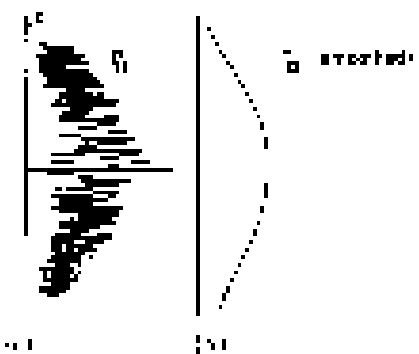

Fig. 37-5. Interference pattern with (a) both slits open; (b) one slit covered.

detector of finite size one could not distinguish between passing and missing. What we see is only a kind of average which is not classical wave. In Fig. 37-4 we have tried to indicate schematically what happens with large-scale objects. Part (a) of the figure shows the probability distribution for one might predict by billiards, using classical mechanics. The two bounces are supposed to represent the interference pattern and get two waves of very short wavelength; b) Any physical detector, however, smudges several wiggles of the probability curve, so that the measurements show DeBroglie's curve shown in part (b) of the figure.

37-7 Basic principles of quantum mechanics

We will now write a summary of the most important of the experiments. We will, however, put the results in a form which makes them more or less a general class of such experiments. We can write our summary more simply if we first define an "ideal experiment" as one in which there is no uncertainty or error influence, i.e., no jiggling or other things going on that we cannot take into account. We should be quite precise if we want an ideal experiment to mean a situation in which all of the initial and final conditions of the experiment are completely specified. When we will call "an event" as, in general, just a specific set of time, position conditions. (For example: "an electron leaves the gun, arrives at the detector, and nothing else happens.") Now for our summary:

Summary

- (1) The probability of an event in an ideal experiment is given by the square of the absolute value of a complex number ψ which is called the probability amplitude.

$$\begin{aligned} \psi &= \text{probability}, \\ &\quad \times \text{probability amplitude} \\ P &= |\psi|^2 \end{aligned} \quad (37.6)$$

- (2) When an event can occur in several alternative ways, the probability amplitude for the event is the sum of the probability amplitudes for each way (classical superposition). There is ADDITION.

$$\begin{aligned} \psi &= \psi_1 + \psi_2, \\ \psi &= \psi_1 + \psi_2 = \psi_1^2 + \psi_2^2. \end{aligned} \quad (37.7)$$

- (3) If an experiment is performed which is capable of determining whether one or another alternative is actually taken, the probability of the event is the sum of the probabilities for each alternative. The difference is lost.

$$P = P_1 + P_2. \quad (37.8)$$

One might still like to ask: "How does it work? What is the machinery behind the law?" We might wonder "machinery" while saying, "No one can explain" any more than we have just "explained". No one will give you any deeper representation of the situation. We have no idea about the mechanism from which these rules were derived.

We would like to emphasize a very important difference between classical and quantum mechanics. We have been talking about the probability that an electron will arrive in a given circumstance. We have recalled that in the experimental arrangement (or even in the best possible one) it would be impossible to predict exactly what would happen. We can only predict the *event*. This would mean, if it were true, that physics has given us on the problem of trying to predict exactly what *will* happen in a definite circumstance. Yet physics has given up. We do not know how to answer what *could* happen in a given circumstance, and we believe now that it is impossible that the only thing that can be predicted is the probability of different events. It can be recognized that this is a mechanism in our castle, ideal of understanding nature. It may be a backward step, but no one has ever a way to avoid it.

The more now is the news. It can suggest that something has been made to be by the description we have given. "Perhaps the electron has some kind of internal structure which is not visible. Or we do not yet know enough. Perhaps that is why we cannot predict where it will appear." If we could look more closely at the electron, we could be able to see where it would end up. So far as we know, this is impossible. We would still be in difficulties. Suppose we were to assume and inside the electron there is some kind of machinery that determines where it is going to end up. That machine must also determine which hole it is going to go through in this way. But we must note again that what is inside the electron should not be dependent on what we see, and in particular you wouldn't expect a choice one of the holes. So the electron, before it comes, has already made up its mind the other hole it is going to pass through when it is going to land. We should then say, for those electrons that have chosen hole 1, P_1 for those that have chosen hole 2, and correspondingly the sum $P_1 + P_2$ for those that come through the two holes. There seems to be no way around this. But we have verified experimentally that that is not the case. And no one has figured a way out of this puzzle. And he probably finds it very difficult to compute probabilities. We say "at the present time," but we expect very strongly that it is something that will be with us forever. But it is impossible to beat that puzzle—that this is the way nature really is.

37-8 The uncertainty principle

This is Heisenberg's and the uncertainty principle originally: If you make the measurement to any greater and greater accuracy the component of the momentum with uncertainty Δp , you cannot at the same time know its position more accurately than $\Delta x = \hbar/k$. The uncertainty in the position and momentum of any particle must have this product \hbar/k . This is Planck's constant. This is a special case of the uncertainty principle that was stated above. Quantitatively, The more general statement says that one cannot design experiments to say anything about a particle's position without, at the same time destroying the pattern of interference.

Let us show for example with this Fig. the kind of relation given by Heisenberg must be true in order to keep from getting contradictory. We imagine a modification of the experiment of Fig. 37-2, in which we go with the holes consists of a polarizer and a plate, both can respectively, stand down (just like 37-2), or stand in Fig. 37-6. By watching the motion of the pulse carefully we can try to tell which 1 or 2 an electron goes. I mean, imagine what happens when the deflector is placed at $x = 0$. We would expect that an electron which passes through hole 1 must be deflected downward by the plate to reach the deflector. Since the vertical component of the electron's initial momentum is unchanged, the plate must receive wave equal momentum in the opposite direction. The pulse will get an upward kick. If the electron goes through the lower hole, the pulse shot off from downward kick. If however the horizontal position of the deflector, the momentum received by the plate will have a different value for a lower hole than for a higher hole. Only if $P_1 = P_2$ will the distribution of the electrons match, but just by watching the plates, we can tell which path the electron took.

Now in order to do this it is necessary to know where the momentum of the electron is before the slit in your slit. So when we measure the momentum after the electron goes by, we ask, figure out how much the electron's momentum has changed. But, of course, according to the uncertainty principle we cannot at the same time know the position of the electron with an arbitrary accuracy. But if we do not know exactly where the electron we cannot say precisely where the two holes are. They will be in a different places for every electron that goes through. This means that the pattern of our interference pattern will have a different location for each electron. The wiggles of the interference pattern will be continually. We shall discuss quantitatively in the next chapter that if we determine the momentum of the plate sufficiently accurately by determining from the result measurement which hole was used, then it is consistent if the position of the plate was according to the con-

Fig. 37-6. An experiment in which the recoil of the wall is measured.

certainty principle, he enough to this case problem observed at the detector up and down in the scattering plane. In other words, there is no need to do better than this. Such a randomness is just enough to smear out the pattern of the interference I observed.

The uncertainty principle "protects" quantum mechanics. Heisenberg imagined that if it were possible to measure the momentum and the position simultaneously with a greater accuracy, the electron would collapse. So he proposed that it must be impossible. Two people sat down and tried to figure out ways of doing it, and suddenly Schrödinger cut a way to measure the position and the momentum of anything—a screen, an electron, a hill and everything—with very greater accuracy. Quantum mechanics remained as perhaps the accurate existence.

The Relation of Wave and Particle Viewpoints

38-1 Probability wave amplitudes

In this chapter we shall discuss the relationship of the wave and particle viewpoints. We already know, from the last chapter, that between the wave viewpoint and the particle viewpoint there is a conflict. Usually we have tried to present things adequately, or at least precisely enough, but they will not have to hand except when we learn more. It may be extended, but it will not be complete. The idea we try to talk about, the wave picture in the particle picture, both are approximate, and both will change. Therefore what we learn in this chapter will not be accurate in a certain sense; it is a kind of half-truthive fragment that will be much more precise later, but certain things will become really clear when we interpret them exactly in quantum mechanics. The reason for doing such a thing, of course, is that we are not going to go directly into quantum mechanics, but we want to have at least some idea of the kinds of effects that we will find. But first we will say again that we think waves and particles, and so it is rather fancy to use the wave and particle ideas except under standing circumstances. In other circumstances either we know the amplitude or the probabilities of the quantum-mechanical amplitudes. We shall try to illustrate the weaker places as we go along, but most of it is very much easier. It is not a matter of interpretation.

Very often we know that the best way of representing the world in quantum mechanics—*the best framework*—is to give an amplitude for every event that we can, and if the event involves the position of one particle then we can give the amplitude to find that particle at different places and at different times. The probability of finding the particle is then proportional to the absolute square of the amplitude. In general, the amplitude to find a particle in \vec{r} is not given by a different expression than position has time:

In a special case the amplitude varies sinusoidally in space and time like $e^{i(k\vec{r}-Et)}$, you must forget that these amplitudes are complex numbers, not real numbers; and involves a definite frequency ω and wave number k . I can ignore all that this can depend on a certain limiting situation where we would have believed that we have a particle whose energy E was known and is related to the frequency ω :

$$\mathcal{E} = \hbar\omega, \quad (38.1)$$

and where ω in electron-volts is also known and is related to the wave number by

$$\omega = \frac{\hbar k}{m}. \quad (38.2)$$

This means that the idea of a particle is limited. The idea of a particle—in location, its momentum, etc.—which we use so much, is in certain ways incorrect. For instance, if we amplitude to find a particle at different places is given by $e^{i(k\vec{r}-Et)}$, where ω and k are constant, that would mean that the probability of finding a particle is the same at all places. That means we do not know where it is—it can be anywhere. There's a great uncertainty in its position.

On the other hand, if the position of a particle is more or less well known and we can predict it fairly accurately, then the probability of finding it at different places will be confined to a certain region, which I will call S . Outside this region, the probability is zero. Now this probability is the absolute square of an amplitude, and since the absolute square is zero, the amplitude is also zero, so that

or have a wave train whose length is Δx (Fig. 38-1), and the wavelength (the distance between nodes of the waves in the train) of the wave train is what corresponds to the particle momentum.

This is an interesting & strange thing about waves: a very simple thing which has nothing to do with quantum mechanics really. It is something that anybody who works with waves, even if he knows no quantum mechanics, knows: namely, we cannot define a unique wavelength for a wave train. Such a wave train does not have a definite wavelength; there is an indeterminacy in the wave number that is related to the size or length of the train, and thus there is an indeterminacy in the momentum.

38-2 Uncertainty of position and momentum

Let us consider two examples of the idea—*to see the reason why there is an uncertainty in the position and/or the momentum if quantum mechanics is right*. We have already seen, before that if there were no such a thing—*i.e.*, if we had a model of the position and the momentum of anything simultaneously—we would have a paradox, it is terrible that we do not have such a paradox, and the fact that such a uncertainty exists naturally from the wave picture shows the consistency is naturally consistent.

There is one example which shows the relationship between the position and the momentum in a continuous way, is very instructive and—Suppose we have a single slit, and particles are coming from very far away with a certain energy. As they are all coming, essentially horizontally (Fig. 38-2). We suppose a constant v_0 is the horizontal component of momentum. All of these particles have a certain horizontal momentum v_0 , say, in a constant sense. So, in the classical sense, the vertical momentum v_y , because the particle goes through the slit, is definitely known. The particle is moving either up or down, because it comes from a source that is far away—and so the vertical momentum is of course zero. But now let us suppose that it goes through a hole whose width is Δ . Then after it has come out through the hole, we know the position vertically—the position—was considerable uncertainty, exactly Δ . That is, the uncertainty in position, Δx , is of order Δ . Now we might also want to say, since we know the momentum is reasonably horizontal, that Δp , is zero; *but that is wrong*. We don't know the momentum was horizontal, but we do not know it any more. Before the particles pass through the hole, we did not know their vertical positions. Now that we have forced the vertical position by having the particle come through the hole, we have lost our information on the vertical momentum! Why? According to the wave theory there is a spreading out, or dispersion, of the waves after they go through the slit, just as the light. Therefore there is a certain angle for that particles coming out of the slit are not coming exactly straight. The pattern is spread out by the diffraction effect, and the angle of spread, which we can define as the angle of the first minimum, is a measure of the uncertainty in the final angle.

How does the pattern become spread? To say it is spread means that there is some chance for the particle to be moving up or down, that is, to have a component of momentum v_y in given. Which starts and particle has, we can detect this diffraction pattern with a screen to the right, say, when the screen receives the particle, say at C (Fig. 38-2), it receives the entire particle, so that it is observed where the particle has a certain momentum, in order to go from the slit up to C.

To get a rough idea of the spread of the momentum, the vertical momentum v_y has a spread which is equal to $\lambda/\Delta x$, where λ is the horizontal wavelength. And how big is Δx is the spreading parameter? We know the first minimum occurs at an angle θ_1 such that the waves from one edge of the slit have to travel one wavelength farther than the waves from the other side. We worked that out before (Chapter 30). Therefore $\theta_1 = \lambda/v_0$, and $\Delta x = \lambda v_0 \theta_1$ by experimentally justified. Note that if we make Δx smaller and make a more accurate measurement of the position of the particle, the CII makes pattern gets wider. Remember, when we choose the slit for the experiment with the monochromes, we had more intensity there, but. So the narrower we make the slit, the wider the pattern gets on the

—you is to like "most" the we could find that the particle has sides be momentum. Thus the uncertainty in the vector momentum is inversely proportional to the uncertainty in λ . In fact, we see that the product of the two is equal to $\hbar/2$. But λ is the wavelength and p_x is the momentum, and in accordance with quantum mechanics, the wavelength from the momentum is De Broglie's formula. So we obtain the rule that the uncertainties in the vector momentum and in the vector position have a product of the order \hbar .

$$\Delta p_x \Delta x \approx \hbar \quad (38.1)$$

We cannot prepare a system in which we know the vertical position of a particle and can predict how it will move vertically with greater certainty than given by (38.1). That is, the uncertainty in the vertical momentum has crossed here, where Δx is the uncertainty in our knowledge of the position.

Sometimes people say that this statistics is all we do. When the particle passes through the slit, its vertical momentum is very small. And now that I have gone through the slit, its position is known. Now position and momentum seem to be known with infinite accuracy. It is quite true that we can receive a particle, and on reception determine what its position is and what its momentum is. We would have had to have been to have gone there. That is true, but that is not what the uncertainty relation (38.1) refers to. Equation (38.1) refers to the probability of a situation, not merely about the past. I then we good to say "I know what the momentum was before it went through the slit, and now I know the position," does not now he moment of knowledge: it does. The fact that it went through the slit no longer permits us to predict the vertical momentum. We are talking about a predictive theory, not just measurements after the fact. So we must talk about what we can predict.

Now let us take the thing the other way around. Let us take another example of the same phenomenon, a little more quantitative. In the previous example we measured the momentum by a classical method. Namely, we calculated the deflection and the velocity and the angles, etc., so we got the momentum by classical analysis. But since momentum is related to wave number, there exists an entirely different way to measure the momentum of a particle: *grating*, otherwise which has no classical analog, because it uses Eq. (38.1). We measure the wave length of the waves. Let us try to measure momentum in this way.

Suppose we have a grating with a large number of lines (Fig. 38-3), and send a beam of particles at the 45° slit. We have often discussed this problem: if the particles have a definite momentum, then we get a very sharp pattern in a certain direction, because of the interference. And we have also allowed that, however, only we can determine our momentum, that is to say, whatever measuring power of such a grating is to be then there is again we refer to Chapter 33, where we found that the relative uncertainty in the wavelength that can be measured with a given grating is $1/N^m$, where N is the number of lines on the grating and m is the order of the diffraction pattern. Then is,

$$\Delta \lambda/\lambda = 1/N^m. \quad (38.4)$$

Now De Broglie (38.1) can be rewritten as

$$\Delta p_x/\lambda = 1/N^m = 1/d, \quad (38.5)$$

where d is the distance shown in Fig. 38-3. This distance is the difference between the total distance that the particle is away in whatever it is sent to travel if it is reflected from the bottom of the grating, and the distance that it has to travel if it is reflected from the top of the grating. That is, the waves which form the diffraction pattern are waves which come from different parts of the grating. The first ones that come come from the bottom edge of the grating, from the beginning of the wave train, and the rest of them come from later parts of the wave train, coming from different parts of the grating until the last one. Finally we have, and that involves a point in the wave train a distance d behind the first point. So in order that we shall have a spot in our spectrum corresponding to a definite momentum

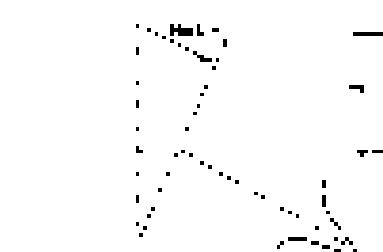

Fig. 38-3. Determination of momentum by using a diffraction grating.

With our birth control plan in (35.4), we have to have wave train of total length L . If the wave train is too short we are not using the entire train. The waves which form the structure are being reflected from only a very short section of the grating. If the wave train is too short, and the grating will not work right—we will find a big angle spread. In order to get a narrower one, we need to use the whole grating, so that at least at some moment the whole wave train is scattering simultaneously from all parts of the grating. Thus the wave train must be of length L in order to have an uncertainty in the wavelength less than that given by (35.5) incidentally,

$$\Delta \lambda \approx \frac{c}{(L/\lambda)} = \frac{c\lambda}{L}, \quad (35.6)$$

Therefore

$$\Delta \lambda = 2\pi/L, \quad (35.7)$$

where L is the length of the wave train.

This means that if we have a wave train whose length is less than L , the uncertainty in the wave number must exceed $2\pi/L$. Or the uncertainty in the wave number times the length of the wave train. We will see that for a moment $\Delta \lambda$ exceeds $2\pi/L$. We call it $\Delta \lambda$ because that is the uncertainty in the position of the particle. If the wave train exists only in a finite length, then that is where we would find the particle, within an uncertainty Δx . Now this property of waves, the "length of the wave train" gives the uncertainty of the wave number associated with it. This is a property that is known to everyone who studies them. It has nothing to do with quantum mechanics. It is simply that if we have a finite train, we cannot count the waves in it very precisely. Let us try another way to see the reason for that.

Suppose that we have a finite train of length L ; then because of continuity it has to have Δx . As shown in Fig. 35-1, the number of waves in the length L is uncertain by something like ± 1 . But the number of waves is $L = cL/\lambda$. Thus λ is uncertain, and we cannot get the result (35.7), a property of many waves. The same thing works whether the waves are in space and L is the number of radiations per centimeter and λ is the length of the train, or the waves are in time and L is the number of oscillations per second and $T \rightarrow L$ is the "length" in time; that the waves exist during L . That is, if we have a wave train lasting only for a certain finite time L , then the uncertainty in the frequency is given by

$$\Delta \omega = 2\pi/L. \quad (35.8)$$

We have tried to emphasize that these are properties of waves alone, and they are well known, for example, in the theory of sound.

The point is that in quantum mechanics we interpret the wave number as being a measure of the momentum of a particle. With the rule that $p = \hbar k$, equation (35.7) tells us $\Delta p = \hbar \Delta k$. This, then, is a formulation of the classical idea of momentum. (No, it's k , it has to be modified in some ways if we are going to represent particles by waves). It is like this: we have found a rule that gives us some idea of when there is a failure of classical ideas.

35-2 Crystal diffraction

Now let us consider the reflection of parallel waves from a crystal. A crystal is a little thing which has a whole lot of smaller crystals— we will include some complications later—in a nice lattice. The question is how to set up energy in this lattice, so that it reflects maximum in a given direction, not a given beam of, say, light (or X-ray electrons, or photons, or anything else). In order to obtain a strong reflection, the scattering from all of the lattice must be in phase. Thus, if each harmonic has a phase in phase and out of phase, the waves will cancel out. The way to arrange things is to find two regions of constant phase, as we have already explained; they are places where waves begin in phase with the initial and final vibrations (Fig. 35-4).

If we consider two parallel planes as in Fig. 35-4, the waves scattered from the two planes will be in phase provided the difference in distance travelled by a wave

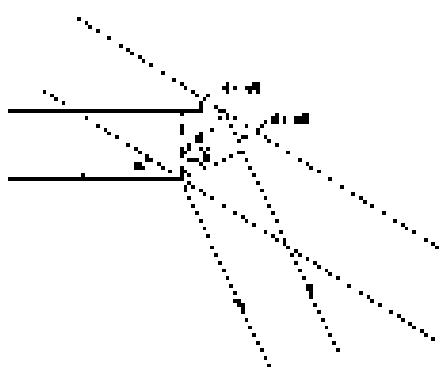

Fig. 35-4. Scattering of waves by crystal planes.

front is an interval on the back of wave-lengths. This difference can be seen to be $2\pi \sin \theta / d$, where d is the perpendicular distance between the slits. Thus the condition for coherent reflections is

$$2\pi \sin \theta / d = (n - 1) \lambda \quad (38.9)$$

In other words, the crystal is said that no wave-changes will occur when the angle of reflection (Eq. 9) with $n = 1$, i.e. there will be a strong reflection. If, on the other hand, there are other n 's instead of the same $n = 1$ (spaced in a certain regularity however), then the inter-plane plates will also scatter equally strongly and will interfere with the others and produce an effect. But it is (Eq. 9) must refer to adjacent planes, not to distant planes far away. Interference will not be this simple.

As a matter of fact, actual crystals are not usually as simple as a single kind of atom arrangement; it is certainly not. Instead, if we make a two-dimensional model, they are much like wallpaper, in which there is some kind of "figure" which repeats all over the wall-paper. By "figure" we mean, in the case of atoms, some arrangement—either more or less random three-arrangements, e.g., for calcium carbonate, or, however, what may happen a practically any number of atoms. But whatever it is, the figure is repeated in a pattern. This basic figure is called a unit cell.

The basic pattern of repeating defines what we call the lattice law: the lattice spacing can be immediately determined by looking at the reflexions and seeing which axes of symmetry it has. In other words, if we see distinct reflections of all directions, the law is true. But in order to determine what is in each of the elements of the lattice one must take into account the intensity of the scattering in the various directions. These directions are independent of the type of lattice, but their intensity each successive is determined by what is inside each unit cell, and in that way the structure of crystals is worked out.

Two photographs of x-ray diffraction patterns are shown in Figs. 38-3 and 38-4. Crystalline scattering from rock salt are monoplatinum respectively.

Incidentally, an interesting thing happens if the spacings of the two unit planes are less than $\lambda/2$. In this case (Fig. 9) the reflection law is violated. Look at Fig. 9 again. Notice the distance between adjacent planes. Now there is no side diffraction pattern, and the light—on which even it's wavelength λ —goes through the material without being scattered or reflected back. So in the case of light, where λ is much bigger than the spacing, when it's scattered through there is no return of reflection from the planes of the crystal!

This behavior is an interesting consequence of waves which make everything there are physically justified. No everybody's money is. If we take two carbons and let them into a tiny block of graphite, the neutron diffuse and work that was done (Fig. 34-7). They diffuse now, so they are bounded by the atoms, but strictly in the wave theory, they are bounded by the atoms because of diffraction from the crystal planes. I think that if we take a very long piece of graphite, the neutrons that come out the far end, in all of long wavelength. In fact, if one plane can, in reality as a function of wave-length, we get nothing except for scattering. It's easier than a certain minimum (Fig. 38-8). In other words, we can get very short neutrons this way. Only the lowest frequency can do. Though, they are not scattered or scattered by the crystal, it is of the property, but been going right through like light through glass, and so, not scattered out the sides. There are many other demonstrations of the validity of neutron wave and waves of other varieties.

46-4 The idea of selection

We have considered another application of the wave-length relation, Eq. (38.5). It must not be taken too seriously, the idea is right but the subject is not fully understood. The idea has to do with the transmission of the wave of atoms, and the fact that, specifically, electrons would reduce light and sound until they settle down right on top of themselves. But that cannot be right quantitatively, because then we would know where each electron was and then tell it was moving

Fig. 38-3

Fig. 38-4

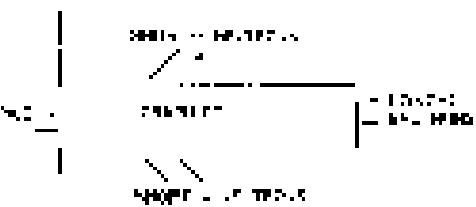

Fig. 38-5. Diffraction of plu neutrons from graphite block.

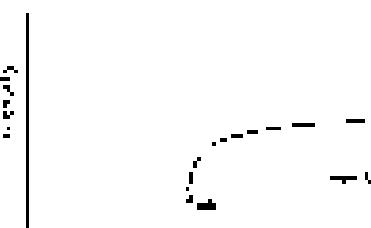

Fig. 38-6. Intensity of neutron scattering from graphite and its behavior at low-wavelength.

Suppose we have a hydrogen atom, and measure the position of the electron; we must not be able to decide exactly where the electron will have the momentum associated with the sum out to be infinite. Every time we look at the electron, it is somewhere, but it has an amplitude to be in different places. These places cannot all be in the nucleus. We shall suppose the radius a is in picometers of order 6. Let us, the distance of the electron from the nucleus is usually about a . We shall determine a by minimizing the total energy of the atom.

The spread of momentum is roughly due to because of the uncertainty relation, so that if we try to measure the momentum of the electron in some manner, such as by scattering x-rays off it and looking for the Doppler effect from a moving scatterer, we would expect not to get zero every time—the electron is not standing still—but the momenta must be of the order $\sim m\omega a$. Then the kinetic energy is roughly $m\omega^2 a^2 = e^2/2m = h^2/2ma^2$. In a word, this is a kind of dimensional analysis. And out in when vary the kinetic energy tends upon Planck's constant, upon a , and upon the size of the atom. We need not treat our atoms as with the classical law $F = kx$. We have now even defined a very precisely just how the potential energy is minus e^2/r for distances from the center, say $-e^2/a$, where the parameter e^2 is the charge of an electron squared divided by $4\pi\epsilon_0$. Now the point is that the potential energy is reduced if a goes smaller, but the smaller a is, the bigger the momentum required, because of the uncertainty principle, and therefore the higher the kinetic energy. The total energy is

$$E = \hbar^2/2ma^2 - e^2/a. \quad (16.1)$$

We do not know what a is, i.e., we know that the atom is going to arrange itself in \rightarrow in some kind of compromise so that the energy is as little as possible. In order to minimize E , we collaborate with respect to a , see the derivative with respect to a . The derivative of E is

$$dE/da = -e^2/m a^2 + e^2/a^2, \quad (16.1b)$$

and setting $dE/da = 0$ gives for a the value

$$a_0 = \hbar^2/m e^2 = 0.055 \text{ angstrom} \\ = 0.055 \times 10^{-10} \text{ meter} \quad (16.1c)$$

This particular distance is called the Bohr radius, and we have thus learned that atomic dimensions are of the order of angstroms, which is right. This is pretty good—in fact, it is amazing, since until now we have had no basis for understanding the size of atoms! Atoms are completely impossible from the classical point of view, since the electrons would spiral in to the nucleus.

Now if we put the value (16.1c) for a , into (16.1b) to find the energy, we come out

$$E_0 = -e^2/2a_0 = -mc^2/2a_0^2 = -13.6 \text{ ev}. \quad (16.1d)$$

What does a negative energy mean? It means that the electron has less energy when it is in the atom than when it is free. It means it is bound. If you give it more energy, it sinks the electron out; it takes energy of the order of 13.6 ev to ionize a hydrogen atom. We have an answer to think that it is not twice or three times this—or half of this, or $1/\pi$ times this, because we have used it as a sloppy argument. However, we have obtained, we have used all the constants in such a way that it happens to come out the right number! This number, 13.6 electron volts, is called a **Radius of energy**; it is the ionization energy of hydrogen.

So we now understand why we do not fall through the floor. As we walk on streets with their masses of atoms push against one floor with its mass of atoms. In order to squash them closer together, the electrons would be confined to a smaller space and, by the uncertainty principle, their momenta would have to be bigger, on the average; and that means high energy; the resistance to atomic compression is a quantum-mechanical effect and not a classical effect. Classically,

we would expect that if we were to draw all the electrons and protons closer together, the energy would be reduced, until further, and the last arrangement of possible and reasonable charges in classical physics is all on top of each other. This was well known in classical physics and was a puzzle because of the existence of the atom. Of course, the early scientists invented some ways out of the trouble—but never mind, we have the right way out now. (Maytag.)

Incidentally, although we have no reason to understand it at the moment in a situation where there are many electrons, it turns out that they try to keep away from each other. If one electron is occupying a certain space, then another does not occupy the same space. More precisely, there are two spin rules, so that two electrons in a single orbital can't both be spinning one way and not the other way. But after that we cannot put any more there. We have to put others in another place, and that is the real reason that matter has volume. If we could put all the electrons in the same place, it would have no volume—more than it does. It is the fact that the electrons cannot all get on top of each other that makes bodies and everything else solid.

Obviously, in order to understand the properties of matter, we will have to use quantum mechanics and not be satisfied with classical mechanics.

38-3 Energy levels

We have talked about the atom in its lowest possible energy condition, but it turns out that the electron can do other things. It can, spiral and wiggle at a more energetic minimum, and so there are many of the low possible minima for the atom. According to quantum mechanics, in a stationary condition, there can only be definite energies for an atom. We make a diagram (Fig. 38-9) in which we plot the energy vertically, and we make horizontal lines for each allowed value of the energy. When the electron is free, i.e., when its energy is positive, it can have any energy; it can be moving at any speed. Our bound energies are not arbitrary. The atom must have one of another out of the set of allowed values, and so there is Fig. 38-9.

Now let us call the allowed values of the energy E_1, E_2, E_3, \dots . If an atom is excited in one of these "normal states," E_1, E_2, \dots , it does not remain in that state forever. Sooner or later it drops to a lower state and radiates energy as the form of light. The frequency of the light that is emitted is determined by conservation of energy plus the quantum-mechanical understanding that the frequency of the light is related to the energy of the light by (38.1). Therefore the frequency of the light that is released in a transition from energy E_3 to energy E_1 (for example) is

$$\omega_{31} = (E_3 - E_1)/\hbar. \quad (38.11)$$

This then, is a characteristic frequency of the atom and defines a spectral emission line. Another possible transition would be from E_3 to E_2 . That would have a different frequency

$$\omega_{32} = (E_3 - E_2)/\hbar. \quad (38.12)$$

Another possibility is that the atom were excited to the state E_2 , it could drop to the ground state E_1 , emitting a similar kind of frequency

$$\omega_{21} = (E_2 - E_1)/\hbar. \quad (38.13)$$

The reason we bring up these transitions is to point out an interesting relationship. It is easy to see from (38.11), (38.12) and (38.13) that

$$\omega_{32} = \omega_{31} - \omega_{21}. \quad (38.14)$$

In general, if we find two spectral lines, we should expect to find another line at the sum of the frequencies (or the difference of the frequencies), and that all the lines can be understood by finding a series of levels such that every line corresponds to the difference in energy of some pair of levels. This remarkable correspondence

Fig. 38-9. Energy diagram for an atom showing several normal conditions.

spectral frequencies are valid before quantum mechanics was discovered, and it is called the *Ritz combination principle*. This is again a mystery from the point of view of classical mechanics. Let us note besides the point that classical mechanics is a failure in its attempt, during two centuries to have determinism, but pretty well.

We have already noted above: quantum mechanics as being represented by amplitudes which behave like waves, with certain frequencies and wave numbers. Let us observe now it comes about from the point of view of amplitude that the atom has definite energy states. This is something we cannot understand at all. etc. This has been said so far, but we recall familiar with the fact that classical waves have definite frequencies. For instance, if sound is confined to the organ pipe or acoustics, like that, then there is a note there, or a note there, or a note there, but it can't have very high or very low frequency. Then an organ in which the waves are confined has certain resonance frequencies. It is therefore a property of waves in a confined space - a cavity, which we will discuss in detail will further tell us that they exist only at certain frequencies. And once the general relation exists between frequencies of the amplitude and energy, we are not surprised to find definite energies associated with the quantum of energy.

28-6 Philosophical implications.

Let us consider briefly some philosophical implications of quantum mechanics. As we know, there are two aspects of the problem: one is the philosophical implications for physics, and the other is the extrapolation of philosophical methods to other fields. The philosophical ideas associated with science are extrapolated into another field, they are usually completely altered. Therefore we shall confine our remarks as much as possible to physics itself.

First of all, the most interesting aspect is the idea of the uncertainty principle; making an observation : *Don't you phenomena?* It has always been known that making observations affects a phenomena, but the point is that the effect cannot be disregarded or minimized in decreased arbitrarily by decreasing the apparatus. When we look for something to phenomena we cannot help but disturb it in a certain minimum way, and the disturbance is necessary for the existence of the observer. The observer, we sometimes, is present in quantum mechanics, but only in a rather trivial sense. Our problem has been resolved if it is really in a sense that there is nobody there to hear it. Does it make a noise? And let's follow our old forest makes a sound, of course, even if nobody is there. Even if nobody is there, to hear it, there are other leaves left. The sound will change some leaves, and if we were careful enough we might find somewhere just some don't had rubbed against leaf and made a tiny scratch that could not be registered unless we examined the leaf with a microscope. So in a certain sense we would have to admit that there is a sound made. We might ask: Was there a sound of sound? No, musicians have to do, presumably, with a mechanism. And what is music and consciousness and whether there was intention before, or whether the tree was conscious, we do not know. Let us leave the problem at that level.

Another thing that people have emphasized since quantum mechanics was developed is the idea that we cannot not speak about those things which we cannot measure. Actually relativistic theory does not say that. If something can be defined by measurement, it is no problem in a theory. And since an exact definition of the mechanics of a localized particle cannot be defined by measurement, it therefore has no place in the theory. The idea that this is what we must do, with classical theory or with the quantum theory, is a complete analysis of the situation. But this means cannot measure position and momentum precisely does not a word mean that we cannot talk about them. To only means that we need not talk about them. The situation is, in the science is this: A concept or an idea which comes by measurement or cannot be reduced directly to experiment not or may not be useful. It need not exist in a theory. In other words, suppose we compare the classical theory of the world with the quantum theory of the world, and suppose that it is found exponentially that we can measure position and momentum only imperfectly. The question is whether the idea of the exact position of a particle and the exact

inclusion of a causal or not. The classical theory admits the idea; the quantum theory does not. This does not in itself mean that classical physics is wrong. When the new quantum mechanics was discovered, most classicists— which included everybody except Heisenberg, Bohr, Dirac, and von Neumann— said: "Look, you know it is not easy to understand quantum mechanics, but nevertheless certain quantities like ψ are the exact position of a particle, which tells about its properties, and state others." Heisenberg's answer was: "I do not need to answer such questions as what is your name, and such a question I can't answer." It is that we do not have to. Consider now theories (a) and (b); they are not necessarily incorrect by classical theory but which is used at the analysis, and the either (b), does not contain the idea of "They always act in their predictions, one could see them, but (b) is false because it cannot explain this idea, that is in (a), because that idea is one of the things that cannot be checked directly. I, & always want to know what ideas cannot be checked directly, but it is not necessary to remove them. From a & b it is clear that we can pursue course completely by using only those concepts whose validity is tested at experiment...

In quantum mechanics the "there is a wave function amplitude, there is a potential, and there are many constants that we cannot measure directly. The basic idea of determinism is probably to predict what will happen in an experimental situation and has been known since Newton: How can we do that? By assuming that we know what is there, independent of the experiment. We must extrapolate the experiments to a region where they have not been done. We must take our knowledge & extend them to places where they have not yet been checked. If we do not do that, we have no prediction. So it was perfectly sensible for the classical physicists to go rapidly along and suppose that "in your room—which obviously has something for a base—... means something else for an electron. It was not stupidity. It was sensible prediction. Today we say that the law of causality is supposed to be true in all energies, but everyday situation may contradict and say how stupid we were. We do not know where we are "stupid" until we "turn over next card" and the whole idea is to put our neck out. And the only way to find out that we are wrong is to find out if we can predict something. That is already necessary to make predictions.

We have already made a few remarks about the indeterminacy of quantum mechanics. That is, that we are unable now to predict what will happen in physics in a given physical situation and what is true as far as exactly as possible. If we drop an atom that is in an excited state and it is going down it is stable. We cannot say when it will emit the photon. It has a certain probability to emit the photon every time, and we can predict only a probability for emission; we cannot predict the precise energy. This has given rise to all kinds of metaphysical questions on the meaning of free will, etc. still, and of the other, that the world is uncertain.

If you ask me, I am notimplausible that classical physics is also indeterminate, in a sense. It is usually thought that this indeterminacy, i.e., we cannot predict the future, is an important quantum-mechanical thing, and this is said to explain the behavior of the mind, feelings of free will, etc. But if the world were classical—if the laws of mechanics were classical—it is not very obvious then the mind would not feel more or less the same. It is true classically that if we knew the position and the velocity of every particle in the world, then, of course, we could predict exactly what would happen. And therefore the classical world is deterministic. Suppose, however, that we have a finite account of the world, but we do not know exactly where just one atom is, say to one part in a billion. Then as it goes along it hits another atom, and because we did not know the position better than to one part in a billion, we hit an even larger error in the position after "one" step. And that is something, of course, i.e., the next collision, so that if we start with only a tiny error, a rapidly magnifies this tiny error exponentially. To give an example: if water falls over a dam, it splashes. If we want exactly, every tiny sand grain a drop will land at our nose. This appears to be completely random, yet such a behavior would be predicted by purely classical laws. The exact position of all the drops depends upon the precise positions of the water before it goes over the dam. Now? The water drops, it's this we recognized in falling, ... that we get complete randomness. Otherwise,

viously, we cannot really predict the position of the drops unless we know the motion of the water molecules exactly.

Speaking more precisely, given an arbitrary accuracy, no matter how precise, one can find a time long enough that the exact predictions will be valid long enough. Now the point is that this length of time is not very large. It is not that the time is millions of years; the accuracy is one part in a billion. The time goes, in fact, only logarithmically with the error, and it turns out that, in only a very, very tiny time we lose all the information. If the accuracy is taken to be one part in billions and billions and billions—no matter how many billions we take provided we do stop somewhere—that we can find a time less than the time it took to state the accuracy—after which we can no longer predict what is going to happen! It is therefore not free to say that from the apparent freedom and indeterminacy of the laws of mind, we should have realized that classical "deterministic" physics could not ever hope to understand it, and to welcome quantum mechanics as a release from a "completely mechanistic" universe. For already, in Classical mechanics there was indeterminacy from a practical point of view.

The Kinetic Theory of Gases

39-1 Properties of matter

With this chapter we begin our study of objects which we occupy in for some time. It is the first part of the analysis of the properties of matter from a physical point of view, in which, recognizing that the gas is made up of a great many atoms, or elementary parts, which interact *exactly* according to the laws of mechanics, we try to understand why various aggregates of atoms behave the way they do.

This is a new and this is a difficult subject, and we emphasize at the beginning that it is in fact a extremely difficult subject, and the we have to deal with it differently than you have dealt with the other subjects so far. In the case of mechanics and in the case of light, we were able to begin with a simple statement of some law, say Newton's law, or the formula for the field produced by an accelerated charge, laws which a whole host of phenomena could be essentially understood, and which would provide a basis for our understanding of mechanics and of light from that time on. That is, we must learn more law, and we do not learn different physics, we only learn better methods of mathematical analysis related to the situation.

We cannot use this approach effectively at studying the properties of matter. We can discuss matter only in a most elementary way; it is much too complicated a subject to analyze directly from its specific basic laws, which are more clutter than the laws of mechanics and electricity. But there are a bit too many for every one the properties we wish to study, and too many ways to put them. Newton's laws to the properties of matter, and these steps are, in themselves, fairly complicated. We will now start to take some of these steps, but the way of our analysis will be quite accurate, but not eventually get back to the results. We will have only a rough understanding of the properties of matter.

One of the reasons can we have to perform the analysis so imperfectly is that the mathematics of it requires a deep understanding of the theory of probability: we are not going to want to know what every atom is actually moving, but rather, how many move here and there on the average, and what the odds are for different effects. So this subject involves a knowledge of the theory of probability, and our inabilities is not you, you may really not we don't want to start from here.

Secondly, and more important from a physical standpoint, the actual behavior of the atoms is not according to classical mechanics, but according to quantum mechanics and a correct understanding of the subject cannot be gained until we understand quantum mechanics. Here, in the millions of billions, bulk and poly-nuclei, the difference between the classical mechanical laws and the quantum mechanical laws is very important and very significant, so that many things that we are deduced by classical physics will be fundamentally incorrect. Therefore there will be certain things to be possibly unlearned, however, we shall indicate in every case when a result is incorrect, so as we will know where the "edge" are. One of the reasons for discussing quantum mechanics in the preceding chapters was to get an idea as to why, in fact, less classical mechanics is incorrect in the real world.

Why do we need with the subject now to start? Why not wait a half a year, or a year, until we cover the mechanics of a building tower, and we learn a little quantum mechanics, and then we can do it in a more fundamental way? The answer is that it is a different subject and the best way to learn it is to do it slowly! The first thing to do is to get some idea, more or less, of what ought to happen. If

39-2 Properties of matter

39-3 The pressure of a gas

39-4 Compressibility of radiation

39-5 Temperature and kinetic energy

39-6 The heat equation

different circumstances, and then, later, when we know the laws better, we will formulate them better.

Anytime we want to analyze the properties of matter in a real problem, we might want to start by writing down the fundamental equations and then try to solve them mathematically. Although there are people who do try to do such an approach, these people are the failures in the test; the two, however, come in those who can, from a physical point of view, people who have enough idea where they are going and then begin by making certain kind of approximations, knowing what is big and what is small in a given complicated situation. This problem—so uncomplicated now even an elementary student could follow, although incomplete and incomplete, is something like that, and so the subject will be one that we shall go over again and again, each time with more and more accuracy, as we go through our course in physics.

A good reason for beginning the subject right now is that we have already used many of these ideas in, for example, chemistry, etc., the other four hours of work at least in high school. This is enabling us to use the physical basis for these things.

As an interesting example, we all know that equal volumes of gases at the same pressure and temperature, contain the same number of molecules. The law of multiple proportions, that when two gases combine in a chemical reaction the volumes needed always exist in simple integral proportions, was understood ultimately by Avogadro to mean that equal volumes have equal numbers of atoms. Now why do they have equal numbers of atoms? Can we deduce from Newton's laws that the number of atoms should be equal? We shall address ourselves to that specific matter in this chapter. In succeeding chapters, we shall discuss various other phenomena involving pressure, volume, temperature, and heat.

We have also felt that the subject can be attacked from a mathematical point of view, and that there are many interesting aspects of the group that we can attack. That treatment, when we compare something, it reveals, if we need it, it rewards. There is a relationship between these two facts which must be deduced independently of the machinery one needs. This subject is called thermodynamics. The deepest understanding of thermodynamics comes, of course, from understanding the actual machinery underlying, and that is what we shall do; we shall take the most simple point from the beginning and use it to understand the various properties of matter and the laws of thermodynamics.

Let us, then, discuss the properties of gases from the standpoint of Newton's laws of motion, etc.

34-2 The pressure of a gas

First, we know that a gas exerts a pressure, and we might clearly understand what this is due to. If our ears were a few times more sensitive, we would hear a perpetual rushing noise. Evolution has not developed the ear to this point because it would be useless if it were so much more sensitive—we would hear a perpetual roar. The reason is that the ear is in contact with the air, and air is a lot of molecules in perpetual motion and these bump against the surfaces in bumping against the ear-membrane. Let us imagine, let us, boom, boom, boom... what we do not hear because the atoms are so small that the sensitivity of the ear is not quite enough to notice it. The result of this perpetual bumping is to push the drum away, but since nothing is stopped perfectly, reboundance follows so the side of the ear-membrane, so the net force on it is zero. If we were to take the ear away from one side, or change the relative amounts of air on the two sides, the ear-membrane would then be pushed one way or the other, because the amount of reboundance on one side would be greater than on the other. We sometimes find the unexplainable effect when we go up too fast in an airplane, especially if we also have the cold (when we have a cold, inflammation above the ear which can lets the air on the inside of the ear-membrane with outside air through the throat, so that the two pressures cannot readily equilibrate).

In working out to analyze the situation quantitatively, we imagine that we have a volume of gas in a box, at one end of which is a piston which can be moved (Fig. 39-1). We want to find out what happens if the piston moves fast enough to knock atoms in this box. The atoms of the gas will tend to hit the piston more often and move it back with certain velocities they bring against the piston. Suppose there is a atom, m , on the x -axis of the piston. What will happen if the piston were to advance, and velocity v_0 onto it, each time it got stopped it would pick up a little momentum and it would gradually get kicked out of the box. So in order to keep it from being pushed out of the box, we have to hold it with a force F . The question is how much force? One way of expressing this force is to talk about the force per unit area, which is the area of the piston. Then the force on the piston will be written as a number times the area. We define the pressure, then, as equal to the force that we have to apply on a piston, divided by the area of the piston.

$$P = F/A. \quad (39.1)$$

To make sure we understand the idea let's have us derive it for accuracy purposes anyway; the differential work done on the gas in compressing it by moving the piston in a differential amount dx would be the force times the distance that we compress it, which, worked up as (39.1), would be the pressure times the area times the distance, which is equal to transfer the pressure into the change in the volume:

$$dW = F dx = -F dx = -P dV. \quad (39.2)$$

(The last d has the dimensionality of the volume changed.) The minus sign is there because, as we are pressing x , we decrease the volume; if we think about it we can see that if a gas is compressed, work is done on it.

How much does do we have to apply to balance the bunching of the molecules? The piston moves from rest collides a certain amount of time Δt . A certain amount of atoms — say n — will move into the piston, and it will start to move. To keep it from moving, we must push back into it the same amount of momentum per second from our force. Of course, the force is the amount of momentum per second that we are applying. There is another way. In addition to the force of the piston it will pick up speed because of the bump it makes; with each collision we get a little more speed, and this adds thus increases. The rate at which the piston picks up speed, or accelerates, is proportional to the force on it. So we see that the force which we already have said is the pressure times the area is equal to the momentum per second delivered to the piston by the colliding molecules.

To calculate the momentum per second we may — we can — do it in two parts: first, we find the momentum delivered to the piston by one particle, and then, if collision with the piston then we have to multiply by the number of collisions per second that the atoms have with the wall. The force will be the product of these two factors. Now let us see what the two factors are: In the first place we shall suppose that the piston is a perfect "mirror" for the atoms. If it is not, the whole theory is wrong, and the piston will start to heat up and things will change, but eventually, when eqilibrium is set in, the net result is that the collisions are effectively perfectly elastic. On the average, every particle that comes in bounces with the same energy. Since we'll imagine that the gas is in a steady condition, and we lose no energy to the piston because the piston is standing still. In other circumstances, if a particle comes in with a certain speed, it bounces off with the same speed and, you see, key, with the same mass.

If v_0 is the velocity of an atom, and v_1 is the resultant v , then v_1 is the component of the momentum "lost"; but we also have an equal component of momentum " v_0 " and so the total momentum, delivered to the piston, by the n atoms in one collision, is mv_{1x} , because it is "lost."

Now we need the number of collisions made by the atoms in a second, or in a certain number of time Δt , but we divide by Δt : How many atoms are hit? This is a question that does not fit easily to the volume A , in $m = N/V$ is each cubic volume. By how many atoms hit the piston, we note that, given a certain

Fig. 39-1. Action of a gas in a box with a Mc力学斯 piston.

amongst x -values, if a particle has a certain velocity towards the piston it will hit it in the time t , provided it is close enough. If it is too far away, it goes only part way toward the piston; if the time t but does not reach the piston. The above is clear that only those molecules which are within a distance $v_0 t$ from the piston are going to hit the piston in the time t . Thus the number of collisions in a time t is equal to the number of atoms which are in the region within a distance $v_0 t$, and since the area of the piston is A , the volume occupied by the atoms which are going within the piston is $A v_0 t$. But the number of atoms per unit volume is n_{atom} . Of course we do not care about whether that is in a time t , we want the number per second, so we divide by the time t to get n_{atom} . (This time t might be made very short, if we feel we want to take into account molecular velocities, but it is however, being.)

So we find that the force is

$$F = n_{\text{atom}} \cdot A v_0^2. \quad (38.3)$$

See, the force is proportional to the area, if we keep the particle density fixed or we change it enough. The pressure is then

$$P = A v_0^2. \quad (38.4)$$

Now we notice a little trouble with this analysis: first, all the molecules do not have the same velocity, and they do not move in the same direction. So, all the v_i 's are different! So what we must do of course is to take the average of the v_i 's, since each one makes its own contribution. What we want is the square of v_i , averaged over all the molecules:

$$\bar{v}^2 = \langle v_i^2 \rangle. \quad (38.5)$$

But we forgot to include the factor 2π . No. of all the atoms, only half are located toward the piston. The other half are located in another way, and there take (\bar{v}) . We are averaging the negative v_i 's squared, as well as the positive v_i 's. So when we just take $\langle v_i^2 \rangle$, without looking, we are putting in twice as much as we want. The average of v_i^2 , the positive v_i , is equal to the average of v_i^2 for all v_i , taking one half.

Now as the terms become small, it is clear that there is nothing special about the "x-direction", the atoms may also be moving up and down, back and forth, left and right. Therefore, it is going to be true that $\langle \bar{v}^2 \rangle$, the average motion of the atoms in one direction and the average in the other two directions, are all going to be equal.

$$\langle \bar{v}_x^2 \rangle = \langle \bar{v}_y^2 \rangle = \langle \bar{v}_z^2 \rangle. \quad (38.6)$$

It is only a matter of either a very mathematical intuition, therefore, that they are each equal to one-third of the sum, which is of course the square of the mean value of the velocity:

$$\langle \bar{v}^2 \rangle = \langle \bar{v}_x^2 \rangle = \langle \bar{v}_y^2 \rangle = \langle \bar{v}_z^2 \rangle = \langle \bar{v}^2 \rangle / 3. \quad (38.7)$$

This has the advantage that we do not have to worry about any particular direction, and so we write our pressure in a more compact form in this form.

$$P = (f/m)v^2/2. \quad (38.8)$$

In whom we wrote the last factor as $(f/m)^2/2$; f is the *kinetic energy* of the center-of-mass motion of the molecule. We find, therefore, that

$$PV = (f/m)v^2/2. \quad (38.9)$$

With this equation we can calculate how much the pressure is, if we know the species.

As a very simple example let us take helium gas, or any other gas like mercury vapor, or potassium vapor, at high enough temperature, or argon, in which all the molecules are single atoms, for which we may suppose that there is no collision.

motion in the atom. It has had a complex motion. There might be some internal motion, mixed with others, or something. We suppose that we may disregard this; this is actually a serious matter that we have to come back to, but it turns out to be all right. We suppose that the internal motion of the atoms can be disregarded, and therefore for this purpose that the kinetic energy of the center-of-mass motion is all the energy there is. So for a monoatomic gas, the kinetic energy is the total energy. In fact, if we are going to add up the total energy, it is immediately realized that this internal energy may differ very, since there is no external energy to a gas, i.e., all the energy of all the molecules is the sum of the others, whatever it is.

For a monatomic gas we will suppose that the total energy E is equal to one-half of the average kinetic energy of mV^2 , because without distinguishing any particular of rotation or vibration motions from the others. Then, in these circumstances, we would have

$$PV = \frac{3}{2}E. \quad (39.10)$$

Incidentally, we can stop here and find the answer to the following question. Suppose that we take a can of gas and do nothing; the gas slowly loses much pressure; do we still dissipate the same amount? This is to ask what does the pressure loss of the energy divided by P . As we see now, when we work out the gas and we thereby increase the energy E , we must be willing to have some kind of a differential equation: "If we start in a given circumstance with a certain energy and a certain volume, we then know the pressure." Now we start to suppose, that the important we do, the energy E increases and the volume V decreases, or the pressure goes down.

So, we have to solve a differential equation, and we will solve it in a moment. We don't just emphasize, however, that as we are compressing this gas, we are dissipating that all the work goes into increasing the energy of the atoms inside. We may say, "Isn't that necessary? Where else could it go?" It turns out that it can go another place. There are what we call "heat leaks" through the walls; the heat (i.e., fast-moving) atoms can penetrate the walls, heat the walls, and energy goes away. We shall suppose for the present that this is not the case.

For somewhat more generality, although we are still not in some very special assumptions about our gas, we shall write, for $\delta E = \delta U + \delta T$

$$PV + \delta U = TdV. \quad (39.11)$$

It is exactly $(P - 1) dU + TdV = 0$, conventional results, because we will deal with a few other cases later where the number in front of V will not be $\frac{1}{2}$ but will be a different number. So, in order to do the thing in general, we call it $\gamma = 1$, because people have been calling it that. We already one hundred years ago. This γ , then, is $\frac{1}{2}$, because $\gamma = \frac{1}{2}$ for a monoatomic gas like helium.

We have already noticed that when we compress a gas the work done is PdV . A compression in which there is no heat energy added or removed is called an adiabatic compression, from the Greek α (not) + $\delta\mu\eta$ (through) + $\nu\mu\nu$ (to go). (The word adiabatic is used in physics in several ways, and it is sometimes hard to see what is meant in each theory. That is, for an adiabatic compression all the work done goes into changing the internal energy. That is the essential; there are no other uses of energy.) So, then we have $PdV = -\delta U$. But since $\gamma = PV/\delta U = 1$, we may write

$$\delta U = (PdV - PVdP)/(\gamma - 1). \quad (39.12)$$

So, we have $PdV = (PVdP - \delta U)/(\gamma - 1)$, or, rearranging the terms, $\gamma PdV = -\delta U$.

$$\gamma PdV/PV + \delta U/V^2 = 0. \quad (39.13)$$

Incidentally, assuming that γ is constant, as it is for a monoatomic gas, we can integrate this. It gives $\gamma \ln P - \ln V = C$, where C is the constant of integration. If we take the exponential of both sides, we get two new

$$PV^\gamma = C \text{ (constant).} \quad (39.14)$$

In other words, under adiabatic conditions, where the temperature rises as we compress because no heat is going out, the pressure is proportional to the β power of a constant for a monoatomic gas. Although we derived it theoretically, this β , in fact, is the way monoatomic gases behave experimentally.

24.3 Compressibility of photons

We may give one other example of the kinetic theory of γ gas, one which is not used in everyday science but is useful for science. We take a large number of photons in a box in which the temperature is very high. (The box, of course, is not in a very hot star. The star is not hot enough; these are still too many atoms, but at all higher temperatures in certain very hot stars, we may not use the kinetic model, because the only objects that we have in the box are photons.) Now then, a photon has a certain momentum p . (We always find that we can interpret variables in the kinetic theory; p is the momentum, m is the mass-momentum; v is the velocity, h is the velocity. T is the temperature; but V is the kinetic energy or the time or the energy; sometimes both can't be used nicely. This p is momentum, it's a vector. Going through the same analysis as before, π is the component of the vector p in the direction in which is given in the kick. Thus $\Delta\pi$ indicates Δv , and in evaluating the number of collisions, π is still $\sim \pi_0$ when we get all the way through, as this last term in Eq. (24.11) is listed.

$$\langle \pi \rangle = 2\pi_0 v_0 n. \quad (24.14)$$

Then, in this averaging, we average out the average of $\pi_0 v_0$ (the same factor of β will, finally, pulling in the other two directions, we find

$$PV = Np \cdot v_0^2 / 3. \quad (24.15)$$

This agrees with the formula (24.9), because the number N is now nV ; it is a little more general, that is all. The pressure times the volume is the total number of photons times $(p \cdot v)^2$ averaged.

Now, for photons, what is $p \cdot v$? The momentum and the velocity are in the same direction, and the velocity is the speed of light, so this is the momentum of each of the photons times the speed of light. The momentum times the speed is E , since physics is its energy. $E = pc$, so these terms are the energies of each of the photons, and we should, if we can, take an average energy, times the number of photons. So we have π of the energy, inside the $\langle \rangle$:

$$PV = Nc^2 \langle p c \rangle n \langle pc \rangle \langle pc \rangle \quad (24.16)$$

For photons this gives us zero, in front of $\langle \rangle$ in (24.16); $\langle pc \rangle$, or $\langle \rangle = 0$, and we have discovered that radiation in a box obeys the law:

$$PV^{1/2} = C. \quad (24.17)$$

So we know the compressibility of radiation! That is what "use" is in analysis of the contributions of radiation pressure to a star, but is how we calculate it until there is changes when we compare it. What wonderful things are already within our power!

24.4 Temperature and thermal energy

So far we have not dealt with temperature; we have purposely been avoiding the temperature. As we compare a gas, we know that the square of the momentum increases, and we are not saying that the gas is \propto hotter; we would like to understand whether this is due to the temperature. Is we try to do the experiments, not adiabatically but at what we call constant temperature, whatever it is? We know that two like boxes of gas and the their will move to each other long enough that π at the start they were at what we call different temperatures, they

all at the end come to the same temperature. Now what does this mean? That means that they get to a condition that they would get to if we left the tube long enough. What we mean by this temperature is just that—the final condition when things have been striking each other long enough.

Let us consider now what happens if we have two gases in a container separated by a movable piston as in Fig. 10-2; and for simplicity we shall take two monoatomic gases, say helium and neon. To summarize (by the atoms have mass m_1 , velocity v_1 , and there are n_1 atoms) and others, n_2 is the other containing the atoms have mass m_2 , velocity v_2 , there are n_2 atoms per unit volume. What are the conditions for equilibrium?

Obviously, the bombardment from the left side must be such that it causes the piston to move right and compresses the other gas until its pressure builds up, and the thing will then stand back and forth, and will probably come to rest at a place where the pressures are equal on both sides. So we can assume that the pressures are equal when just atoms from the initial sample get time to escape the piston, in fact the number n times the average kinetic energy on each side are equal. What we have to try to prove, however, is that the average velocities are equal. So first of all we know is that the number times the kinetic energies is equal.

$$n_1 m_1 v_1^2 / 2 = n_2 m_2 v_2^2 / 2,$$

from (10-8), because the pressure is the equal. We must realize that this is not the only equilibrium over the long run, but something else may happen more slowly as the true complete equilibrium corresponding to equal temperatures sets in.

To see the idea, suppose that the pressure on the left side was developed by having a very light piston but a low velocity. By having a very small and a small n we can get a certain pressure by having a small and a large v . Let atoms may be moving slowly but be packed much more closely, or them may believe that they are hitting harder. Will it stay like that? No, I think we might think so, but the two ends swap and find we have forgotten one important point. That is, that the intermediate piston does not receive a steady pressure; it jiggles just like the piston, but we were just talking about it, because the language is not clear of their uniform. There is not a general, steady pressure but a source of the pressure which makes the thing jiggles. Suppose that the atoms on the right side are not jiggling much, but those on the left are fast and far between and very energetic. The piston will, now and then, get a big impulse from the left, and will be driven against the slow atoms on the right, giving them some speed. (As each atom collides with the piston, it either gains or loses energy, depending upon whether the piston is moving one way or the other when the atom strikes it.) As a result of the collisions, the piston finds itself jiggling, jiggling, jiggling, and this shakes the other gas—it gives impetus to the other atoms and they build up faster movement, until they balance the jiggling and the piston is going to them. The system settles to some equilibrium where the piston is moving at a uniform consequent speed that picks up energy from the atoms at about the same rate as it puts energy back into them. So the piston picks up a certain mean, reasonably in speed, and it is our problem to find it. What we do that is, we consider one problem better, because the two will adjust their velocities—just like the rate at which they are taking in power energy is a even other through the piston will become equal.

It is quite difficult to figure out the details of the piston in this particular circumstance, although it is readily simple to understand, it is not so easy to be a little harder to analyze. Before we analyze this, it is another deeper problem to when we have a gas of gas but now we have two different kinds of molecules in it, having masses m_1 and m_2 , velocities v_1 and v_2 , and so forth; there is no a much more intricate calculation. If all of the N_1 molecules, like the scattering off oil, the molecules is not going to last, because they get located by the N_2 molecules and to pick up speed. If they are not jiggling much faster than the N_2 molecules, then maybe that will not last either—they will pass the energy back to the N_2 molecules. So the both gases under the same law. The problem is to find the next and determine the the speed of the two

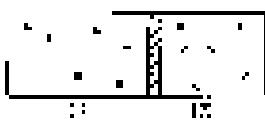

Fig. 39-2. Atoms of two different monoatomic gases are separated by a movable piston.

This is still a very difficult problem, but we will solve it as follows. First we examine the following subproblem: again this is one of those cases where however simple the derivation is, the result is very simple to remember, but the derivation is not. I hope you'll suppose that, at least, two molecules, of different mass, are moving, and that the collision is viewed on the center-of-mass (CM) system. In order to analyze a simplification, we look at the collision in the CM. As we know from the laws of classical mechanics, the conservation of momentum and energy, after the molecules collide, the only way they can move is such that both molecules do not change speed—only they just change their direction. So we have a "circular" collision that looks like that in Fig. 39-1. Suppose, for a moment, that we want to see collisions with the CM at rest. Suppose we're going fast, they are all initially moving horizontally. Of course, at the first collision some of them are moving at an angle. In order words, if they were all going horizontally, then at least some would have to be moving vertically. Now, in such a collision, they would be coming in from another direction, and then they would be forced to still cross the angle. So even if they were randomly organized in the beginning, they would get sprayed around at all angles, and that is why they would be sprayed some more, and sprayed some more, and sprayed some more. Ultimately, what will be the distribution? Answer: it will be equally likely to find any particle moving in any direction in space. After all, since each molecule changes its direction,

They are equally likely to go in $\pi/2$ dimensions, but how do we see this? This is of course an likelihood that they will go at this particular angle; but, because a specific direction is chosen, so we have to talk about *not* "correcting". The fact is that any atom on a sphere centered at a collision point will have many, many molecules going through it as go through any other point on the sphere. So the result of the collisions will be to distribute in directions so that equal areas on a sphere will have equal probability.

Indeed, if we just want to discuss the original dimension and some other direction at angle θ from it, it is clear, intuitively, that the differential area of a sphere of unit radius is $d\Omega = \sin \theta d\theta 2\pi$, and that is the same as the differential of $\cos \theta$. Another reason is that the cosine of the angle between any two directions is equally likely to be anything from -1 to $+1$.

Next, we have to worry about the actual case, where we do not have the collision in the CM system, but we have two atoms which are moving relative with velocities v_1 and v_2 . What happens now? We can analyze this collision with the vector velocities \mathbf{r}_1 and \mathbf{r}_2 in the following way: We can say that there is a certain CM; the velocity of the CM is given by the "average" velocity, which is proportional to the masses, so the velocity of the CM is $v_{CM} = m_1 v_1 + m_2 v_2 / (m_1 + m_2)$. If we have this collision in the CM system, then we have a collision just like that in Fig. 39-1, with a certain relative velocity v equal to $|v|$. The relative velocity is just $v_1 - v_2$. Now consider a real, live CM frame, moving, and in the CM frame v is a relative velocity, v , and the molecule rounds and rounds off in some new direction. All this happens while the CM keeps right on moving without any change.

Now then, what is the distribution resulting from this? From our previous argument we conclude this: for an equilibrating, all directions for v are equally likely, relative to the direction of the motion of the CM.¹ There will be no particular orientation, in the end, between the direction of the motion of the system to the relative velocity, and that is the motion of the CM. Of course, if there were, the collisions would scatter it about, and v is all sprayed around. So the cosine of the angle between v and v_{CM} is zero on the average. That is,

$$\langle \cos \theta_{CM} \rangle = 0. \quad (39-19)$$

¹ This argument, which was not discussed by Maxwell, involves some subtleties. Although he concluded correctly the results does not follow purely from the consideration of symmetry that we used before class, by going to a relative frame moving enough, we may find a different velocity distribution. We can not furnish a simple proof of this result.

But in $\langle \tau_1 \rangle$ we have expressed $\langle v_1^2 \rangle$ in terms of v_1 and v_2 or m_1 :

$$\begin{aligned} \langle v_1^2 \rangle_{\text{ave}} &= \frac{(m_1 v_1) \cdot (v_1 m_1 + m_2 v_2)}{m_1 + m_2} \\ &= \frac{m_1 v_1^2}{m_1 + m_2} + (v_2 - \bar{v}_1) \bar{v}_1 \cdot v_2. \quad (29.20) \end{aligned}$$

Let's go back to $\langle \tau_1 \rangle$ and $\langle \tau_2 \rangle$, what is the average of v_1^2 ? That is, what is the average of the square of velocity of a molecule in the direction of another? Such there is just equal likelihood of finding an atom moving one way or another. The average of the velocities is my definition now. Consider then, is the direction of v_1 , v_2 has zero energy. So, the average of v_1^2 , v_2^2 is zero. Therefore we conclude that the average of v_1^2 must be equal to the average of $m_1 v_1^2$. Then & the average kinetic energy of the molecules must be equal:

$$\langle m_1 v_1^2 \rangle = \langle m_2 v_2^2 \rangle \quad (29.21)$$

If we have two kinds of atoms in a gas, it can be shown, and we probably do have shown it, that the average of the kinetic energy of one is the same as the average of the kinetic energy of the other. When they are both in the same gas so the system has no equilibrium. That means the heavy ones will move slower than the light ones, this is easily shown by experimenting with "atoms" of different masses in air. Crash!

Now we could go on saying "In fact, we say that if we have two different gases separated in a box, they will have equal average kinetic energy when they have finally come to equilibrium & even though they are not in the same box. We can make the argument in a number of ways. One way is to argue that if we have a fixed container w/1. a tiny hole in it (Fig. 29.4) so that one gas could leak out through the holes while the other would not, because the molecules are not big, and I know that in undisturbed equilibrium, the molecules that are free, where they are in fact, they have lower average kinetic energy, but could come through the hole without loss of kinetic energy, so the average kinetic energy in the pure gas and in the mixture must be the same. This is not too satisfactory, because maybe there are no holes, for the kind of selection, the separate one from the other.

So we have to go back to the piston problem. We can make an argument which shows that the kinetic energy of the piston must also be fixed. And also, that would be the kinetic energy due to the pure gas horizontal motion of the piston. So, if you push it up and down motion, it will have to be the sum of $\langle m_1 v_1^2 \rangle$. Likewise, from the equilibrium on the other side, we can prove that the kinetic energy of the piston is $\langle m_2 v_2^2 \rangle$. Although this is not in the middle of the gas, but is on one side of the gas, we can still make the argument, although it is a little more difficult, that the average kinetic energy of the system, and of the gas molecules are equal as a result of all the collisions.

If this still does not satisfy us, you may make an artificial example by which the equilibrium is perturbed by an object which can be hit on all sides. Suppose that you're a short rod with a ball at each end sticking through the piston, or a billiard ball gliding along at your. This ball is much like one of the molecules, and can be hit on all sides. This whole object has a certain total mass, m . Now, we have the piston which has mass m_1 and mass m_2 as before. As a result of the collisions, in the analysis that we made before, is that the kinetic energy of m because of collisions with the molecules on one side, must be kept for the average. Likewise, because of the collisions with molecules on the other side, it has to be $\langle m_2 v_2^2 \rangle$ in the average. So, therefore, both sides have to have the same kinetic energy when they are in thermal equilibrium. So, although we only proved it for a mixture of gases, it is easily extended to the case where there are two different, separate gases at the same temperature, i.e.

Thus when we take the gases at the same temperature, the mean kinetic energy of the CM motion is equal.

The "real" molecular kinetic energy is a property only of the macroscopic gas." Being a property of the "macroscopic," not one of the gas, we can make it as a function of the temperature. The mean kinetic energy of a molecule is thus some

Fig. 29.2 Two gases in a box with a movable piston.

function of the temperature. But we'd like⁷ to what scale to use for the temperature? We may arbitrarily choose K as our temperature +, but the mean energy \bar{E} is linearly proportional to the temperature. The best way to do it would be to call the mean energy itself "the temperature". This would be the simplest possible function. Unfortunately, the scale of temperature has been chosen differently, so instead of calling it temperature directly we use a constant conversion factor between the energy of a molecule and a change of absolute temperature called a *Boltzmann factor*. The constant of proportionality $k = 1.38 \times 10^{-23} \text{ joule}$ (or every degree Kelvin).⁸ So if T is absolute temperature, your definition says that the mean kinetic energy is kT . (The k is put in as a matter of convenience, so as to get rid of it somewhere else.)

We point out that the constant k is only associated with the component of motion in any particular direction, so only $\frac{1}{2}kT$. The other independent directions that are involved divide k by 3.

39.2 The Ideal gas law

Now, of course, we can put this definition of temperature into Eq. (39.9), and so find the law for the pressure of gases as a function of the temperature; it is that the pressure times the volume is equal to the total number of molecules, or the universal constant N_A , times the temperature:

$$PV = N_A kT. \quad (39.10)$$

Put in absolute temperature and pressure and volume, the number of atoms is determined, & this is a universal constant. So equal volumes of different gases, at the same pressure and temperature, have the same number of molecules, because of New ton's laws. That is an amazing conclusion!

In practice, when dealing with molecules, because the numbers are so large, the molecules have uniformly chosen a specific number, a very large number, and called it something else. They have a number which they call a mole. A mole is nearly a Avogadro number. Why they didn't choose 10^4 objects, or it could come out even, is a historical question. They happened to choose, for the convenient number of objects on which they standardize, $N_A = 6.02 \times 10^{23}$ objects, and this is called a mole of objects. So instead of measuring the number of molecules in terms of their mass in grams of molecules, in terms of N , we can write the number of moles, times the number of atoms at a mole, times kT , and if we want to, we can take the number of atoms in a mole times N_A , which is a mole's worth of k , and call it something else, and we do—what we call N . A mole's worth of k is 8.317 joules/K , so $k = N_A k = 8.317 \times 10^{23} \text{ J/K}^{-1}$. That is also just the gas law written as the number of moles (also called N) times N_A , or the number of atoms times kT .

$$PV = NWG \quad (39.11)$$

It is the same thing, just a different scale for measuring numbers. We use N as a unit, and choose the 8×10^{23} as a unit.

We now make one more small adjustment for gases, and that has to do with the law for objects other than monoatomic molecules. We know that only with the 0.02 K motion of the atoms of a monoatomic gas. What happens if there are more atoms? First, consider the case that the atom is like a helical spring, and there are forces on it. The exchange of jiggling motion between atoms will pass on, and momenta does not depend on where the system is at that instant, of course. The equilibrium conditions are the same. No matter where the position is, if a speed of motion comes to a gas fast at some energy, all the molecules will use

⁷ The analogous scale is just $\frac{1}{2}k$ Kelvin scale with a zero chosen at 273.16 K , or $T = 273.16 \text{ J/mole/K}$ temperature.

⁸ What the average ball molecule weighs is the mass in grams of a mole of a molecule. The molecular mass of that is N_A times the mass of one mole of isotopes 12 C , 16 O , 14 N , 17 F , and 18 Ne , so is the nuclear weight of 12 protons.

the right way. So it makes no difference about the timing. The speed at which the piston has to move in the average, is the same. Second theorem, that the center of mass of the entire energy - one direction is $\langle v \rangle$, it does whatever there are forces present or not.

Consider, for example, a diatomic molecule composed of atoms m_1 and m_2 . What we have proved is that the motion of the CM of part A and part B are not the same, $v_{CM} = \langle v \rangle$ and $v_{A,B} = \langle v \rangle T$. How can this be? It may seem odd (although they are held together, what they are spending and forcing in the air when something hits them, exchanging energy with them, the only thing that comes is how fast they are moving). That alone determines how fast they exchange energy in collisions. At the molecular level, the force is not an excentric point. Therefore the same principle is right, even when there are forces.

Let's prove, finally, that the gas law is consistent also with a disregard of the individual masses. We did not really include the internal motions before, we just treated a macromolecule as gas. We want now show that an entire object, consisting of a single body of total mass M , has a velocity of the CM such that

$$\text{Addition: } \langle v \rangle = \frac{\langle v \rangle}{M} M. \quad (4.3.1)$$

In other words, we can consider either the separate pieces or the whole thing. Let us see the reason for that. The mass of the electrons added is $m_1 + m_2 + \dots$, and the velocity of the total mass is equal to $\langle v \rangle = (m_1 + m_2 + \dots) \langle v \rangle / M$. Now we need $\langle v \rangle^2$. If we square both, we get

$$\langle v \rangle^2 = \langle v_1^2 \rangle + 2m_1 \frac{(v_1 - \langle v \rangle)^2}{M^2} + m_2 \frac{(v_2 - \langle v \rangle)^2}{M^2} + \dots$$

Now we multiply M and take the average and thus we get

$$\begin{aligned} \langle M v \rangle^2 &= \frac{\langle (M \langle v \rangle + 2m_1(M \langle v \rangle - \langle v \rangle) + m_2(M \langle v \rangle - \langle v \rangle) + \dots)^2 \rangle}{M} \\ &= \frac{3\langle v \rangle^2 + 2M \langle v \rangle (M \langle v \rangle - \langle v \rangle)}{M} \end{aligned}$$

(We have used the fact that $\langle v_1 \rangle + \langle v_2 \rangle + \dots = \langle v \rangle$). Now what is $\langle v_1 \rangle + \langle v_2 \rangle + \dots$? (It is the kinetic energy). To end out, we can for example, that the relative velocity, $v = v_1 - \langle v \rangle$, is not always likely to go in one direction than in another, but its average component in any direction is zero. This we assume then

$$\langle v_1 - \langle v \rangle \rangle = 0$$

But what is $\langle v_1^2 \rangle$? It is

$$\begin{aligned} \langle v_1^2 \rangle &= \frac{\langle (v_1 - \langle v \rangle)^2 + 2m_1(v_1 - \langle v \rangle)^2 + m_2(v_1 - \langle v \rangle)^2 + \dots \rangle}{M} \\ &= \frac{m_1^2 + (m_1 - M)(M - \langle v \rangle)^2 + m_2^2}{M^2} \end{aligned}$$

Therefore, since $\langle m_i v_i^2 \rangle = \langle m_i v_i \rangle^2$, we do not have to add up all the averages, and we are left with

$$(m_1 - M)(M - \langle v \rangle) = 0.$$

Therefore, if $m_1 = M$, we find that $(M - \langle v \rangle) = 0$ and therefore that the healthy motion of the entire molecule - regarded as a single particle of mass M , has a known average velocity, equal to $\langle v \rangle$.

Incidentally, we have also proved at the same time that the average kinetic energy of the separate motions of the atoms is exactly the same as regarding the healthy motion of the CM is $\langle v \rangle^2$. For, the total kinetic energy of the two molecules is $2m_1 \langle v \rangle^2 + 2m_2 \langle v \rangle^2$, where average is $2\langle v \rangle = \langle v \rangle T$, to be precise because of the center of mass motion is $\langle v \rangle$, so the average kinetic energy of the remaining and everything else from the two atoms inside molecule is $2\langle v \rangle^2 = \langle v \rangle^2 T$.

In classical mechanics, the average energy of the CM motion is *constant*, for any initial condition as a whole, with forces present or not. For every independent direction of motion that there is, the average kinetic energy in that motion is $\frac{1}{2}kT$. These "independent directions of motion" are sometimes called the degrees of freedom of the system. The number of degrees of freedom of a molecule composed of n atoms is $3n$, since each atom needs three coordinates to define its position. The entire kinetic energy of the molecule can be expressed either as the sum of the kinetic energies of the separate atoms, or as the sum of the kinetic energy of the CM motion plus the kinetic energy of the internal motions. The latter case can also be expressed as a sum of two terms, kinetic and $\frac{1}{2}kT$, of the molecular and vibrational energy. In this is an approximation. Our theory, applied to the n -atom molecule, says that the molecule will have, on the average $3nT/2$ units of kinetic energy, of which $3kT/2$ is kinetic energy of the center-of-mass motion of the entire molecule, and the rest, $(3n - 3)kT/2$, is *vibrational and rotational kinetic energy*.

The Principles of Statistical Mechanics

40-1 The exponential atmosphere

We have discussed some of the properties of large numbers of interacting atoms. The subject is now kinetic theory, a description of matter from the point of view of collisions between the atoms. It will turn out, we see, that the macroscopic properties of matter should be explainable in terms of the motion of its parts.

We limit ourselves for the present to conditions of thermal equilibrium, that is, to a subsection of all the phenomena of nature. The laws of mechanics, which apply just in the real equilibrium, called statistical mechanics, and in this section we shall be because acquainted with some of the central features of the subject.

We already have one of the theorems of statistical mechanics, namely, the mean value of the kinetic energy for any system at the absolute temperature T is $\frac{1}{2}kT$ for each independent particle, i.e., for each degree of freedom. That tells us something about the mean square velocities of the atoms. Our objective now is to learn more about the positions of the atoms, to discover how many of them are going to be in different places at thermal equilibrium, and also to go into a little more detail on the distribution of the velocities. Although we know the mean square velocity, we do not know how to answer a question such as how many of them are going three times faster than the mean square, or how many of them are going one-quarter of the mean mean-square speed. Or how they all the same speed exactly!

So, these are the two questions that we shall try to answer; how are the molecules distributed in space when the atoms begin hitting at them, and how are they distributed in velocity?

If there is no force, our questions are completely independent, and that the distribution of velocities is always the same. We already carried a hint of the latter fact when we found that the average kinetic energy is the same $\frac{1}{2}kT$ per degree of freedom, no matter what form it takes, in the molecules. The distribution of the velocities of the molecules is independent of the forces, because the collision rate does not depend upon the forces.

Let's begin with an example—the distribution of the molecules in an atmosphere like our own, but without air winds and other kinds of disturbance. Suppose that we have a column of gas extending to a great height, and at the top is equilibrium, unlike our atmosphere, which as we know gets colder as we go up. We could expect that if the temperature varied at different heights, we could demonstrate lack of equilibrium by connecting a red to some blue at the bottom (Fig. 40-1) where they would pick up ΔT from the molecules there and would shake, via the red, the blue at the top and those would shake the molecules in the way. But, obviously, of course, the temperature becomes the same at all heights in a gravitational field.

If the temperature is the same at all heights, the problem is to determine by what law the atmosphere becomes thinner as we go up. If N is the total number of molecules in a volume V of gas at pressure P , then we know $PV = NkT$, or $P = nk$, where $n = NV$ is the number of molecules per unit volume. In other words, if we ignore the number of molecules per unit volume, we know the pressure, and vice versa, they are proportional to each other, since the temperature is constant in this problem. But the pressure is not constant, it must increase as the altitude is reduced, because it has to hold up its weight, the weight of all the gas above it. That is the clue by which we may determine how the pressure changes with height. If we take a small area dA at height h , then the vertical force from below

so the unit area, is the pressure P . The vertical component of force pointing down at a height $+ \Delta h$ would be less than in the absence of gravity, but here it is not because the force there is less than zero; the force from above has the weight of gas in proportion between Δh and $\Delta h + \Delta h$. Now $\rho g = m/n$ is of gravity on each molecule, where g is the acceleration due to gravity, and m/n is the total mass of molecules in the unit section. So this gives us the differential equation $P_{\Delta h} - P_{\Delta h + \Delta h} = \rho g \Delta h$ — maybe! Since $P = nkT$, and T is constant, we can eliminate either P or n , say P , and get

$$\frac{dP}{dh} = -\frac{\rho g}{n}$$

or the differential equation, which tells us how the density goes. Given this we go up to energy.

We thus have an equation for the partial density n , which varies with height, h , which has a derivative which is proportional to itself. Now a function which has a derivative proportional to itself is an exponential, and the solution of the differential equation is

$$n = n_0 e^{-\rho g h / n} \quad (40.1)$$

Here the constant of integration, n_0 , is the density at $h = 0$, which can be chosen anywhere, and the density goes down exponentially with height.

Note that if we have different kinds of molecules with different masses, they go down with different exponents. The ones which we breathe would decrease with z faster than the light ones. Therefore we would expect that because oxygen is heavier than nitrogen, it would be higher and higher to an atmosphere with nitrogen, and when the proportion of nitrogen would increase. This does not really happen in our own atmosphere, at least at reasonable heights, because there is no such separator which mixes the gases back together again. It is not an insurmountable barrier, however; there is a limit to the height of air currents like cyclones. A derivative is very great heights in the atmosphere is because the index masses continue to mix, while the other exponentials have all died out (Fig. 40.2).

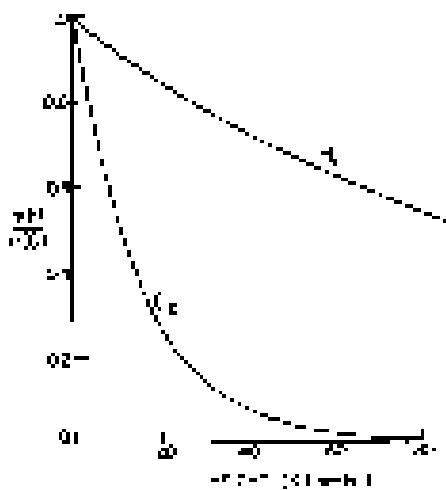

Fig. 40.2. The normalized density n/n_0 versus height z in the earth's gravitational field for oxygen and for nitrogen at constant temperature.

40-2 The Boltzmann law

Here we note the interesting fact that the connection is the exponent of P_0 , exactly in the previous example of expansion. Therefore we can deduce this particular answer: the density n any point is proportional to

$$e^{-\text{constant} \cdot \text{energy of molecule}}$$

This may be an accident, i.e., may be true only for this particular case of a uniform gravitational field. However, we can show that it is a more general proportion. Suppose that there were some kind of force which the molecule feels on the molecules in a gas. For example, the electrons may be charged electrons only, and may be caused to be an electric field or another charge that attracts them. Or, because of the mutual interaction of the atoms for some reason, or for the wall, or for a solid, or something, there is some force of attraction which varies with position x , which acts on all the molecules. Now suppose, for simplicity, that the molecules are all the same, and that the force acts on each molecule i in such a way that the total force on a piece of gas would be simply the difference between the charges on those molecules. To avoid unnecessary complication, let us choose a coordinate system with the x -axis in the direction of the force. In

In the same manner as before, if we take a small Δx distance the i -th molecule moves by a distance dx , then the force on i due from j times the volume per unit Δx is a generalization of the previous single times dx , must be denoted by the previous change, $F_{ij} dx = \partial P = \partial P/dx$. Or, to put the box in a form which will be useful to us later

$$F_i = -\partial \frac{\partial P}{\partial x} \text{ (inert)} \quad (40.2)$$

For the present, however, let us take the work we would do in skin your work from $x = 0$ to $x = \infty$, and if it comes from a potential, i.e., if the work done can be represented by a potential energy at x_0 , then this would be the difference of the potential energy (P.E.). The negative differential of potential energy is the work done, δA_x , and we find that $A_x = -\delta P.E./\delta x$. We also recognize,

$$A_x = \frac{1}{kT} e^{-E_x/kT} \exp(-E_x/kT). \quad (40.2)$$

Therefore what we called to a specific case may well be true in general. When this does not come from a potential, then (40.2) has no solution at $x = \infty$. Energy can be generated, as well as consumed, in small intervals of position for which the work done is not zero, and the equilibrium can be maintained at x^* . Thermal equilibrium cannot exist if the external forces on the atoms are non-conservative! Equation (40.2), known as Boltzmann's law, is another of the principles of statistical mechanics. Let the probability of finding molecules in a given "specific" arrangement varies exponentially with the negative of the potential energy of that arrangement divided by kT .

Now, how much will the distribution of molecules change? Suppose that we had a probability p in a given, interacting system where each atom, how many of them would have off-set distances? If the potential energy is known, we can calculate, then the proportion of them at different distances is given by this law, and so on through many applications.

40-3 Evaporation of a Liquid

In more developed statistical models we are likely to solve the following important problem. Consider an assembly of molecules which scatter each other, and suppose that the force between any two, say i and j , depends only on their separation r_{ij} , and can be represented as the derivative of a potential function $P(r_{ij})$. Figure 40-3 shows a form such a function might have. For $r > r_0$, the energy decreases as the molecules come together, because they attract, and then the energy increases very sharply as they come still closer together, because they repel at short range, which is characteristic of the very molecules behave, roughly speaking.

Now suppose we have a whole collection of such molecules and we would like to know how they arrange themselves on the average. The answer is $e^{-E_x/kT}$. The total potential energy E_x is obviously the sum over all pairs of atoms, plus, that the forces are all in pairs (there may be three-body forces in more complicated things like electricity, for example, the potential energy is \propto $1/r^2$). Then the probability for having molecule in any particular combination of r_{ij} 's will be proportional to:

$$e^{-\frac{1}{kT} \sum_i P(r_{ij})/kT_j}$$

Now, if the temperature is very high, so that $kT \gg E_x$ [Fig. 40-3], the exponent is relatively small, being everywhere and the probability of having a molecule at some fixed position. Let us now, however, take two molecules far apart, $r_{ij} \gg r_0$; then $P(r_{ij})$ would be the probability of finding them at extreme mutual distances r . Clearly, when the potential goes most toward zero, the probability is largest, and when the potential goes toward infinity, the probability is almost zero, which occurs for very small distances. This means that for molecules in a gas, there is no chance that they are on top of each other, since they repel so strongly. And here it goes without saying that, along them far apart, there are no points, the r , at any other point. Now, more pointed, again, on the temperature. If the temperature is not large compared with the difference in energy between $r = r_0$ and $r = \infty$, the exponent is always one by unity. In the case, when the mean kinetic energy is about kT , greater than the potential energy, the boxes do not make much difference. But as the temperature falls, the probability of finding the atoms too far apart (at distance r) gradually increases relative to the probability of finding them close together and, in fact, if kT is much less than $-P(r_0)$, we have a relatively

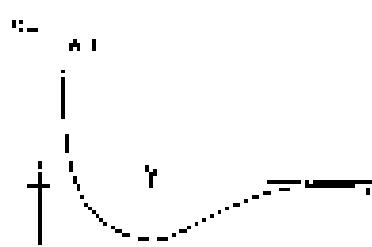

Fig. 40-3. A potential-energy function for two molecules, which depends only on their separation.

large positive exponent at the neighbor level. Furthermore, in a given volume they are much more likely to be at the distance of minimum energy than far apart. As the temperature falls, the atoms fall together, closer in liquids, and nearer to liquids, and solids, and molecules until you heat them up they evaporate.

The experiments for the determination of exactly how things evaporate, exactly how things should happen in a given circumstance involving the following law, to describe the correct nucleation-form: law $\propto e^{-\frac{E}{kT}}$ which does come from something else quantum mechanics, say, or experiment. But given the law of force by most the molecules, to discover what a billion molecules are going to do necessarily consists of studying the function $e^{-\frac{E}{kT}}$ surprisingly enough since it is such a simple function and with an easy idea, given the potential, to have it numerically computed; the difficulty is the huge number of variables.

In short, it's difficult to be subject to quite exciting and interesting. It is often called an example of a "many-body problem," and it really is an extremely interesting thing. In that single formula one has contained all the details, the example, about the solidification of gas, or the form of the crystals that the solid can take, and people have been trying to squeeze it out, but the mathematical difficulties are very great, not in writing the law, but in dealing with so enormous a number of variables.

Then there is the distribution of particles in space. That is the end of classical statistical mechanics, practically speaking because if we know the forces, we can, in principle, find the distribution in space, and the distribution of velocities is something that we can work out, more or less, and is not something that is different for the different cases. The given problems are to get the particular information out of our formal solution, and that is the main subject of classical statistical mechanics.

40-4. The distribution of molecular speeds

Now we go on to discuss the distribution of velocities, because sometimes it is interesting or useful to know how many of them are moving at different speeds in order to do this, we may make use of the fact which we discussed with respect to the gas in the triangle. We took it to be a perfect gas, as we have already assumed it, writing the potential, energy, dissolving the energy, "inside" distribution of the atoms. The only potential energy that we included in our first example was gravity. We would, of course, have something more complicated if there were forces between the atoms. Then we assume that there are no forces between the atoms and, for a moment, disregard collisions also, returning later to the justification of this. Now we saw that there are fewer molecules at the height than there are at the height 0 , according to formula (40.1), they decrease exponentially with height. How can there be fewer at greater heights? After all, consider the molecules which are moving up at height 0 with a v of 0 ft./sec. Because some of these which are moving up at 0 are going too slowly, and cannot climb the potential hill up. Well, therefore, we can calculate how many must be moving at various speeds, because from (40.1) we know how many are moving with low enough speed to climb given distances. These are just the ones that occur for the fact that the height at h is lower than at 0 .

Now let us put that idea a little more precisely. In a room, how many molecules are passing down below to cross the plane $v = 0$ (by calling it height $= 0$, we do not mean that there is a floor there; it is just a convenience), and there is gravitational field. These are molecules not moving around in every direction, but some of them are moving through the room, and at any instant a certain number per second of them are passing through the plane "from below" above with different velocities. Now we note the following: if we call v the velocity which is just needed to get up to the height h (kinetic energy $m v^2/2 = mgh$), then the number of molecules per second which are passing upward through the lower plane in a vertical direction with velocity component greater than v is exactly the same as the number which pass through the upper plane with low v of velocity. These molecules whose vertical velocity does not exceed v cannot get through the upper plane.

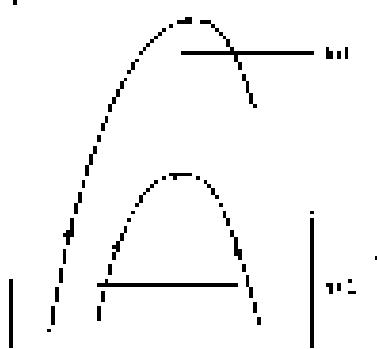

Fig. 40-4. Only those molecules moving up at h with sufficient velocity can cross at height 0 .

where we find that

$$\text{Number passing } h = \text{constant} \cdot v > v - \text{number passing } h = \text{constant} \cdot v > h.$$

But the number which pass through h with any velocity greater than h is less than the number which pass through any lower height with any velocity greater than h , because the number of atoms is greater, *except at the top*. We know already that the distribution of velocities is the same after the argument we made earlier, the temperature being constant all the way through the gas molecule. So since the velocity distributions are the same, *i.e.* v is just that there are more atoms having, clearly the number of atoms passing with positive velocity v height h over the number passing passing with positive velocity v height 0 are in the same ratio as the densities of the two heights which is constant. If $\rho_{\text{gas}}(h) = \rho_{\text{gas}}(0)$ and therefore we find that

$$\frac{\rho_{\text{gas}}(h)}{\rho_{\text{gas}}(0)} = e^{-\frac{mv^2}{2kT}} = e^{-\frac{m(v-h)^2}{2kT}},$$

since $h < v$ right. Thus in words, the number of molecules per unit area per second passing the height h with a component of velocity greater than h is *exactly* $e^{-\frac{m(v-h)^2}{2kT}}$ times the total number passing through the plane with velocities greater than zero.

Now this is not only true at the initial $h=0$ chosen height h , but of course it is true at any other height h , and thus the distributions of velocities are *all* the same. The final statement does not involve the height h , which appeared only in the intermediate argument. The total *one-particle* proportion that goes over the distribution of velocities. It tells us that if we drill a little hole at the side of a gas pipe, a very tiny hole, so that the exit ports are permanent for bacteria, *i.e.* are *farther* apart than the diameter of the tube, then the particles which are coming out will have *different* velocities, but the fraction of $v>h$ molecules which come out is *exactly* greater than $e^{-\frac{m(v-h)^2}{2kT}}$.

Now we return to the question about the reflection coefficient. Why does it not make any difference? We could have pursued the same argument, now with a finite height h , but with an infinite initial height h , where is so small that there would no longer be v values between them? h ? But that was not necessary, the $v>h$ term is evidently *exact* in an analysis of the energies involved, the conservation of energy, and at the collisions that occur there is an exchange of energies between the molecules. However, we do *not* really *know* whether the following statement makes sense: energy is entirely exchanged with another molecule. But it is *extremely* hard if the collision is *inelastic* irreversibly, and it is more difficult than ρ_{gas} , to do a rigorous job, and it makes no difference in the result.

It is interesting that the velocity distribution we have found is per

$$n_{\text{gas}} = \rho_{\text{gas}}^{1/2} m^{1/2} e^{-mv^2/2kT}. \quad (40.4)$$

For very often they the distribution of velocities, by giving the number of molecules that pass a given area with a certain maximum component, is not the most convenient way of giving the velocity distribution. For instance, inside the gas, one often wants to know how many molecules are moving with a component of velocity between two given values, and that of course, is not directly given by Eq. (40.4). We would like to state our result in the more convenient form, even though what we already have written is quite general. State that it is not possible to say with any moderate law exactly how many velocity components of v has a velocity exactly equal to v , 795289/73 meters per second. But if one wants to be a meaningful statement, we have to ask how many are to be found in some range of velocities. We have to say how many v 's exist between v , 795289/73, and $v+dv$. Or, *another* way to ask it is to be the fraction of all the molecules which have velocities between v and $v+dv$, *i.e.* what is the corresponding if this is calculated, all that have a velocity in that range dv . Figure 40-3 shows a graph for the function ρ_{gas} , and the shaded part, of width dv of v , which height ρ_{gas} , represents this fraction $\rho_{\text{gas}}(v) dv$. That is, the ratio of the central

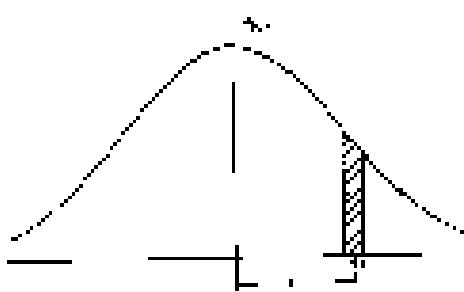

Fig. 40-3. A velocity distribution function. The shaded area is $\rho_{\text{gas}}(v) dv$, the fraction of particles having velocities within a range dv .

area to the total area of the curve is the relative proportion of molecules with velocity v within dv . If we define $f(v)$ as the fraction having a velocity in this range, it is given directly by the shaded area, that is, the total area must be 100 percent of room, that is,

$$\int_{-\infty}^{\infty} f(v) dv = 1. \quad (40.4)$$

Now we have only to get this distribution, by comparing it with the fluxes we derived before. First we set what is not the flux of molecules passing through an area per second with a velocity greater than v , expressed in terms of flux. At first we might think it is merely the integral of $\int_v^{\infty} f(v) dv$, but it is not because we might not have lost the passing flux in just v . The latter case may occur often, we know, than the above case, and in order to compare both fluxes, you have to multiply by the velocity. (We discussed this in the previous chapter when we talked about the number of collisions.) In a given time the total number which pass through the v flux is $\frac{1}{2} v$ of those which have been able to rise in the stream, and this number will then be given from a calculation of the number of molecules which arrive at exactly the number which pass here. But the numbers are there per unit volume, multiplied by the distance that they sweep through in rising for the time through which they are supposed to go, and that distance is proportional to v . It is evident the integral of a curve $f(v) dv$, an infinite integral with a lower limit v , and this must be the same as we found before, namely $e^{-\frac{mv^2}{2kT}}$, with a proportionality constant which we "fix" as follows:

$$\int_v^{\infty} v f(v) dv = \text{constant} e^{-\frac{mv^2}{2kT}}. \quad (40.5)$$

Now if we differentiate the integral with respect to v , we see the thing just is inside the integral, i.e., the integral (with a definite upper limit) is zero, and if we differentiate the other side, we get v times the same exponential (and some constants). This is canceled and we find

$$f(v) dv = C e^{-\frac{mv^2}{2kT}} dv. \quad (40.6)$$

We make the air or heat value as a standard that it is a probability, and this is what the proportion is that velocity between v and $v + dv$.

The constant C must be so determined that the integral is unity, according to Eq. (40.4). Now we can prove that

$$\int_0^{\infty} e^{-\frac{mv^2}{2kT}} dv = \sqrt{\pi}.$$

Using this fact, it is easy to find that $C = \sqrt{\pi/(2m k T)}$.

Since velocity and momentum are proportional, we may say that the distribution of molecules is also proportional to $e^{-\frac{p^2}{2mkT}}$ per unit momentum range p . It is noted that this relation is more or less relative now, if it is in terms of momentum, while it is in velocity it is not, so it is best to keep momentum instead of velocity:

$$dP/dp = C e^{-\frac{p^2}{2mkT}} dp. \quad (40.7)$$

So we find that the probability is of different conditions of energy, kinetic and potential, are both given by $e^{-\frac{E}{2mkT}}$, a very easy thing to remember and a rather beautiful proportion.

* The general value of the integral is:

$$\int_{-\infty}^{\infty} e^{-\frac{p^2}{2mkT}} dp = \text{constant}$$

$$= \sqrt{\pi} \cdot \int_{-\infty}^{\infty} e^{-x^2} dx = \int_{-\infty}^{\infty} e^{-x^2} dx = \sqrt{\pi},$$

which is a double integral over the whole xy plane. But the condition of solution is polar coordinates $r\theta$:

$$P = \int_0^{\infty} r e^{-\frac{r^2}{2mkT}} dr = \pi \int_0^{\infty} r e^{-r^2/2} dr = \pi$$

So far we have, of course, only the distribution of the velocities "vertically." We might want to ask, what is the probability that a molecule is moving in a given direction? Of course if we do this for all directions, and one can obtain the complete distribution from the one we have, because the complete distribution depends only on the square of the magnitude of the velocity, not upon the component. It must be something that is independent of direction, and there is only one function involved, the probability of different orientations. We have the distribution of the components, and therefore we can get the distribution of the other components from it. The result is then the probability is still proportional to $e^{-\frac{1}{2}kT\cos^2\theta}$, but now the kinetic energy involved there is $\frac{1}{2}m(\dot{x}_1^2 + \dot{x}_2^2 + \dot{x}_3^2)$, summed in the expression. So we can write it as a product:

$$f(x_1, x_2, x_3, \dot{x}_1, \dot{x}_2, \dot{x}_3)$$

$$= e^{-\frac{1}{2}kT} \cdot e^{-\frac{1}{2}\dot{x}_1^2/kT} \cdot e^{-\frac{1}{2}\dot{x}_2^2/kT} \cdot e^{-\frac{1}{2}\dot{x}_3^2/kT} \quad (40.3)$$

You can see that the formula must be right because, first it is a function only of T , as required, and secondly the probabilities of various values of x_i are given by integrating over all \dot{x}_j and x_j is just (10^{-3}) . But the x_i function (10.9) can do both these things.

40-5 The specific heats of gases

Now we shall look at some ways to test the theory, and to see how useful is the classical theory of gases. We expect that, if E is the internal energy of N molecules, then $PK = NkT = E/N = \frac{1}{2}N$ holds, since as we saw before, maybe, if it is a monoatomic gas, we know this is also true. In a diatomic molecule, if the vector of mean motion of the atoms T is independent of mass, then the kinetic energy is equal to the potential energy, and therefore $T = \frac{1}{2}E$. But suppose it is, say, a monoatomic molecule made of one spin zero atom, and it's a simple system (turns out to be the according to classical mechanics) that the energies of the internal vibrations are also proportional to kT . Then at a given temperature, in addition to kinetic energy ET , it has thermal vibrational or rotational energy. So the total E includes not just the internal kinetic energy, but also the rotational energy, and we get a different value of T . Let's do γ , the best way to measure γ is by measuring the specific heat, which is the change in energy with temperature. We'll return to γ later. For our present purposes, we may suppose γ is found experimentally from the E/T curve for different temperatures.

Let us make a table of γ for some cases. First, for a monoatomic gas N is the total energy, the sum of the kinetic energy, and we know already that right. If it's a diatomic gas, we may take, as an example, oxygen, by adding double, hydrogen, etc., and suppose that the diatomic gas can be approximated as two atoms held together by some kind of force, as in one of Fig. 40-1. We may also suppose, and it seems to be quite true, that all the energies of γ that are of interest for the diatomic gas, are pairs of terms that add linearly to the total energy γ_1 , the distance of potential minimum. If this were not true, if the probability were not strongly varying enough to make the potential energy tilt from the bottom, we would have to remember that oxygen, for instance, is a pure single oxygen along in a 2:1 ratio. We know that these are, in fact, very few single oxygen atoms. This means that the potential energy minimum is very much greater in magnitude than kT , as we have seen. Since they are all held so strongly around r_0 , the only form of vibration that is excited is the one near the minimum, which must be approximated by a parabola. A parabolic potential implies a γ that is usually positive. In fact, to an excellent approximation, the oxygen molecule can be represented as two atoms connected by a spring.

Now γ is the total energy per mole divided at temperature T . We know that for each of the two atoms, each of the kinetic energies should be $\frac{3}{2}kT$, so the kinetic energy of both of them is $\frac{3}{2}NkT = \frac{3}{2}kT$. We can also put γ in a different way; the so-called γ' can also be looked at as $\text{internal energy}/\text{decrease in temp}$

Table 40-1

Values of the quantum level ratio, γ ,
for various gases

Gas	T (K)	γ
He	-140	1.661
Si	19	1.68
Ar	15	1.688
H ₂	100	1.706
O ₂	100	1.709
III	100	1.70
Br ₂	300	1.72
I ₂	385	1.73
NH ₃	71	1.77
C ₂ H ₆	15	1.77

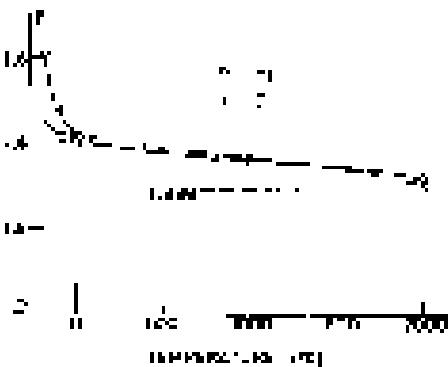

Fig. 40-6 Experimental values of $1/\gamma$ as a function of temperature for hydrogen and oxygen. Classical theory predicts $1/\gamma = 1.726$, independent of temperature.

(6), kinetic energy of rotation (5), and zeroth-order of vibration (3). We know that the kinetic energy of vibration is 0, since there is no displacement involved other than degrees of freedom for θ . Regarding the rotation, it can be a silent player or two seats, so there are two independent choices. We assume that the silent ones are some kind of pairs, and cannot spin around the joining atom, this is something we have in mind, however if we get a disagreement, maybe that is where the trouble is. But we have one more thing, which is the quantum energy of vibration; how much is that? In a diatomic oscillator the average kinetic energy and the zero-point energy are equal, and therefore the total total energy of vibration is $\hbar\omega_0$, also. The ground total of energy is $\hbar\omega_0 + \frac{1}{2}\hbar\omega_0$, or $\hbar\omega_0$ is 20% per atom. That means that $\hbar\omega_0/2$ is below $\hbar\omega_0/6$, i.e., 1.226.

We may compare these numbers with the relevant mean of values shown in Table 40-1. Looking first at helium, which is a monatomic gas, we find very nicely $\hat{\gamma} = 1.661$, and the value reported by experimentalists at such low temperatures may be some forces between the atoms. Hydrogen and neon, both monatomic, agree also within the accuracy of the experiment.

We turn to the diatomic gases and find hydrogen with 1.706, which does not agree with the theory, 1.726. Oxygen, 1.709, is very similar, but again not in agreement. Hydrogen sulfide again is similar at 1.70. Hydrogen to look at enough the right answer is 1.70, but it is not because they took hundred of measurements, we see 1.70, since 2.30 is reasonably close to 1.70, nothing may be said to agree with us, but oxygen is off. So here we have a dilemma. We know it right for one molecule, we do not have it right for another molecule, and we may need to be really ingenious in order to explain how.

Let us look further at a more complex diatomic molecule with three numbers of particles, for example, C₂H₆, which is ethane. It has eight atoms, and they are all rotating and translating in various combinations. The total amount of internal energy must be an even-integer number of \hbar^2 's, at least 12.5% the kinetic energy alone, and $\gamma = 1$ must be very close to zero, or 2 almost every time. If it is lower, but 1.22 is much lower, and is higher than the 1.70 calculated from the kinetic energy alone, and it is just understandable.

Furthermore, this whole system is deep, because the distance and orientation between rigidly coupled atoms make the coupling weaker increasingly, although it might not vibrate much, or would nevertheless keep vibrating. The vibrational energy inside is still $\hbar\omega$, since it does not depend on the strength k of the coupling. But, if we want to give absolute rigidity, erasing all vibrational $\hbar\omega$'s, eliminate a variable, then we would get $\gamma = 2.37$ and $\gamma = 1.66$ for the diatomic case. This looks good for H₂ & O₂. On the other hand, we would still have problems because γ is off the hydrogen or oxygen series with temperature. From the measured values shown in Fig. 40-6, we see that for H₂, γ varies from about 1.8 at -165°C to 1.3 at 200°C. The variation is more substantial in the case of hydrogen than for oxygen, but nevertheless, even in oxygen, γ tends definitely to drop as we go down in temperature.

40-4 The failure of classical physics

So, in all, we realize now that we have some difficulty. We might try some force law other than a spring, but I think that anything else will only make γ higher. If we include more forms of energy, i.e. appreciates only more closely, surrounding the atom. All the classical theoretical things that we can think of will only increase γ . That is to say, there are obstacles in each atom, and we know from their theory that there are internal vibrations; each of the electrons should leave at least 40% of kinetic energy, e.g. in falling for the potential energy, so when these are added in, γ gets off further. It is probably, it is probable.

The big open paper on the dynamics theory of gases was by Maxwell in 1861. One the basis of ideas we have been discussing, he was able accurately to explain a great many known relations, such as Boyle's law, the diffusion theory, the viscosity of gases, and things we shall talk about in the next chapter. He listed all these great successes in a final summary, and at the end he said, "Finally, in 45-1

establishing a necessary relation between the motions of molecules and rotation (he's talking about the $\frac{1}{2}kT$ theorem): if all particles did spherical, we would then have a system of such systems would not precisely satisfy the known relation between the two sp. like heats." He is referring to r (which we've discussed) is due to two ways of measuring specific heat, and he says we know we cannot get the right answer.

Two years later, in a lecture, he said, "I now know well what you asked. I consider it to be the greatest difficulty not surmounted by the molecular theory." These words represent the first discovery that the laws of classical physics were wrong. This was the first indication that there was something fundamentally impossible, because a rigorously general theorem did not agree with experiment. After 1900, Debye was to talk about the previous year. On another level, he said that physicists at the latter part of the nineteenth century thought they knew all the significant physical laws, and that all they had to do was to calculate more decimal places. Some time must have told them that was not so. But a thorough reading of the literature of the time shows they were ... worrying about something that's said above this paper ... but it is a very mysterious concern, and it seems to bring us to the conclusion that certain kinds of motions "frozen out."

If we could assume that the vibrational velocity, did not exist at low temperature and did exist at high temperature, then we might imagine that a gas might exist at a temperature sufficiently low that vibrations continue to be important, say $T = 1.40$, or a higher temperature, at which they begin to cease. In so far, this same might be argued for the rotation. If we can eliminate the rotation, say it "freezes out" at sufficiently low temperature, then we can understand the fact that there is hydrogen appearance. It goes on going down in temperature. Here one sees problems of such a phenomenon. Of course that mass motion "frozen out" cannot be understood by classical mechanics. It was only understood when quantum mechanics was discovered.

Without proof, we may state the results of quantum mechanics of the quantum mechanical theory. We recall that according to quantum mechanics, a system which is bound by a potential, for vibrations, for one atom, will have a discrete set of energy levels, i.e. states of definite energy. Now in quantum mechanics, statistical mechanics is no modified according to quantum-mechanical theory. But it is not, it is amazingly strong, nor although most problems are indeed difficult in quantum mechanics, less in classical mechanics, problems in quantum mechanics are much easier in quantum theory. The simple case we have in classical mechanics, that a $\text{e}^{-E/kT}$, becomes the following very important theorem. If the energies of interest of individual states are listed, say, E_1, E_2, E_3, \dots , the probability in thermal equilibrium, the probability of finding a molecule in the particular state of having energy E_i , is proportional to $e^{-E_i/kT}$. That gives the probability of being in various states. In other words, the relative chance, the probability, of being in state E_i , relative to the chance of being in state E_j , is

$$\frac{P_i}{P_j} = e^{\frac{-E_i/kT}{-E_j/kT}} \quad (40.10)$$

at kT , of course, is the same as

$$P_i = n_p e^{(E_i - E_p)/kT}, \quad (40.11)$$

where $P_i = n_i/n$ and $P_p = n_p/N$. So it is likely to be in a higher energy state than in a lower one. The ratio of the number of atoms in the upper state to the number in the lower state is n times to the power $(E_p - E_i)/kT$, whence, over N , it is very close to preservation.

Now, it turns out that for a harmonic oscillator the energy levels are evenly spaced, including the lowest energy, $E_1 = 0$ (it actually is not zero, but it's different, but it does not matter if we shift the energies by a constant, just that one is then 0). And the second one is $2\omega_0$ and the third one is $4\omega_0$, and so on.

Now let us see why happens. We suppose we are studying the vibrations of a diatomic molecule, which we approximate as a harmonic oscillator. Let us see

that is the relative chance of finding a molecule in state E_1 , instead of in state E_2 . This is given by the chance of finding a molecule E_1 , relative to the probability of finding it in state E_2 , goes down as $e^{-E_1/kT}$. Now suppose that kT is much less than E_2 , and we have a λ to "quantum" corresponds. Then the probability of finding it in state E_1 is extremely small. Obviously all the atoms are in state E_2 . If we change the temperature but still keep kT very small, then the chance of its being in state E_1 is the natural limit, and the energy of the oscillator remains nearly zero in excess of change with temperature so long as the temperature is much less than E_2 . All oscillators are in the fundamental state, and hence motion is effectively "frozen"; there is no contribution of kT to the specific heat. We can judge, then, from Table 40-1 that at 100°C, which is 373 deg. absolute, kT is much less than the vibrational energy in the oxygen or hydrogen molecules, but not so in the iodine molecule. The reason for this difference is that an iodine atom is very heavy, composed with nitrogen, and although the mass may be comparable of iodine and by 2 nitrogen, the iodine molecule is so heavy that the natural frequency of vibration is very low compared with the natural frequency of hydrogen. At the upper limit $kT > E_2$, room temperature the hydrogen has lower frequency, only the latter, incident, exhibits the classical vibrational energy. As we increase the temperature kT , first, starting from a very low value of kT , with the molecule almost all in their lowest state, they gradually begin to have an appreciable probability to be in the next state, and then in the next state, and so on. When the probability is appreciable for many states, the breakdown of the probability method that given by classical physics, because the quantized states become really indistinguishable from one in our mind, and the system can have classical energy. Thus in the temperature range, we should again get the results of classical mechanics, as indeed seems to be the case in Fig. 40-6. It is possible to show in the same way that the molecular vibrations $> kT$ to contribute, but the states are so much closer together that the ordinary correspondence kT is broken: hence the energy "lawn" energy levels are excited, and the rotational thermal energy in the system contributes in the classical way. The same example where this is done up to a certain temperature is for hydrogen.

This is the time that we have already discussed, by comparison, with classical mechanics. I.e., one was comparing wrong with classical physics, and will be looked for a modification of the classical mechanics in mechanics in much the same way as it was done in optics. It was 10 or 20 years before the next difficulty was discovered, and that had to do again with quantum mechanics, but this time the mechanics of a phenomenon. The problem was solved by Planck in the early part of this century.

The Brownian Movement

41-1 Experimental Discovery

The Brownian movement was discovered in 1827 by Robert Brown, a naturalist. While he was studying microorganisms, he noticed little particles of plant pollen jiggling around in the liquid he was looking at in the microscope, and he was wise enough to realize that these were not living, but were just little pieces of dirt moving around in the water. In fact, he tried to determine that this had nothing to do with life by putting from the ground an oak piece of gorse in which there was some water trapped. It must have been trapped for millions and millions of years. But when he would see the same jiggling. When you look at the tiny tiny particles and jiggling particles,

This was later proven to be one of the effects of molecular motion, and we can understand it very easily by thinking of a good push to a jiggling billiard ball from a great distance, with a lot of people understand all pushing the ball in random directions. We can not see the people because we imagine that we are too far away, but we can see the ball, and we notice that it moves straight in a zigzag. We also know, from the treatment that we have developed in a previous chapter, that the mean kinetic energy of a small particle suspended in a liquid or a gas is $\frac{1}{2}mv^2$, even though it is very many compared with a molecule. If it is very heavy, then clearly the speed will relatively slow, but it will still, usually, be. This speed is not really so slow. In fact, we can not see the effect of such a particle very easily because although the mean kinetic energy is $\frac{1}{2}mv^2$, which represents a speed of a million miles per second, it is about a million times larger than this. This is very hard to measure in a microscope, and so the particle immediately comes to a collision and does not get anywhere. How far it does get we will discuss at the end of this present chapter. This problem was first solved by Einstein at the beginning of the present century.

Inside talk, when we say that the total kinetic energy of the particle is $\frac{1}{2}mv^2$, we claim to have derived this result from the kinetic theory, that is, from Newton's laws. We shall find that we can derive all kinds of things—magnetism, things from the kinetic theory, and this is not interesting that we can apparently get much from nothing. Of course we cannot measure the Brownian Brownian "little"

—they are thought to do it easily. What we need is that we did not do very much. How do we prove that? The way is that we have been continually making a certain assumption implicitly, which is this: if a given system is in thermal equilibrium at some temperature, it will also be at thermal equilibrium with anything else at the same temperature. For instance, if we were to let some little granules move in water, and we were counting with water, we could imagine that the water present, composed of another kind of particle, little fine pellets that you supposed do not interact with water, but only by being in contact with them. Suppose the water has a strong sticking surface, all our pellets have to stick to the water. We know that without this kind of a vapor of little sticks at the surface, that is an ideal gas. Water is complicated, it is an ideal gas simple. Now, our particle has to be in equilibrium with the gas of water. Therefore, the total motion of the particle must be zero. We get for average velocity a number if it were not moving at the right speed relative to the water but say, were moving faster, that would mean the pellets would pick up energy from it and get farther from the water. But we had started them at the same height, and if we assume that at time t there is once in equilibrium, it stays in equilibrium— $v = 0$ if it is not pushed and other gas is with, again exactly.

41-1equipartition of energy

41-2 Thermal equilibrium of radiation

41-3 Equipartition and the quantum oscillator

41-4 The random walk

This proposition is true and can be proved from the laws of mechanics, but the proof is very complicated and can be established only by using advanced mechanics. It is much easier to prove in quantum mechanics, but it is in classical mechanics. It was proved by by Heisenberg, but for now we may take it to be true, and then we can argue that one particle has no temperature if it is at rest with zero power, so it can move freely (in space) it is being hit with wave at the same temperature and we take among the particles, as it is good. It is a stronger line of argument, not perfectly valid.

In addition to the rotating cylindrical surfaces for which the temperature was first determined, there are a number of other phenomena, both in the laboratory and in other situations, where one can see Brownian movement. If we are trying to build the most delicate possible thermometer, say a very small mirror on a thin wire fiber for a very sensitive ballistic galvanometer (Fig. 41-1), the mirror does not stay still, but jiggles all the time. On the same wire between we have a spot on it, and when we look at the position of the spot, we do not have a perfect instrument because it is moving all the time. Why? Because we are not kinetic energy. Creation of the vibration has to be in the average. Not

What is the measurement angle over which the mirror will vibrate? Suppose we find the natural vibration period of the mirror by tapping on one side and seeing how long it takes to oscillate back and forth, and we also know the moment of inertia, I . Well now the formula for the kinetic energy of rotation, it is given in Eq. (10.5-3) — $\frac{1}{2}I\omega^2$. That is the kinetic energy and the potential energy that goes with it will be proportional to the square of the angle — it is $E = \frac{1}{2}I\omega^2$. Then if we know the period T , we calculate from this the natural frequency $\omega = 2\pi/T$, then the potential, E_p , is $E_p = \frac{1}{2}I\omega^2T^2$. Now we know that the average kinetic energy is kT , but since it is a cosine it is small, so the average potential energy is also kT . Thus

$$\begin{aligned} \langle E \rangle &= \langle E_p \rangle + \langle E_k \rangle \\ \langle E \rangle &= kT + kT \end{aligned} \quad (41.1)$$

In this way we can calculate the oscillations of a galvanometer mirror, and therefore find what the limitations of our instrument will be. If we want to have small oscillations, we have to cool the mirror. An interesting question is, where to cool it. This depends upon where it is getting its "ticks" from. If it is through the fiber, we cool it at the top. If the mirror is surrounded by a gas and is getting its energy by collisions in the gas, it is better to cool the gas. As a matter of fact, if we know where the damping comes the natural energy from, it turns out that there is always the source of the fluctuations after a point which we will come back to.

The same thing works, amazingly enough, in electric circuits. Suppose that we are building a very sensitive, accurate amplifier for a certain frequency and then a resonant circuit (Fig. 41-2) in having to go to twice it, or, whatever, to the natural frequency, like a radio receiver, but a really good one. Suppose we want to go down to the very lowest limit of things, so we take the voltage very off the inductor, and send it into the rest of the amplifier. Of course, in my circuit like this there is a certain amount of loss. It is not a perfect resonant circuit, but it is very good one (as there is in a resonance). Say (we will be interested in ω) we can see it, but it is supposed to be small. Now we want to find out: How much does the voltage across the inductor fluctuate? Answer: We know that $\langle E \rangle^2$ is the "kinetic energy" — the energy associated with a coil in a resonant circuit (Chapter 22). Therefore, the mean value of $\langle E \rangle^2$ is equal to kT — that means that the inductor is big we can just cut what the rms voltage below the maximum. For this voltage the voltage across the inductor the current is $I = \omega L/V$, and the mean, square voltage on the inductor is $\langle V^2 \rangle = I^2 L^2 / R^2$, and putting in $\langle E \rangle^2 = I^2 L^2 / R^2 T$, we obtain

$$\langle E \rangle^2 = I^2 L^2 / R^2 T \quad (41.2)$$

So now we can design circuits and all when we are going to get what is called Johnson noise, the noise associated with thermal fluctuations.

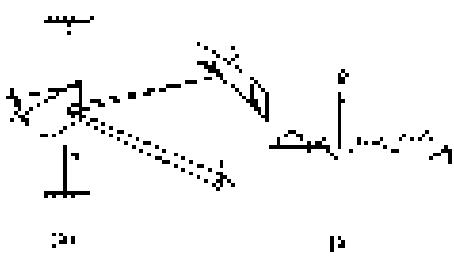

Fig. 41-1. (a) A rotating cylindrical surface. Light from a source S is reflected from a small mirror and is seen. (b) A sinusoidal record of the reading of the scale as a function of the time.

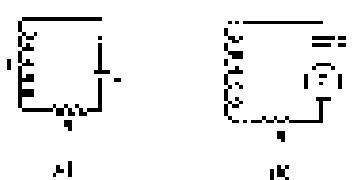

Fig. 41-2. A high-Q resonant circuit. (a) Actual circuit at resonance. (b) Artificial circuit, with or noise (indicated resistors and a "noise generator" G).

Where do the fluctuations come from? They come out from the resistor. They come from the heat that the electrons in the resistor are picking up because they are in thermal equilibrium with the resistor, and they make fluctuations in the density of electrons. They thus make tiny currents that will drive the current circuit.

Electrical engineers represent the current in another way. Physically, the noise is reflecting the source of noise. However, we may replace the real noise by having an instant, brief signal source which is making noise, by an artificial current which contains a little generator that is trying to reproduce the noise, and now the resistor is otherwise dead. So noise comes from it. All the noise is in the artificial generator. And so I think the characteristics of the noise produced by a resistor, if we had the formula for it, then we could calculate what the noise is going to be in response to that noise. So, we need a formula for the noise fluctuations. Now remember that is generated by the resistor is at all frequencies, since the resistor by itself is not resonant. Of course the resistor circuit only "hears" in the part that is near the right frequency, but the resistor has many different frequencies in it. We may describe how strong the generator is as follows. The mean power that the resistor would absorb if it was connected directly across the noise generator would be $\langle P \rangle$, P , $\langle \cdot \rangle$ means the voltage from the generator. But we would like to know τ more than just how much power there is at every frequency. There is very little power in any one frequency; it is a distribution. Let $P(s)$ be the power that the generator would deliver in the frequency range s into the rest of the resistor. Then we can prove (we shall prove it for another time), that the characteristic is exactly the same that the power remains out

$$P(s) ds = \langle P(s) \rangle \delta(s), \quad (41.3)$$

and is independent of the resistance when put this way.

41-1 Thermal equilibrium of radiation

Now we go on to consider a still more advanced and interesting problem in that is called "Suppose we've got a charged oscillator like those we were talking about when we were discussing light, let's say an electron oscillating up and down in an atom. If it oscillates up and down, it radiates light. Now suppose that this oscillator is in a very thin gas of oscillators, and let's say it's time to time the atoms collide with it. Then it's at equilibrium after a long time this oscillator will pick up energy until the total kinetic energy of the oscillator is kT , and since it is a harmonic oscillator, its total energy of motion will become kT . That is, $\langle E_{kinetic} \rangle$, a strong distribution of E , because the oscillator carries electric charge, and if it loses an energy kT it is shaking up and down and radiating light. Oscillating it is impossible to have equilibrium unless matter along with it is changing in it emitting light, and as light it is losing energy. Hence away, the oscillator loses its kT as time goes on, and then the whole gas which is oscillating with the oscillator gradually cools off. And that is, of course, the way a hot star cools off and might be radiating the light into the sky, because the atoms are losing their charge and they are continually recombining, and thereby breaking off from radiation. So it's continually cooling off.

On the other hand, if we enclose the whole thing in a box so that the photons are going out continually, then we've eventually get thermal equilibrium. We may either put the gas in a box where we can say that there are other oscillators in the box walls sending light back to us, or take a other example, we may say that the box has mirror walls. It is easier to think about that case. Then we assume that all the radiation that goes out from the oscillator stops running around in the box. Then, of course, it is true that the oscillator tends to radiate, but pretty soon it can maintain its kT of total energy in spite of the fact that it is radiating, because it is being compensated, we may say, by its own light reflected from the walls of the box. This is like a while there's a present of light running around in the box, and through the oscillator is radiating some, the light comes back and reflects off of the walls of the box and is radiated.

We shall now determine how much light there must be in such a box at frequency ν in order for the shifting of the light on the oscillators will generate just enough energy to account for the light it receives.

Let the two boxes be very few and far between, so that we have an idealized "intermittent" or "resonance" case of the lattice resistance. Then we consider that at thermal equilibrium the oscillator is doing two things at the same time. First, it has a mean energy $\mu_0 \omega T$, and second it is doing some radiation as well. Second, this radiation should be exactly the amount that would result because of the fact that the light shifting of the oscillator is not zero. Since there is nowhere else the energy can go, the effective radiation is really just scattered light from the light that is in there.

This we call spontaneous luminescence, but is generated by the oscillator at second, if the oscillator has a certain energy. (We learn more later, Chapter 12 on radiation resistance a number of equations without going into over their derivation.) The energy radiated per second divided by the energy of the oscillator is called β/α (Eq. 12.3): $\beta/\alpha = 2\pi^2 \mu_0 \omega_0 \sinh(\hbar \omega_0/kT)$. Unlike the quantity α , the damping constant, this can also be written as $\beta/\alpha = 2\pi \omega_0$, where ω_0 is the natural frequency of the oscillator. (Remember why ω_0 ? ω_0 is very large. The energy scattered per second is, then,

$$\frac{dE}{dt} = \frac{\omega_0 E^2}{2} = \frac{2\pi^2 \mu_0 \omega_0}{m} \cdot \omega_0 E. \quad (41.4)$$

The energy radiated per second is thus simply gamma times the energy of the oscillator. Now, the oscillator starts to have an average energy $\mu_0 T$, so we see that gamma β/α is the average amount of energy radiated per second:

$$\langle dE/dt \rangle = \beta/\alpha T. \quad (41.5)$$

Now we only have to know what β/α is. Gamma is easily found from Eq. (32.72), that is,

$$\gamma = \frac{\omega_0}{Q} = \frac{2\pi \omega_0^2}{\lambda \cdot e}, \quad (41.6)$$

where $r_s = \lambda^2/m^2$ is the classical electron radius, and we know $e = -e\hbar c/4\pi r_s$.

Our "int" result for the average rate of radiative of light and the frequency ω_0 is therefore

$$\frac{dE}{dt} = \frac{2\pi \omega_0^2 \mu_0 T}{\lambda^2 e}. \quad (41.7)$$

Next we ask how much light must be shifted on the oscillator. It must be enough that the energy received from the light (and the upshift scattered) is just exactly this much. In other words, the emitted light is accounted for as scattered light from the light that is shifting on the oscillator. In order to do this, we must now calculate how much light is scattered from the oscillator if there is a certain amount, unknown, of radiation incident on it. Let $I(\nu, d\nu)$ be the energy of light energy density $d\nu$ at the frequency ν within a certain range $d\nu$ (because there is no light at exactly one particular frequency, it is spread out over the spectrum). So $I(\nu, d\nu)$ is a certain spectral distribution which we are now going to "integrate" to get a value of a quantity at temperature T . Just as you do when you open the door and look at the hole. How more light is absorbed? We worked out the amount of radiation absorbed from a given incident light frequency, and we substitute it in terms of a cross section. It is just as though we did that since the light can thus on a certain cross section is absorbed. So the total amount that is radiated (additively) is the incident intensity $I(\nu, d\nu)$ multiplied by the same factor σ .

The form to for the cross section which we derived (Eq. 21.16) is $\sigma = \sigma_0$ and has the damping included. Let us look at it through the derivation again and put in the results less terms which we neglected. If we do that, and calculate the cross section the same way, we get

$$\sigma_0 = \frac{8\pi^2}{3} \left(\frac{\omega^2}{(\omega_0^2 + \omega^2)^2 + \gamma^2 \omega^2} \right). \quad (41.8)$$

Now, σ is a function of frequency, ω , so of significant size only for ω very near to the natural frequency ω_0 . (We realize that the σ for an oscillating oscillator is equal to σ_0^2). The oscillator scatters very strongly when ω is equal to ω_0 and very weakly for other values of ω . Therefore we can replace ω by ω_0 and $\omega^2 - \omega_0^2$ by $2\omega_0\omega - \omega_0^2$, and we get

$$\sigma_0 = \frac{2\pi^2 k T}{\pi(\omega_0^2 - \omega_0^2 + \gamma^2/4)} \quad (41.7)$$

Now the whole curve is broad and near $\omega = \omega_0$. (We do not really have to make any approximation, but it is easier to do the integral if we simplify the equation). Now we multiply this intensity in a given frequency range by the cross section σ_0^2 scattering power, the amount of energy scattered in the range $d\omega$. The total energy scattered is then the integral of this for all ω . That

$$\begin{aligned} \frac{dE}{dt} &= \int_{-\infty}^{\infty} \text{Intensity} d\omega \\ &\cdot \left(\frac{2\pi^2 k T \omega^2 d\omega}{\omega^2 - \omega_0^2 + \gamma^2/4} \right) \end{aligned} \quad (41.8)$$

Now we set $dW/dt = 3kT$. Why? Well: we made our analysis of the cross section in Chapter 17, we assumed the the particle was one such that the light scattered the oscillator. If we had used an oscillator which could move only in one direction, and the light only was polarized in the ω way, then it would scatter very little. So we must take average the cross section of an oscillator which can move in one direction, over all directions of incidence and polarization of the light or, more easily, we can imagine an oscillator which will scatter the field in either which way the field is pointing. Such an oscillator which can move equally in three directions, would have $3kT$ average energy because there are 3 degrees of freedom in that particular σ and not kT because of the 3 degrees of freedom.

Now we have to do the integral. Let us suppose that the uniform spectral distribution $N(\omega)$ of the light is a smooth curve and constant very very much above the very narrow frequency region where ω_0 is peaked (Fig. 41.3). Then the only significant contribution comes when ω is very close to ω_0 , within a small interval, which is very small. So therefore, although $\sigma(\omega)$ may be an unknown and unpredictable function, let's say plus where it is important, is near $\omega = \omega_0$, and there we may replace the strength curve by a flat-bottom "barrel" at the same height. In other words, we simply take $\sigma(\omega)$ outside the integral sign and call it $\sigma(\omega_0)$. We may also take the rest of the constants out in front of the integral, and what we have left is

$$(2\pi^2 k T \omega_0) \int_{\omega_0 - \gamma/2}^{\omega_0 + \gamma/2} \frac{d\omega}{\omega^2 - \omega_0^2 + \gamma^2/4} = 3kT. \quad (41.11)$$

Now, the integral starts from $\omega_0 - \gamma/2$, but this is so far from ω_0 that the curve is finished by then, so we go instead to $\omega_0 - \gamma$. It makes no difference and it is much easier to do the integral. The integral is an inverse tangent function of the form $\tan^{-1}(x) + C$. If we look it up in a book we see that it is equal to $\pi/2$. So what it reduces to for our case is $\pi/2$. Therefore we get, with some rearranging,

$$N(\omega_0) = \frac{3k^2 T}{4\pi^2 \omega_0^2}. \quad (41.12)$$

Then we substitute the formula (41.6) for σ_0 into (41.12) and we get σ_0 equal to ω_0 , since it is true or may we say just collinear with the formula for σ_0 that we know about.

$$\sigma_0 = \frac{c^2 k T}{4\pi^2 \omega_0^2}. \quad (41.13)$$

And this gives the radiatiton of light in a box formula. It is called the black

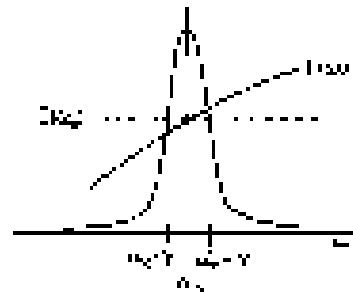

Fig. 41.3. The factors in the integrand (41.11). The peak is the spectrum curve ($N(\omega)$) $\sim \omega^2/4$. To a good approximation the factor that can be replaced by that

black radiation. That became the task in the famous thesis we took up in class when he was a student in 1900.

In a closed box at temperature T , (41.13) is the distribution law of energy of the radiation remaining in classical theory. First let's notice a remarkable feature of this expression. The charge of the oscillator, the mass of the oscillator, all properties specific to the oscillator, are not involved in this distribution function with its equilibrium. We must be at equilibrium with any other oscillator of different mass, or we will be in trouble. So this law imposes a kind of check on the properties that equilibrium does not depend on what we are in equilibrium with, but only on the temperature. Now let us draw a picture of the Rayleigh curve (Fig. 41-1). It tells us how much light we have at different frequencies.

The amount of intensity that there is in our box, per unit frequency range, goes down as the square of the frequency, which means that if we have a box at any temperature of T , then if we look at the x rays that are coming out, there will be a lot of them.

Of course we know this is false. When we open the surface and take a look at it, we do not burn our eyes and catch a fire at all. It is completely false. Furthermore, the total energy in the box, the sum of all the frequency spectrum over all frequencies, would be zero and under this infinite curve. Therefore, something is fundamentally, powerfully, and absolutely wrong.

This was the classic theory absolutely wrong, of course, concerning the distribution of light from a blackbody, just as it was incapable of actually describing the specific heats of gases. My students had better forth over this distribution from many different points of view, and there is no escape. This is the prediction of classical physics. Equation (41.13) is called Rayleigh's law, and it is the prediction of classical physics, and is inherently absurd.

41-3 Equilibrium and the quantum oscillator

The difficulty here was another part of the continual problem of classical physics, which also had with the difficulty of the specific heats of gases, and never has been resolved on the distribution of light in a blackbody. Now, of course, at the same time that theoretical work was being done, there were lots and many measurements of the actual curve. And I found out that the correct curve looked like the dashed curves in Fig. 41-1. That is, the x rays were not there. Low down the temperature the whole curve goes down in proportion to T , according to the classical theory, but the spectral curve also cuts off sooner at a lower temperature. Thus the low-frequency end of the curve is right, but the high-frequency end is wrong. Why? Well Sir James Jeans was worrying about the specific heats of gases, he noted that motions which have high frequency are "chopped out" as the temperature goes too low. That is, if the temperature is too low, if the frequency is too high, the oscillators don't have enough energy to keep going. Now recall our consideration of (41.13) without the aspects on the energy of an oscillator at thermal equilibrium. What did $\langle E \rangle$ ($\langle E \rangle = \langle E \rangle_0$) was, and what the sum at T in (41.13) is, is the mean energy of a 1-m molar oscillator at frequency ω at temperature T . Classically, this is $E_0/2$ experimentally, not necessarily the temperature is too low so the oscillator frequency is too high. At the same time, the curve falls off in the same way as does the specific heat of gases but it is easier to study the blackbody curve than it is the specific heat of gases, which are more complicated. Therefore our job is to proceed on determining the true blackbody curve. However, this curve is a curve which actually tells us, at every frequency, what the average energy of harmonic oscillators actually is as a function of temperature.

Planck studied this curve. He first determined the answer empirically, by fitting the observed curve with a law that can best guess very well. Thus he had to empirical formula for the average energy of a harmonic oscillator as a function of frequency. In other words, he had the right formula instead of E_0 , and then by fiddling around he found a simple definition for it which involved a new postulate. That assumption was that the harmonic oscillator can take up energies only in discrete steps. Before that they can have any energy whatever. Of course, that was not beginning of the end of classical mechanics.

The very first correctly determined quantum-mechanical formula will now be derived. Suppose that the possible energy levels of a harmonic oscillator were equally spaced in frequency, i.e., E_1, E_2, E_3, \dots . In reality, it could take on only these different energies (long, short). Planck made a somewhat more complicated argument than the one that is being given here, because that was the very beginning of quantum mechanics and he had to prove some things. But we are going to make it as short (which is demonstrated in this case) that the probability of occupying a level of energy E is $P(E) = e^{-E/kT}$. If we go along with this, we will obtain the right results.

Suppose now that we have a lot of oscillators, and each is a oscillator of frequency ω . Some of these oscillators will be in the lowest quantum state, some will be in the next one, and so forth. What we would have to know is the average energy of all these oscillators. To find out, let us calculate the total energy over the oscillators and divide by the number of oscillators. That will be the average energy per oscillator in thermal equilibrium, and will also be the energy that is in equilibrium with the "background radiation" and that should be at Eq. 14.13. In place of vE , then let N_ν be the number of oscillators that are in the ground state (the lowest energy state); N_ν the number of oscillators in the excited state; N_ν the number that are in state E_2 ; and so on. According to the hypothesis which we have now proved, that is, quantum mechanics, the law that replaced the principle of $e^{-E/kT}$ or $e^{-Eh\nu/kT}$ in classical mechanics is that the probability goes down as $e^{-Eh\nu/kT}$, where $Eh\nu$ is the excess energy, $h\nu$ the energy of the oscillator, that is, in the first state will be the number N_0 , that are in the ground state, times $e^{-Eh\nu/kT}$. Similarly, N_1 , the number of oscillators in the second state, is $N_1 = N_0 e^{-Eh\nu/kT}$. To simplify the algebra, let us call $e^{-Eh\nu/kT} = x$. Then we simply have $N_0 = N_0 x$, $N_1 = N_0 x^2$, ..., $N_n = N_0 x^n$.

The total energy of all the oscillators must then be worked out. If the oscillator is in the ground state, there is no energy. If it is in the n state, the energy is $E_n h\nu$, and there are N_n of them. So $N_0 E_0$, or $N_0 h\nu$ is how much energy we get from those. Those that are in the second state have $E_2 h\nu$, and there are N_2 of them, so $N_2 E_2 h\nu = N_2 h\nu^2$ is how much energy we get, and so on. Then we add it all together to get $E_{\text{tot}} = N_0 h\nu(0 + x + 2x^2 + 3x^3 + \dots)$.

And now, how many oscillators are there? Of course, N_0 is the number that are in the ground state, N_1 in the first state, and so on, are added together. $N_{\text{tot}} = N_0(1 + x + x^2 + x^3 + \dots)$. Thus the average energy is

$$\langle E \rangle = \frac{E_{\text{tot}}}{N_{\text{tot}}} = \frac{N_0 h\nu(0 + x + 2x^2 + 3x^3 + \dots)}{N_0(1 + x + x^2 + \dots)}. \quad (4.12)$$

Now the two sums which appear here we shall leave for my reader to play with and have some fun with. When we are all finished summing up, after subtracting for N_0 the sum "washout" if we make no mistakes in the sum,

$$\langle E \rangle = \frac{h\nu}{e^{h\nu/kT} - 1}. \quad (4.13)$$

This, then, was the first quantum-mechanical formula ever known, in 1900. Planck, and it was the "quantum" solution of decades of puzzlement. However, knew very then was turning wrong, and the question was, what was right? Here is the quantitative answer of what is right (constant of kT). This expression should, of course, approach kT as $x \rightarrow 0$ (as $T \rightarrow \infty$). See if you can prove that it does—learn how to do the mathematics.

This is the famous "exact factor" that Jeans was looking for, and if we use it instead of kT in (4.12), we obtain for the distribution of light in a black box

$$dN/d\lambda = \frac{h\nu^3 d\nu}{c^2 \lambda^5 (e^{h\nu/kT} - 1)}. \quad (4.14)$$

We see that for a large ν , even though we have a small numerator, that is more used in a denominator power in the denominator, as the curve comes down again and even not "blows up"—we never get a positive light wave—why?—that we did expect them!

E_1	$E_1 = 0$	$E_1 = \text{lowest energy}$
E_2	$E_2 = 2E_1$	$E_2 = \text{second energy}$
E_3	$E_3 = 3E_1$	$E_3 = \text{third energy}$
E_4	$E_4 = 4E_1$	$E_4 = \text{fourth energy}$
E_5	$E_5 = 5E_1$	

Fig. 41-2. The energy levels of a harmonic oscillator are evenly spaced.

You might complain that in our derivation of (41.17) we used the quantum theory for the energy levels of the harmonic oscillator and the classical theory in determining the cross sections. The nonclassical theory of light interacting with a harmonic oscillator gives exactly (41.17), a result that agrees with the classical theory. That is just as it was when just that in studying vacuum fluctuations our analysis of the theory of refraction and the scattering of light, using a model of atoms like that of Section 18, the quantum mechanics substantially disagreed.

Now let us return to the Johnson noise in a resistor. We have already mentioned that the theory of this noise power is exactly the same theory as that of the classical Blackbody Radiation Law. In fact, rather amazingly, we have already done this. When we did it, in a circuit with zero resistance, our "radiation resistance" had no effect because it radiates nothing; a radiation resistance as it would be easy for us to understand, the power would be. It would be just the power loss in multiplying the spectrum from the light that is all around, and we would get the same distribution, unchanged by such noise in two terms. We can also prove that the source is a generator with an unknown power (just from (41.1)). The spectrum is determined by the fact that this noise generator, connected to a resonant circuit at say frequency ω , in Fig. 41.1(b), generates in the inductance a voltage $\sim \omega I$ (approximately as in Fig. 41.2). One has just in the same integral as in (41.10), and the same method works to give Eq. (41.11). For low temperatures (say 57 K) (41.21) must of course be replaced by (41.15). The two theories of resistive noise in solid conductors may be also closely related physically, for we may of course connect a resonant circuit to the resistor, so the resistance is a pure resistive resistance. Since (41.9) does not depend on the physical origin of the resistance, we know the generator to be a real resistance and for resistance resistance is the same. What is the origin of the generated power? First of all the resistance R is only an ideal current in e.g. like number its cross-section at temperature T ? If it is a radiation source, the question is, at what temperature? which impinges on the inductor and is "received again," makes an effective generator. Therefore one can deduce a direct relation of P_{rad} and P_{int} , leading from (41.15) to (41.1).

All the things we have been talking about—the cooled Johnson noise and Planck's distribution, and the exact theory of the Brownian movement—will be considered further in the development of the first theory of noise in the resistivity. Now with these points and that history in mind, we return to the Brownian movement.

41-4 The random walk

Let us consider now the position of a jiggling particle whose change with time, we say, is x , is compared with the time between "steps." Consider a "true" Brownian movement—particle which is jiggling about because it is surrounded on all sides by irregularly jiggling water molecules. (Query: After a given length of time, does the noisy x in (41.1) have to be bunched along? That is, is it often surrounded by lone air and sometimes by water? If we imagine that we divide the time into Δt intervals, let us say a millionth of a second or so, then after the first hundredth of a second it moves here, and in the next hundredth it moves some more, and in the next hundredth it moves to another somewhere else, and so on. In terms of the rate of bounces, n , and with Δt a second, n is very large. The reader may easily verify that the number of collisions a single molecule with water molecules in a second is about 10^{11} , or a hundred million second is about 10^{13} collisions, which is not. There is also a limit on the "bounce rate" per unit time, but what happens before? In other words, how collisions are all measured so that one "step" is not related to the previous "step"? It is like the famous drunken sailor problem: Can you always get home, and when a sequence of steps has each step is chosen at an arbitrary angle, at random (Fig. 41-6)? The situation is: After a long time, where is the sailor? Of course we do not know! It is impossible to say. (Perhaps we mean he is just somewhere near or has gotten "lost." But, then, in the average, where is he?) On the average, how far off from the spot you've gone? We have already answered this question. (Indeed, that is what we were discussing, the

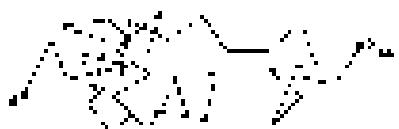

Fig. 41-6. A random walk of 30 steps of length L . Here for $L = 3\lambda$, from 37 days about 6000 λ away.

size position of light from a whole lot of different sources at different angles, and (2) meant adding a list of several different angles (Chapter 12). There, we discovered that the mean square of the angle, from one end to the other of the chain of random steps, which was the intensity of the light in the sum of the intensities of the separate pieces. And so, by the same kind of argument as we did above immediately that if R_N is the mean distance from origin after N steps, the mean square of this distance from the origin, is proportional to N^2 , or, in other words, $\langle R_N^2 \rangle = N^2$, where L is the length of each step. Since the number of steps is proportional to the time in our present problem, the mean square distance is proportional to the time.

$$\langle R^2 \rangle = \text{const} \quad (11.13)$$

This does not mean that the mean distance is proportional to the time. If the mean distance were proportional to the time it would mean that the driving is at a nice uniform velocity. The only way making some steady sensible trajectory, however, such that the mean square distance is proportional to time, that is the characteristic of a random walk.

We may show very easily that in fact $\langle R^2 \rangle$ among the squares of the distances increases, on the average, by L^2 . For, start with $R_0 = R_{N-1} + L$, we find that R_N^2 is

$$R_N \cdot R_0 = R_0^2 + R_{N-1}^2 + 2R_{N-1} \cdot L + L^2,$$

and averaging over many trials, we have $\langle R_N^2 \rangle = \langle R_0^2 \rangle + L^2$, since $\langle R_{N-1} \cdot L \rangle = 0$. Thus, by induction

$$R_N^2 = \text{const}^2 \quad (11.14)$$

Now we would like to calculate the last constant in Eq. (11.13), and here we are most likely to trip up. We are going to suppose that if we were to put a force on the particle, nothing would go with the Brownian movement. We are taking a side track for the moment; then it would just increase following way again. In fact, there would be inertia, m , or, at the coefficient of inertia, the effective mass of the object, not necessarily the sum of the real mass of the solid particle, because the water has to move around the particle if $m \neq M$ (unlike). Thus if we talk about myself, I would realize, there is a term like m/L^2 , when one side. And next, we want also to assume that if we kept a steady p_\perp on the object, there would be a drag on it from the fluid, proportional to its velocity, v . Besides the inertia of the fluid, this is a realistic assumption due to the viscosity and the complexity of the fluid. It is absolutely essential that there be some irreversible losses, something that is irreversable, in order that the law $F = \dot{p}$ takes place. There is no way to prevent the fluid under these conditions to be source of the F in the form's being closely related to these losses. We'll the mechanism of this drag is *viscous dissipation*, or, in words talk about forces that are proportional to the velocity and where they come from. That let us suppose to have that there is such a viscous η . Then the formula for the net force due to external forces, whenever we are putting out from motion, is

$$M \frac{d^2x}{dt^2} + \eta \frac{dx}{dt} = F_{\text{ext}} \quad (11.15)$$

One quantity is now determined directly from experiment. For example, water falls in a drop from the ceiling. Then we know that the force is mg , and g is to be divided by the square of L , the drop falling velocity v_0 . Or we could put the lamp in a room, and see how fast it wobbles. Or if it is charged, we can put another field on it. Since it is measurable thing, it is an artificial thing, and it is known for every type of artificial particles etc.

Now let us use the same formula in the case where the force is a constant, not equal to the singular forces of the source, or, in general. We shall then try to determine the mean square distance for the object goes. Instead of taking the distances in three dimensions, let's take the first dimension, and find by means of $\langle x^2 \rangle$, not to express ourselves. Obviously the mean of x^2 is the same as the mean of x , is the square of the size of x , and therefore the mean square of the distance

In just 1 line what we are going to take, since The averagement of the irregular forces is, of course, just as irregular as any other component. What is the rate of change of x^2 ? It is $d(x^2)/dt = 2x(dx/dt)$, so what we have to find is the average of the positive times the velocity. We shall show that this is a constant, and that therefore the mean square radius will increase proportionally in the time, and at what rate? Now, we multiply Eq. (41.19) by $m \frac{d(x^2)/dt}{dx} = m(2x) \frac{dx}{dt} = 2x^2$. We want the time average of $x^2(dx/dt)$, so let's take the average of the whole equation, and multiply the three terms. Now this is a little like Eq. 3.27. If the particle happens to leave your system at distance x from it, since the irregular force is completely irregular and does not know where the particle started from, the next impulse could be in any direction relative to x . It is positive; then in the reason why the average force should then be in that direction. It is just as likely to be one way as the other. The component forces are not during t in a definite direction. So the average value of x^2 times F is zero. On the other hand, for the term $m(x^2)^2/dt^2$ we will have to be a little fancy, and write this as

$$m \frac{d^2x}{dt^2} = m \frac{d(x^2)/dt}{dt} = m \left(\frac{dx}{dt} \right)^2.$$

Now we put in these two terms and take the average of both. So let us see how many x times the velocity should be. Now x times the velocity has a sense that does not change with time, because when it gets to some position it has no remembrance of where it was before, so things are no longer averaging with time. So this quantity, or the average, is zero. We have left the constant, m^2 , and that is the only thing we know, $m^2/2$ is a mean value $\langle x^2 \rangle$. Therefore we find that

$$\left\langle m^2 \frac{d^2x}{dt^2} \right\rangle + \langle m \frac{d(x^2)/dt}{dt} \rangle = \langle x^2 \rangle,$$

implies

$$- \langle m x^2 \rangle + \frac{m}{2} \frac{d}{dt} \langle x^2 \rangle = 0,$$

or

$$\frac{d\langle x^2 \rangle}{dt} = \frac{m}{2} \langle x^2 \rangle. \quad (41.20)$$

Therefore the object has a mean square distance $\langle x^2 \rangle$, at the end of a certain length of t , occurs to

$$\langle x^2 \rangle = \langle x_0^2 \rangle e^{mt^2/2}. \quad (41.21)$$

And so we can actually determine λ for the particles g . We first must determine how many x equal to a theory force, say, that they drift under a known force F for t , and then we can determine how far they go in their random motion. This equation, was of considerable importance historically, because it was one of the first ways by which the constant λ was determined. After all, we can measure λ , the time, how far the particles go, and we can take an average. The reason that the determination of λ was important is that in the law $\langle x^2 \rangle = R t$ for a move we know that R , which can also be measured, is equal to the number of atoms in a mole times λ . A mole was originally defined as a mole of many grams of oxygen—6 (now carbon is used), so the number of atoms in a mole was not known, originally. This, of course, a very interesting and important problem. How big is λ alone? How many atoms? Some of the earliest determinations of the number of atoms was by the determination of how far a single little particle would move if we pushed it patiently until a microscope for a certain length of time. And thus Boltzmann's constant k and the Avogadro number N_A were determined to values λ had already been measured.

Applications of Kinetic Theory

42.1 Evaporation

In this chapter we shall discuss some of the applications of kinetic theory. In the previous chapter we emphasized one particular aspect of latent heat, namely, that the change in latent heat is one degree of freedom of a molecule or other object. Now, the mutual motion of what we call "molecules" on the other hand, is the fact that the probability of finding a particle in different places, per unit volume, is $e^{-E/kT}$. From $e^{-E/kT}$, we shall calculate a number of applications of rays.

The phenomena which we want to study are relatively complicated: a liquid evaporating, a substance in a metal coming out of the surface, or a chemical reaction in which there are a large number of intermediate steps. In such cases it is no longer possible to make from the kinetic theory only simple and correct statements, because the situation is too complicated. Therefore, this chapter, except where otherwise emphasized, is quite modest. One idea to be emphasized is only that we can understand from the kinetic theory, how or how many things ought to be how. By using thermodynamic arguments, or some empirical measurements of certain related quantities, we can get a more accurate representation of the phenomena.

However, it is very useful to know more, not so much why something behaves as it does, so that when the situation is a new one, we can use what we have not yet learned. In addition we can learn more about what ought to happen. So this discussion is highly inaccurate but essentially right—right in idea, not in the fine detailed, let us say, in the specific details.

For example, first, we shall consider is the evaporation of a liquid. Suppose we have a box with a large volume, partially filled with vapor in equilibrium and at the vapor at a certain temperature. We shall suppose that the molecules of the vapor are relatively far apart, and that inside the liquid, the molecules are packed close together. The problem is to find out how many molecules there are in the vapor at a given temperature, and how this depends on the temperature.

Let us say that n equals the number of molecules per unit volume in the vapor. Then, however, N equals nV at the box temperature. If we add heat, we get more evaporation. Now let another quantity, N_1 , equal the number of atoms per unit volume in the liquid. We suppose that each molecule in the liquid occupies a certain volume, σ^3 . If the N_1 are next to each other, they then all together they occupy a bigger volume. But if N_1 is the volume occupied by one molecule, the number of molecules in a unit volume is N_1 and volume divided by the volume of each molecule. For definiteness, we suppose that densities of molecules between the molecules is to help them together in the liquid. Otherwise we cannot understand why it condenses. This requires that there is a force and that there is an energy of binding of the molecules in the liquid which is less when they go into the vapor. That is, we are going to suppose that, in order to take a single molecule out of the liquid into the vapor, it is fair amount of work W has to be done. There is a certain difference, E , in the energy of a molecule in the vapor from what it would have if it were in the vapor, because we have to pull it away from the other molecules which attract it.

Now we get the general principle that the number of atoms per unit volume in two different regions is $n_1 e^{-E/kT} = n_2 e^{-E/kT}$. Let N_1 be the number of particles per unit volume in the vapor divided by N_1 times N_1 per unit volume in the liquid, is equal to

$$N_1' = e^{-E/kT}. \quad (12.1)$$

42.1 Evaporation

42.2 Thermodynamics

42.3 Thermal insulation

42.4 Thermal insulators

42.5 Einstein's law of radiation

because $\ln \frac{p}{p_0}$ is the general rule. It is fine to assume that in equilibrium under gravity, vapor density is proportional to density just below the top because of the work required to lift the gas system to the height h . In the liquid, the molecules are thrown from the vapor because we have to put the latent energy "into" h , and this is if the densities is $e^{-\frac{U}{kT}}$.

This is what we wanted to prove—that the vapor density varies as $e^{-\frac{U}{kT}}$ the more precisely we do it, over 10⁻³⁰ to 10⁻³² the better it is and is extremely interesting to us, because in most cases the vapor density is very small. Now if the liquid density ρ , in these circumstances, were constant, then for the vapor density where they are almost the same, but where the vapor density is much lower than the liquid density, then the fact that ρ is very much less than $1/V_0$ is compensated by the factor ρ is very much greater than $1/V_0$. So to make such as (42.1) are interesting only after ρ is very much larger than $1/V_0$, because in most circumstances, since we are trying to measure a tremendous amount if we change V a little bit. But temperature does change a lot, and the change is indeed kT . The equilibrium factor is very much more important than any change that might occur in the factors not in front. Why should there be any change in such factors as V_0^2 ? I suppose this was an appropriate analysis. After all, there is no really a definite velocity for one molecule, so we change the temperature, the volume V , this is also constant—the liquid expands. There are other little factors like that, and so on, and allusion is more meaningful. There are slowly varying temperature dependent factors all over the place. In fact we find that V_0^2 does vary slightly with temperature, because at a higher temperature, at a kT constant molecular volume, there would be different average attractions, and so on. So while we might think that if we have a formula in which every thing varies at an unknown way with temperature then we have no formula at all. We realize that the exponential factor is, in general, very large, except that in the case of the vapor density as a function of temperature most of the variation is accommodated by the exponential factor and it is to a first moment and the coefficient $1/V_0$, as usually constant, is a good approximation for most temperatures the case. Most of the variation, in other words, is of the general nature $e^{-\frac{U}{kT}}$.

In fact, well then there are many, many phenomena in nature which are characterized by having to use up energy from somewhere, and in which the central feature of the temperature variation is $e^{-\frac{U}{kT}}$ minus the energy over kT . This is a useful fact only when the energy is large compared with kT , without most of the variation is contained in the variation of the $e^{-\frac{U}{kT}}$ and not in the constant and in other factors.

Now let us consider another way of obtaining a somewhat similar result for the vaporization, but seeking still in more detail. To prove it off, we simply suppose a rule which is valid at equilibrium, but in order to understand things better there is no harm in trying to look at the details of what is going on. We may also assume the what is going on in the following way. The molecules can and do leave continually the surface of the liquid; when they do it, they may fly off or they may get stuck. There is an unknown factor for that—maybe 50%, maybe 10 to 90% we do not know. For many the others get stuck—we can assume this over again later on the assumption that they do not always get stuck. Then we can calculate the N_0 , the total number of atoms which are碰撞ing only the surface of the liquid. The number of molecules moving, the number that leave on a unit area, is the number n per unit volume times the velocity v . This velocity of the molecules is related to the temperature, because we know that v^2 is proportional to kT on the average. So it is some kind of a mean velocity. Of course we should integrate over the v 's to get some kind of an average, but it is roughly proportional to the root-mean-square velocity, within some factor. This

$$N_0 = n v \quad (42.2)$$

is the number which units per unit area and are colliding.

At the same time, however, the atoms in the liquid are jiggling about, and from time to time one of them gets kicked out. Now we have to estimate how fast they get kicked out. The idea will be that at equilibrium the number that are kicked out per second and the number that come per second are equal.

How many get kicked out? In order to go kicked out, a gas molecule has to have acquired by accident an excess energy over its equilibrium—a considerable excess energy, because it is all used up straight for the other molecules in the liquid. Ordinarily it does not have that, so it is only slightly off track, but in the collisions sometimes one of them gets an excess energy by accident. And the chance that it gets the extra energy, if which it needs . . . our case is very small $\approx 10^{-10}$. In fact, $\approx 10^{-10}$ is the chance that a collision has picked up enough to do it much energy. That's the problem in kinetics theory; in order to know an excess energy IP have to suppose, he believes at the time the energy that we have to know, over E_0 . Now suppose that some molecules have been given this energy. We now have to estimate how many leave the surface per second. Of course, just because a molecule has the necessary energy does not mean that it will actually evaporate, since it may be buried too deeply inside the liquid or, even if it is near the surface, it may be travelling in the wrong direction. The number that are going to leave a unit area per second is going to be something like this. The number of course there are near the surface, per unit area, covered by the liquid. Is one atom a centip, and is likely the probability $\approx 10^{-10}$ that they are ready to escape in the sense that they have enough energy.

We shall suppose that each molecule at the surface of the liquid has plus a certain excess energy A . Then the number of molecules per unit area of liquid surface will be N_0 . And now, how long does it take a molecule to escape? If the molecule has a certain average speed v , and goes to move, say, one molecular diameter d , the thickness of my film layer, then the time it takes to get across that thickness is the time needed to escape, if the molecule has enough energy. The time will be $t = d/v$. Thus the number evaporating should be approximately

$$n = (N_0 d v / 2) e^{-A/kT} \quad (42.3)$$

Now the area of each atom, times the thickness of the layer, is approximately πd^2 , so if the volume V_0 occupied by a single atom. And we consider again benzene, we must have $N_0 = V_0 / \pi$.

$$n = (V_0 v / 2) e^{-A/kT} \quad (42.4)$$

We may assume the v 's since they are equal; even though one is the velocity of a molecule in the vapor and the other is the "velocity" of an evaporating molecule. These are to be set, because we know their sum, known energy (in one dimension) is A . But one may object, "Well No! These are the especially fast-moving ones; these are the ones that have probably excess energy." Not really, because the moment they start to pull away from the liquid, they have to lose the excess energy against the potential energy. As we decrease in the surface they are pulled down to the velocity; this is the same as was in our discussion of the distribution of molecular velocities in the atmosphere. At the bottom, the molecules had a uniform distribution of energy. The ones that came up, the ones that have the same distribution of energy, because the new ones are not important, and the old ones were thrown down. The ones that are evaporating have the same distribution of energy as the ones inside—a quite remarkable fact. Anyways, it is useless to try to impose artificially slow, or normal, or excess velocities, never, such as the probability of breaking back rather than leaving the "liquid" & so on. Let us now, a rough idea of the rate of evaporation and condensation, and we see, of course, that the vapor density varies in the same way as before, but now we have understood it in a systematical rather than just a qualitative, *ad hoc* mode.

This deeper understanding permits us to analyze some things. For example, suppose that we start evaporates the water at such a great rate that we removed the vapor as fast as it formed. "we had very good pump, and the liquid was evaporating very slowly"; how fast would evaporation be? . . . if we maintained a liquid temperature $\approx T^*$. Suppose that we have already experimentally measured the equilibrium vapor density, at this we know, at the given temperature. How many molecules per unit volume are in equilibrium with the liquid? Now we would like to know *how fast* it will evaporate. Even though we have used only a rough cut *ad hoc* for as the evaporation part of it is concerned. The number of vapor

unknown quantity was now there as badly, aside from the unknown factor of refection coefficient. We therefore we may let the first law number that are leaving at equilibrium, is the same as the number that are hitting. Thus, if vapor is very evanescent and if the molecules are only coming out, but if the vapor were left alone, it would remain in equilibrium - that is, at which the number that come back would equal the number that are evaporating. Therefore, we can easily see that the number that are coming out the surface we denote is equal to the unknown reflection coefficient θ times the number that would come down on the surface second were the vapor still there, because that is how many go to the balancing evaporation in equilibrium:

$$N_1 = \theta N_0 = (\sigma R T_{\text{atm}})^{-\frac{1}{2}} \cdot \theta. \quad (18.1)$$

Of course, the number of molecules that hit the liquid from the vapor is very, very large, since we do not need to know so much about the forces as we do when we are worrying about how they go in and get through the liquid surface; it is much easier to make the argument the other way.

47.2 Thermionic currents

We now give another example of a very practical situation that is similar to the evaporation of a liquid—namely, that it is not water striking a separate surface. It is basically the same problem. In a metal, there is a source of electrons, namely, a heated tungsten filament, and a positively charged plate to attract the electrons. Any electron that escapes from the surface of the tungsten is immediately attracted to the plate. This is our ideal "pump," which is "pulling" the electrons away from the wire. Now the question is: How many electrons per second can we get out of a piece of tungsten, and how does that number vary with temperature? The answer to this problem is the same as (18.1) because it turns out that one process of most electrons is extracted to the ions, or to atoms, of the metal. They are attracted, or may stay in, to the metal. In order to get an electron out of a piece of metal, it takes a certain amount of energy or work to pull it out. This work varies with both the substance of metal. In fact, it varies even with the character of the surface of a given kind of metal. But the total work may be a few electron volts, which, incidentally, is typical of the energy it takes in chemical reactions. We can remember the battery by noting that the voltage in a dry cell will like a flashlight battery, which is produced by chemical reactions, is also a constant.

How can we find out how many electrons come out per second? It would be quite difficult to analyze the effects on the electrons going out; it is easier to analyze the situation the other way. So, we could start out by imagining that we'd not let the electrons out, and that the electrons were held, just, and could come back to the metal. Then there would be a certain density of electrons at equilibrium which would, of course, be given by exactly the same formula as (18.1), where Z_e is the volume per electron in the metal, roughly, and \mathcal{W} is again eV , where V is the work of work function, or the voltage needed to pull an electron off the surface. This would tell us how many electrons would have to be in the metal holding constant striking the metal in order to balance the ones that are coming out. And thus it is easy to calculate how many are coming out if we sweep away all of them, because the number that are coming out is really equal to the number that can fit by going in with the above density of electron "trap." In other words, the answer is just the current of electricity that can be just one ampere equal to the charge on each times the number that comes per second per volt amp, which is the number per unit volume times the velocity, as we have seen many times.

$$I = q \cdot n = (q \cdot \sigma V_e) e^{-\frac{\mathcal{W}}{kT}}, \quad (18.2)$$

Now one electron volt corresponds to 1.602×10^{-19} coulombs. At 1000 degrees, the lifetime τ of the tungsten is 10 seconds at a temperature of, say, 1000 degrees, so the conversion factor is simply $(10^3)^{-1}$; when we change the temperature to

Since λ , the exponential factor changes a lot, thus, again, the central feature of the formula is $e^{-\beta E}$. As a matter of fact, the factor in front is quite interesting— it turns out that the behavior of electrons in metal is not correctly described by the classical theory, but by quantum mechanics, our λ only changes the factor in front a little. Actually, no one has ever been able to get the things right even not very well, even though many people have used the high-class quantum-mechanical theory for their calculations. The big problem is, does H' change a little with temperature? If it does, one cannot distinguish it from changing slowly with temperature but one can distinguish it from H' if it changes linearly, say, with temperature, so that $H' = H_0 - \alpha T$, then we would have

$$e^{-\beta H'} = e^{\beta H_0} e^{-\alpha T \beta} = e^{-\alpha T \beta} e^{-\beta H_0}.$$

Thus a linearly temperature-dependent H' is equivalent to a "slope" ("constant"). It is really quite difficult and usually impossible to try to obtain this coefficient in the first accuracy.

42-3 Thermal ionization

Now we go on to a clear example of the same idea: always the same idea. This time let's do with ionization. Suppose that in a gas we have a whole lot of atoms which are in the neutral state, say, but the gas is hot and the atoms can become ionized. We would like to know how many ions there are in a given circumstance if we know a certain density of atoms per unit volume at a certain temperature. Again we consider a box in which there are N atoms which can hold electrons. (If an electron has come off a atom, it is called an ion, and if the atom is neutral, we simply call it an atom.) Then suppose that, at any given moment, the number of neutral atoms is n_0 , the number of ions is n_1 , and the number of electrons is n_2 , all per unit volume. The problem is: What is the relationship of these three numbers?

In the first place, we have two conditions or two pairs of the numbers. For instance, as we vary different conditions, like the temperature and so forth, n_0 , n_1 , would remain constant, because this would be simply the number N of atomic nuclei that are in the box. If we keep the number n_0 fixed per unit volume fixed, and change, say, the temperature, then as the ionization proceeded some atoms would turn to ions, but the total number of positive plus negative would be unchanged. That is, $n_0 + n_1 + N$. Another condition is that if the entire gas is to be electrically neutral (and if we neglect double ionization), this means that the number of ions is equal to the number of free negative charges, or $n_1 = n_2$. These are certainly requirements that simply express the conservation of charge and the conservation of atoms.

These equations are true, and we ultimately will use them when we consider a real problem. But we want to obtain another relationship between the quantities. We can do this as follows. We again use the idea that it takes a certain amount of energy to lift the electron out of the atom, which we call the ionization energy, and we let V be the volume. In order to make all of the numbers look the same, we let H' equal the energy needed to pull an electron out of an atom and m be the mass. Now we say it's say that the number of free electrons per unit volume is the "mass" is equal to the number of bound electrons per unit volume in the x -axis, times e to the minus the energy difference between being bound and being free, times λ . That is the basic equation again. How can we write it? The number of free electrons per unit volume would, of course, be n_2 , however that is not definition of n_2 . There will be a number of electrons per unit volume that are bound to atoms. The total number of places that we could put the electrons is approximately $n_0 + n_1$, and we will suppose that when they are bound you ignore being within a certain volume V . So the total number of volume which is available to electrons which would be bound is $(n_0 + n_1)V$, so we might want to write it as follows:

$$n_2 = \left(\frac{n_0}{(n_0 + n_1)V} \right) e^{-\beta E_0}.$$

The formula is wrong, however, in one essential feature, which is the following: σ electron is energy or not cross. Another electron cannot come to the volume occupied. In other words, all the volumes of all the possible sites are not really available for the new electron. When trying to make up its mind whether it's to be in x -direction or in the conjugated position, because in this particular there is an available feature that when one electron is where another electron is, it is not allowed to go there & repeat. For that reason, it comes out that we should count only that part of the volume which is available for another nucleation event. That is, those sites are already occupied - so no point in the total available volumes, but the only volumes which is allowed is rest of the site, where the one present does not let the electron to go. Thus, in these circumstances, we find that a better way to write our formula is

$$\frac{d\sigma}{dt} = \frac{1}{V_0} e^{-E/kT} \quad (16.5)$$

This formula is called the Saha ionization equation. Now let us see two other undesirable complications why a formula like this is right by arguing about the same things we are comparing.

First, every once in a while an electron comes to another and they combine to make a atom. And it may come in a while, an atom goes into a collision and breaks up into an ion and an electron. Now these two rates must be equal. How fast do electrons and ions "find each other"? The rate is certainly increased if the number of electrons per unit volume is increased. It is also increased if the number of ions per unit volume is increased. That is, the rate at which recombination is occurring is certainly proportional to the number of electrons times the number of ions. Now consider this at which ionization is occurring due to collisions must be dependent. Heavily on how many atoms there are in volume. And so the rates will balance when there is some relationship between the product of n_e and the number of ions, n_i . This is what the relationship happens to be given by this particular formula, where kT is the ionization energy, but it's a little bit more in question, but we can easily understand that the formula would necessarily involve the concentrations of the electrons, ions, and atoms in the ionization and/or to conclude a result it is independent of the kT , that depends only on E , kT , n_e , n_i . The other three factors are other constant factors.

We may also note that, since the equation involves the numbers per unit volume, if we were to do an experiment with a given total number N of some substance, that is, a certain fixed number of atoms, but using boxes with different volumes, the n 's would all be smaller in the larger box. But since V_0 is constant, since the same, the total number of electrons and ions must be greater in the larger box. To see this, say, say that there are N nuclei inside a box of volume V , and the electron concentration is denoted. Then $n_e = N/V \approx n_i$, and $n_i = N - N/V$. Then, our equation becomes

$$\frac{d^2N}{dt} \approx - \frac{e^{-E/kT}}{V_0} \quad (17.6)$$

In other words, if we take a small V and smaller density of electrons, we have the volume of the our sites bigger and bigger, so each of the electrons had less room increase. And ionization, and then "expansion" is the density goes down, is the reason why we believe that at very low densities, n_e and n_i in the solid state between them, there may be ions present, even though we didn't understand it from the point of view of the available one σ . At density n , takes many, many kT of energy to make them, there are ions present.

Why can there be ions present when there is so much space around, while σ is infinite the density, the ions tend to disappear? Answer: Consider an ion. Every atom in a solid, light or another atom, or an ion, or whatever it is just maintains thermal equilibrium, strikes it. Very hard, because it takes such a little amount of energy, an electron comes off and on the is left. Now the electron, if the space is enormous, wanders and wanders and does not come near anything for years, perhaps. But once in a very long time, it does come back to V .

in motion, and then continue to make collisions. So the rate at which electrons leave moving out from the source is very low. But if the voltage is very small, an electron which has escaped takes so long to find another ion to recombine with that probability of recombination is very, very small, thus, despite of the large excess energy source, there may be a reasonable number of electrons.

42-4 Chemical kinetics

The same idea for the way we have just called "ionization" is also found to be the case in reaction. For instance, if two atoms *A* and *B* combine to form a compound *AB*, then if we think about it, we will observe the *AB* molecule is formed in form *A* \pm *B*. Well we call an electron, and it is what we mean by ion. Well, these calculations the equations of equilibrium are exactly the same in form:

$$\frac{d[R]}{dt} = k_1[A][B] - k_2[R]^2 \quad (42-3)$$

This formula, of course, is not clear, since the "probability" depends on how much value is allowed for the *A* and *B* atoms, and so on, but by the hydrodynamic argument we can identify what the meaning of the *kF* in the coefficient is, and it turns out that it is very close to the energy needed in the reaction.

Suppose that we want to understand it by formulating a model of collision as much as the way that we understand the evaporation formula, by asking about how many electrons come out & how many of them come back *A* & *B* and *C*. Suppose that *A* and *B* something is occurring every time one *A* will be formed compound *AB*. And suppose that the compound *AB* is a complicated molecule which breaks around and is hit by other molecules and for some time it sees enough energy to break and hasn't enough time into *A* and *B*.

Now it actually turns out, in chemical reactions, most of the atoms, come together with *A* and *B* and even though they may be released to the reactant *A* + *B* \rightarrow *AB*, the fact that *A* and *B* may bump each other does not necessarily make the reaction start. It usually is required that the collision be rather hard, i.e. fast enough to "knock" a "soft" collision between *A* and *B* apart, but doing even enough energy may be necessary in the process. So let's suppose that it is very common in chemical reactions that in order for *A* and *B* to form *AB*, they must just hit each other, but they have to hit each other with sufficient energy. This energy is called the activation energy—the energy needed to "knock" the reaction. Of course activation energy, the energy-energy needed in a collision in order that the reaction may really occur. Then the rate *R* at which *A* and *B* produce *AB* would involve the number of atoms or *N* times the number of atoms *N*/*R*, times the rate at which a single atom would do a certain cross section σ , times a factor $e^{-E/RT}$, which is the probability that they have enough energy:

$$R = N \sigma v N e^{-E/RT} \quad (42-4)$$

Now we have to find the opposite rate, *R*. The rate at which chance that *AB* will split. In order to split, it not only must have the energy *E* which it needs to break, it gets over, but, just as it was harder for *A* and *B* to come together, so there is a kind of hill top. And it has to climb over the activation energy, *E*, they don't have just enough energy just to get ready to pull apart, but a certain amount. So the climbing a hill up to a deep valley, they have to climb the hill coming in and they have to climb out of the valley and then over the hill come up back (Fig. 42-1). Thus the rate at which *AB* goes to *A* and *B* will be proportional to the number *N*/*R*, the one present times $e^{-E/RT}$:

$$R = N \sigma v N e^{-E/RT} \quad (42-5)$$

The *v* will depend the volume of atoms and the rate of collisions, where we can work out as $v = \pi d^2 n / 3$, d is the diameter and n is the density and thickness, but we shall not do this. The main feature of interest to us is that when these two

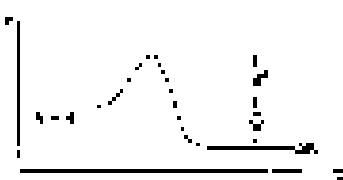

Fig. 42-1. The energy relationship for the reaction *A* + *B* \rightarrow *AB*.

ratio are equal, the ratio of their is equal to unity. This allows that $k_{\text{eff}} = k_1 k_2 \dots k_n = \frac{1}{e^{-E_1/kT} + e^{-E_2/kT} + \dots + e^{-E_n/kT}}$, where E_i denotes the activation energies, v_i denotes the collision velocities, and k is the Boltzmann constant.

The interesting thing is that the rate of the reaction also varies as $e^{-E/kT}$, although the exponent is not the same as that which governs the overall velocity. The activation energy A^* is quite different from the energy E . If you vary the proportion of A , B , and C that are left at equilibrium, then if you want to know how the A^* changes (Fig. 4.9), that is not a question of equilibrium, and there is a different energy, the activation energy A^* , given by the ratio of reaction times² an exponential factor:

Furthermore, A^* is not a fundamental constant like R . Suppose that at the surface of the wall—say at some other place— A and B could temporarily stick there in such a way that they could combine more easily. In other words, we might find a "tunnel" through the hill, or perhaps a lower hill. By the conservation of energy, when we let all particles we have still made ΔE in A of A and B , so the energy difference. If w^* be quite independent of the way the reaction occurs, but the activation energy A^* will depend very much on the way the reaction occurs.

This is why the rates of chemical reactions are very sensitive to outside conditions. We can change the rate by putting A on top of a different kind, we can put it in a "different barrel" and it will go at a different rate, that depends on the nature of the surface. Or, if we put in a third kind of object C , may change the rate very much since things produce enormous changes in rate simply by adding the A^* a little here—they are called catalysts. A reaction might accidentally not occur at all because $A^* > kT$ (Fig. 4). The given temperature, but when we put in this special stuff, the catalyst, then the reaction goes very fast indeed, because A^* is reduced.

Incidentally, there is some trouble with such a reaction, I think. Imagine A , B , C do not interact conserve both energy and momentum when they bump two objects together to make one that is more stable. Therefore, we need at least a rare object C , so the overall reaction is much more complicated. The forward rate would involve the product momenta, and it might seem that one formula is giving wrong, but not. What we look at the rate at which A 's goes, he takes away, we find that it has to collide with C , so there is no change in the reverse rate; that's carried out in the formula for the equilibrium concentration. They are in equilibrium, (4.2), which we first wrote down is obviously guaranteed to be true, no matter what the mechanism of the reaction may be.

42.5 Einstein's law of radiation

We now turn to calculating the energy distribution coming out with the black body radiation law. In the last chapter we worked out the alternative view to the radiation is to carry the way Planck did, considering the radiator, common oscillator. The oscillator had to lose its mean total energy, and since it was oscillating, it would radiate until would keep pumping radiation into the cavity until it piled up enough radiation to balance the absorption and emission. In fact, very few, until just the intensity of emission at frequency ν was given by the formula

$$I(\nu) d\nu = \frac{A \nu^3 h}{e^{h\nu/kT} - 1}. \quad (42.19)$$

This result involved the assumption that the oscillator whose was generated, radiation had definite, equally spaced energy levels. We did not say that light had to be a photon or anything like that. There was no discussion about how when an atom goes from one level to another, the energy must come out at one unit of energy. As, in the theory of light, Planck's original idea was that the nuclear was quantized but not the light, meaning oscillators can't take up just any energy, but have to take it in lumps. Furthermore, he trouble was the derivation is that it was partially circular. We calculated the rate of radiation from an oscillator according to classical physics, then we turned around and said, "No, the oscillator has a lot of energy levels. So gradually, as we do that, the light with the completely quantum mechanical result, from which a slow development.

ment which culminated in the quantum mechanics of 1927. But in the meantime there was one jump by Einstein to convert Planck's viewpoint that only oscillators or atoms were quantized, to the idea that light was really photons and could be considered as a certain way as particles with energy E . Furthermore, Bohr had pointed out that we knew of atoms having energy levels, but they are not necessarily equally spaced like Planck's model says. And so it became necessary to calculate, i.e., first, deduce the accurate law from a more accurately quantum-mechanics viewpoint.

Einstein assumed that Planck's law formula was right, and he used that formula to obtain some new information, previously unknown, about the transactivity of radiation from an atom. This discussion will be taken up later in the chapter on energy levels of an atom, say the nth level, in the Bohr model (Fig. 47-2). Now Einstein proposed that when such an atom has light of the right frequency striking it, it can absorb this photon of light and make a transition from state n to state $n+1$. And the probability that this occurs per second depends upon the two fields, of course, but is proportional to the intensity of light in that it is *linear* with it. Let us call this proportionality constant α , merely because of us that this is indeed a fixed constant of nature, but depends on the particular pair of levels being used. In reality, some levels are bound to exist. Now what is the formula going to be for the rate of emission from $n+1$? Einstein proposed that this must have two parts to it. First, even if there were no light present, there would be some chance that a photon in an excited state would fall to a lower state, emitting a photon; this is called spontaneous emission. An oscillator with a certain amount of energy, even in classical physics, does not keep that energy, but loses it by radiation. Thus the meaning of spontaneous radiation is this. The real situation is that if the atom is in an excited state there is a certain probability β , which depends on the levels again, so it will drop down to a lower level, and this probability is independent of whether light is striking on the atom or not. But then Einstein went further, and by comparison with the classical theory, and by a bit of simple reasoning, concluded that emission was also influenced by the presence of light, and other light of the right frequency is striking on an atom. It has an increase, α , of radiation, a photon loss, proportional to the intensity of the light, with a proportionality constant $\beta\alpha$. Later, if we calculate it, this coefficient turns out, then we will find that Einstein was wrong. Up to now we will find he was right.

This Einstein assumed that there are three kinds of processes: an absorption process from the intensity of light, an emission proportional to the intensity of light, and a pairwise removal or some interconversion involving, and a spontaneous emission independent of light.

Now suppose that we have, at equilibrium at temperature T , a certain number of atoms N_0 in the system and another number N_1 in the state n . Then the total number of atoms that are going up is to be the number that are in the state n . This however assumed that if we take N_0 it gives us to us, we have a formula for the number that are going from n to higher levels:

$$R_{1 \rightarrow n} = N_0 K_B T \beta(\nu). \quad (47-13)$$

The number that we go from n to $n+1$ is proportional to the same number, i.e., the ratio N_1/N_0 , but, in addition, to the fact that per second that each one goes down to n . This gives our expression is

$$N_{n+1} = N_0 (K_B T \beta(\nu) - R_{n+1}(\nu)). \quad (47-14)$$

Now we shall suppose that in thermal equilibrium the number of atoms going up is equal the number coming down. That is the way of heat, in which the number will be sure to stay constant is guaranteed.* So we take these two ratios

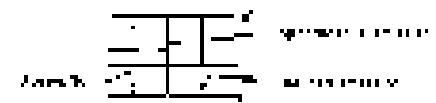

Fig. 47-2. Transitions between two energy levels of an atom.

*. It is not the only way we can change to keep the numbers of atoms in the various levels constant, but it is very naturally works. The steady process, in thermal equilibrium, is balanced by a zero gradient is called the principle of detailed balance.

to be zero, at equilibrium. But we also need the place of information, we know how large δ_{ν} is compared with χ ,—the ratio of those two is $\sim \chi/\delta_{\nu}$. The first Naes Finsen experiment had the only light which was effective in making the transition from n_0 to n_1 is the light which has the frequency corresponding to the energy difference, or $E_{n_1} - E_{n_0}$ in electron-volts. Thus

$$\delta_{\nu} = N_{n_0} \delta_{\nu}^{(1)}, \quad (42.15)$$

Thus if we set the term χ/δ_{ν} equal to $\delta_{\nu}/(\delta_{\nu} - \delta_{\nu}^{(1)})$, or $\delta_{\nu}/(\delta_{\nu}^{(1)})$, and divide by N_{n_0} , we get

$$E_{n_0} (\delta_{\nu})^{1/2} = \delta_{\nu} + \delta_{\nu}^{(1)} \quad (42.16)$$

From this equation, we can calculate δ_{ν} . It is as follows:

$$\delta_{\nu} = \frac{\delta_{\nu}^{(1)}}{N_{n_0} \delta_{\nu}^{(1)/2} + 1}. \quad (42.17)$$

But N_{n_0} has already told us that the formula must be plus 1%. Therefore we can deduce something. First, the N_{n_0} must equal $\delta_{\nu}^{(1)}$, since otherwise we would get the $(\delta_{\nu})^{1/2} = 1$. So Einstein discovered some time ago that he did not know very much about it, namely that the emission probability and the absorption probability must be equal. This is interesting. And afterwards, in order for (42.15) and (42.16) to agree,

$$\delta_{\nu}/\delta_{\nu}^{(1)} \text{ must be } = \delta_{\nu}^2/\delta_{\nu}^{(1)^2}. \quad (42.18)$$

So, if we know, for instance, the absorption rate for a given level, we can deduce the spontaneous emission rate and the stimulated emission rate, or any combination.

This is as far as Einstein or anyone else could go using such arguments. To actually compute the absolute spontaneous emission rate, i.e., the other rates for any specific atomic transition, one needs a knowledge of the mechanics of the atom, called quantum electrodynamics, which was not discovered until eleven years later. This work of Landau was done in 1930.

The possibility of address emission has, today, some interesting applications. If there is big pressure, it is hard to excite the downward transition. The electrons then tend to stick to the available energy, e.g., if there were some atoms stilling in the upper state. Now you can imagine, by some mechanism, caused to have a gas in which the number in the states is very much greater than the number in the states. This is not equilibrium, and so is not given by the formulae $\delta_{\nu}^{(1)}/\delta_{\nu}$, which is for equilibrium. We can even arrange it so that the number in the upper state is very large, while the pressure at the lower state is practically zero. The light which has the frequency corresponding to the energy difference $E_{n_1} - E_{n_0}$ will not be strongly absorbed, because there are not many atoms available. On the other hand, when that light is present, it will induce the emission from this upper state! So, if we took a lot of atoms in the upper state, there would be a sort of chain reaction, in which, the moment the atoms began to emit, more would begin to emit, and the whole lot of them would start again repeating. This is what is called a laser, or, in the case of the忘者, a maser.

Various devices have been obtained in this situation. There may be higher levels to which the atoms can get if we shine in a strong beam of light of high frequency. From these high levels, they may cascade down, emitting various photons, until they get stuck at the state n_0 . If they don't lie in the state of upward emission, the state is called metastable. And then they are all stimulated down together by induced emissions. One more technical point—if we put this system in a ordinary box, it would radiate in so many different directions spontaneously, compared with the induced effect, that we would not be in trouble. But we can enhance the required effect, because its efficiency, by putting nearly perfect mirrors on each side of the box, so that the light which is emitted gets reflected back and forth many, and another chance, to induce the re-emission. Although the mirror is almost one hundred percent reflecting, there is a slight amount of transmission of the mirror, and a little light gets out. In the end, of course, from the conservation of energy, all the light goes out in a single straight direction which makes the strong light beams that are possible today with lasers.

Fig. 42.2. By exciting, say an atom, into a higher state, which may emit a photon having energy $E_{n_1} - E_{n_0}$, the number in this state increases rapidly enough to start laser action.

Diffusion

47-1 Collisions between molecules

We have concentrated so far only the molecular motions in a gas which is in thermal equilibrium. We want now to discuss what happens when things are near, but not exactly in equilibrium. In a situation far from equilibrium things are extremely complicated, but in a situation very close to equilibrium we can easily work out what happens. To see what happens, we must, however, return to the kinetic theory. Since the mechanics and thermodynamics deal with the equilibrium situation, but even from equilibrium we can only analyze what occurs away from equilibrium.

As a simple example of a nonequilibrium circumstance, we can consider the diffusion of ions in a gas. Suppose that in a gas there is a relatively small concentration of free—electrically charged molecules. If we put an ion in it, and let it go, then it will have a force acting which is dependent on the forces on the negative constituents of the gas. If there were no other molecules present, the ion would have a constant acceleration until it reached the wall of the container. But because of the presence of the other molecules, it can see that its velocity increases only until it collides with a molecule and loses its momentum. It starts again to pick up its speed, but then it loses its momentum again. This is not efficient; it does not make a very efficient erratic path, but such is the motion in the direction of the electric force. We shall see that the ion loses on the average half its speed which is proportional to the electric field—the stronger the field, the faster it goes. While the field is on, and while the ion is moving along, it is, of course, not in thermal equilibrium; it is trying to get to eq. equilibrium, which is to be visited at the end of the motion. By means of the kinetic theory we can compute the drift velocity.

I leave out that with our present mathematical abilities we cannot really compute precisely what will happen, but we can obtain approximate results which exhibit all the essential features. We can, without loss of generality, start with one particle, and do it, but it will not be possible to get precisely the exact numerical answers in four or all the terms. We can, therefore, in our derivations, not worry about the precise value of summed factors. They can be obtained only by some much more sophisticated and complex treatment.

Before we consider what happens in nonequilibrium situations, we shall need to look a little closer at what goes on in a gas in thermal equilibrium. We don't need to know, for example, what the average time between successive collisions of a molecule is.

Any molecule experiences a sequence of collisions with other molecules—in a random way, of course. A particular molecule will, in a long period of time T , have a certain number, N , of hits. If we denote the length of time, there will be noncolliding time, so the number of hits is proportional to the time T . We would like to write it this way:

$$N \propto T^{\alpha} \quad (47.1)$$

We have written the constant of proportionality as $1/\tau$, where τ will have the dimensions of a time. The constant is the average time between collisions. Suppose, for example, that in six hours there are one million hits, that is, 6,000,000. We would say that a given molecule is the average time between 1,000,000 hits.

We may often wish to ask the following question: "What is the chance that a molecule will experience a collision during the next small interval of time $d\tau$?" The answer we must intuitively understand is $d\tau$. Let us, if trying to make a more

47-2 Collisions between molecules

47-2 The mean free path

47-3 The drift speed

47-4 Friction coefficient

47-5 Molecular diffusion

47-6 Thermal conductivity

continuing unchanged. Suppose now there were a very large number N of molecules. How many will have collisions in the next interval of time Δt ? If N is so large, nothing is changing on the average over time Δt . At time t we will have the same number of collisions as we have at time $t + \Delta t$. That number we know is $N\delta(t)$. So the number of Δt 's of N molecules is $N\delta(t)/\Delta t$, and the chance, or probability, of a hit for any one molecule is just $1/N$ or $\delta(t)/(N\Delta t)\delta(t) = \delta(t)$, as we guessed above. That is to say, the fraction of the molecules which will suffer a collision in the time Δt is $\delta(t)$. To take an example, if $\delta(t)$ is one billion, then in one second the fraction of particles which will suffer collisions is .0001. What this means, of course, is that 1/1000 of the molecules happen to be close enough to other they are going to hit next. One collision will occur in the next minute.

When we say that τ is the mean time between collisions, in one minute, we do not mean that all the collisions τ occur at times separated by exactly one minute. A particular particle does not have a τ time, wait one minute, and then have another collision. The time between successive collisions is quite variable. We will not need to do our later work over, but we may make a small diversion to answer the question "What are the times between collisions?" We know that for the case above, the average time is one minute, but we might like to know, for example, what is the chance that we get no collision for the population?

We shall find the answer to the general question, "What is the probability that a molecule will go for a time τ without suffering a collision?" At some arbitrary instant—that we call $t = 0$ —we begin to watch a certain molecule. What is the chance that it goes by until t without suffering with another molecule? To compute the probability, we observe what is happening to all the molecules in a container. After we have set out N molecules, how many have suffered up to the time t ? $N\delta(t)$, or fewer, less than $N\delta(t)$. We can think this because we know how it changes with time. If we know that $N\delta(t)$ molecules have got by until t , then $N\delta(t) - dt$ the number which get by until $t + dt$ is less than $N\delta(t)$ by the number that had collisions in dt . The number that collide in dt we have written above in terms of the mean time τ as $\delta(t) - \delta(t+dt)$. We have the equation

$$N(t + dt) = N(t) - N(t) \frac{dt}{\tau}. \quad (41.21)$$

The τ cancels on the left-hand side, $dN = -N/dt$, and we write, according to the definition of derivative, as $dN(t) = -dN(t)/dt dt$. Making this substitution, Eq. (41.21) yields

$$\frac{dN(t)}{N(t)} = -\frac{dt}{\tau}. \quad (41.22)$$

The numbers that are being lost in the interval of time dt is proportional to the number that are present, and inversely proportional to the mean time τ . Equation (41.22) is easily integrated if we rewrite it as

$$\frac{dN(t)}{N(t)} = -\frac{dt}{\tau}. \quad (41.23)$$

Each side is a perfect differential, so the integral is

$$\ln N(t) = -t/\tau + \text{constant}, \quad (41.24)$$

which says the same thing as

$$N(t) = N_0 e^{-t/\tau}. \quad (41.25)$$

We know that the constant must be just N_0 , the total number of molecules present, since all of them start at $t = 0$ to wait for their "first" collision. We can write our result as

$$N(t) = N_0 e^{-t/\tau}. \quad (41.26)$$

If we seek the probability of no collision, (43.6) we can get it by dividing $N(0)$ by $N_{\text{coll}} + 1$:

$$P(0) = e^{-\frac{\tau}{\bar{\tau}}}. \quad (43.8)$$

The result is the probability P that a particular molecule survives at time t without a collision is $e^{-t/\bar{\tau}}$, where $\bar{\tau}$ is the mean time between collisions. The probability starts out at 1 (or certainty) for $t = 0$, and gets less as t gets bigger and bigger. The probability that the molecule avoids a collision for a time equal to τ is $e^{-1} = 0.37 \dots$. This means less than one-half that it will have a greater than average time between collisions. That is all right, because there are enough molecules which go collision-free for times much longer than the mean time between colliding, so that the average time can still be τ .

We empirically define τ as the average time between collisions. The result we have obtained in Eq. (43.7) also says that the mean time from an arbitrary starting point to the next collision is also τ . We can understand this somewhat surprising fact in the following way. The number of molecules which experience their own constant τ at the instant t is the case after an arbitrarily chosen starting time is $N(t)/N_0$. Their "time until the next collision" is, of course, just t . The "average time until the next collision" is obtained the usual way:

$$\text{Avg time until the next collision} = \frac{1}{N(t)/N_0} \int_0^{\infty} t \frac{N(t)}{N_0} dt.$$

Using $N(t)$ obtained in (43.7) and evaluating the integral, we find indeed that τ is the average time from any instant until the next collision.

43-2 The mean free path

Another way of describing the molecular collisions is to talk not about the time between collisions, but about how far the particle moves between collisions. If we say that the average time between collisions is τ , and that the molecules have a mean velocity v , we can expect that the average distance between collisions, which we shall call λ , is just the product of v and τ . This distance between collisions is usually called the mean free path:

$$\text{Mean free path } \lambda = v\tau. \quad (43.9)$$

In this chapter we shall focus on molecular motion, since hardly anyone measures it in any particular case. The various possible averages—the mean, the root-mean-square, etc.—are all usually equal and differ by factors which are near to one. Since a detailed analysis is required to obtain the various numerical factors anyway, we need not worry about which average is required of any particular point. We may also note the reader that the standard symbols we are using for some of the physical quantities (e.g., λ for the mean free path) are not follows generally accepted conventions, mainly because there is no general agreement.

For the time, choose the λ molecule will have a collision in a short time if it is equal to d/v , the chance that it will have a collision in going a distance d is d/v . Following the same line of argument used above, the reader can show that the probability that a molecule will go a distance d before having its next collision is $e^{-d/\lambda}$.

The average distance a molecule goes before colliding with another molecule—the mean free path—will depend on how many molecules there are around, and on the “size” of the molecules, i.e., how big or large they represent. The effective “size” of a target in a collision we usually describe by a “collision cross section,” the same idea that is used in nuclear physics, or in high-energy particle

Consider a moving particle which travels a distance d through a gas which has N molecules (molecules per unit volume; Fig. 43-1). If we look at each unit of area perpendicular to the direction of motion of our selected particle, we find there n molecules. Then, our presents an effective collision area σ , as it is usually called, “collision cross section,” σ , from which a chance induced by the scattering is $n\sigma d/v$.

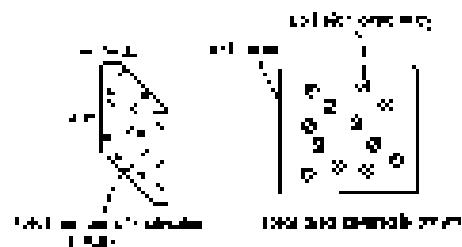

Fig. 43-1. Collision cross section.

By "collision cross section" we mean the area within which the center of our particle must be located if it is to collide with a particular molecule. If molecules were like spheres (a classical picture) we would repeat that as $\pi r_1^2 + \pi r_2^2$, where r_1 and r_2 are the radii of the two colliding objects. The chance that our particle \mathbf{r}_{tot} have a collision is the ratio of the area covered by scattering molecules to the total area, which we let σ_{coll} be to be zero. So, the probability of a collision going a distance d is just σ_{coll}/d .

$$\text{Chance of a collision in } dx = \sigma_{\text{coll}}/dx \quad (43.10)$$

We have seen above that the chance of a collision $= \sigma_{\text{coll}}$ also be written in terms of the mean free path λ as λ^{-1} . Comparing this with (43.10), we can relate the mean free path to the collision cross section:

$$\frac{1}{\lambda} = \sigma_{\text{coll}} \quad (43.11)$$

which is easier to remember than writing σ_{coll}

$$\lambda = \sigma_{\text{coll}}^{-1}. \quad (43.12)$$

The formula can be thought of as saying that the λ should be one collision, or one passage, when the particle goes through a distance λ^2 which leaves letting molecules come just cover the total area. At a cylindrical volume of length λ and radius $\lambda/2$ units, there are $4\pi/3$ surfaces. If each one has a chance, the total chance amounts to $4\pi/3$, which is just one unit of area. The whole area is proportional of course, because some molecules are partly hidden behind others. That is why some molecules go further than λ before they are in equilibrium. It is only for convenience that the mean free path is given by the time they get within area λ^2 . From measurements of the mean free path, we can determine the scattering cross section σ_{coll} , and compare the result with theory based on a detailed theory of atom-molecule. But that is a different subject. So we return to the problem of many-molecule gases.

43-3 The drift speed

We want to describe what happens to a molecule of several molecules, which are different in some way from the large majority of the molecules in a gas. We shall refer to the "numerous" molecules as the "background" molecules, and we shall call the molecule of interest 2, to distinguish the having few molecules ("special" molecule) from 1, the "background". A molecule could be special by any number of ways. It might be heavier than the background molecule. It might be a different element. It might have an electric charge, i.e., be an ion. It may consist of more than molecules. Because of their different masses or charges the forces it may have forces on them which are different from the forces on the background molecules. By considering what happens to these S molecules we can understand the basic effects which come into play in a similar way in many different phenomena. To start, let's use diffusion of gases. Atomic clusters in batteries, colloids, and emulsions, happen to do this.

We begin by concentrating on the basic process of A molecule in a background gas to move on its own specific force F (which might be, e.g., gravitational or due to heat) and to collision by the non-specific force due to collisions with the background molecules. We would like to describe the general behavior of the S molecule. What happens to it, in short, is that it moves around and goes at it will, like a swimmer again with other molecules. But, the point is, we shall see that it does make some net progress in the direction of the force, F. We say that there is a drift speed due to an accumulation. We would like to know what the speed, v_{drift} , is—it's drift velocity due to the force, F.

If we start to observe an S molecule at some instant we may expect that it is somewhere between two collisions. In addition to the velocity it was left with after its last collision, it is picking up some velocity component v_{drift} due to force F. In a

short time for the average, in a time τ , will experience a sufficient number of collisions in a new portion of its trajectory. It will have a new starting velocity, and it gains no acceleration from it.

To keep things simple for the moment, we shall suppose that after each collision our Sand-Dank gets a completely "fresh" start. That is, that it obeys no consequences of its past motion up to t . This might be a reasonable assumption if our Sand-molecule were much bigger than the tiny gas molecule, but it is certainly not valid. (page 2) We shall discuss later the improved assumption.

For the moment, then, our starting fact is that the Sand-molecule leaves each collision with a velocity which may be in any direction or at any speed. The starting velocity will also be equally in all directions and will not contribute to any net motion, so we shall not worry further about its initial velocity after a collision. In addition to its random motion, each Sand-molecule will, however, at any moment, an additional velocity in the direction of the force \mathbf{F} , which it has picked up since its last collision. What is the average *at time t* of the sum of the velocities?

For you, the acceleration F/m , where m is the mass of the molecule, has been the average from many previous collisions. Since the average *at time t* since the last collision must be the same as the average *from time t* to now collision, which we have called τ , equals $F/m\tau$. The average velocity from t to t , of course, is just what is called *the drift velocity*, so we have conclusion

$$\text{d.v.} = \frac{F\tau}{m} \quad (43.17)$$

This last relation is the heart of our subject. There may be some complications in determining what τ is, but the drift velocity is defined by Eq. (43.17).

You will notice that the drift velocity is proportional to the force. There is, unfortunately, no generally accurate or for the constant of proportionality. Different gases have been used for such different kinds of forces. In electrical problems the force is related to the charge times an electric field, $F = qE$. Then the constant of proportionality between the velocity and the electric field is the "mobility." In spite of the possible difficulties of measurement, we shall use the term mobility for the ratio of the drift velocity to the force F in newtons. We write

$$M = \frac{\text{d.v.}}{F} \quad (43.18)$$

In general, and we shall see later why, we have from Eq. 43.17 that

$$\nu = F/M \quad (43.19)$$

The mobility is proportional to the mean time between collisions (there are fewer collisions *as soon as it starts*) and inversely proportional to the mass. From this information we expect M to depend upon the mass.

To get the correct numerical coefficient in Eq. (43.19), which is correct as given, takes some care. Without intending to bore you, we should still point out that the arguments become subtler which can be appreciated only by a careful and detailed study. To illustrate our present difficulties, in spite of agreement, we shall make use again of the argument which led to Eq. 43.17 in a reasonably but unrigorous way (and the way one will find in most textbooks).

We might have said: The mean time between collisions is τ . At a sufficiently particular instant with the random velocity, but it possess a non-additional velocity between collisions, which is equal to the acceleration times the time. Since it takes the time τ to travel at the new velocity, it gets there with a velocity $(F/m)\tau$. At the beginning of the collision, it has zero velocity. Summing the two collisions it has, on the average, a velocity $\frac{1}{2}(F/m)\tau$ of the final velocity on the mean drift velocity $= (F/m)(\tau/2)$ (Eq. 43.17). This result is wrong and the result in Eq. (43.17) is right, although the arguments may sound equally satisfactory. The reason the second result is wrong is somewhat subtle, and we leave with the "fixing." The argument is made as though all collisions were separated by the mean time τ . The fact is that some jumps in velocity and others are longer than the mean. Short jumps occur more often but make less contribution to the drift velocity because they have less

comes "to really get going." If one takes proper account of the distribution of free times between collisions, one can show that there should not be far fewer τ_{coll} than obtained from the second argument. The story was made so trying, in relation to a simple argument, by average free velocity vs. average velocity itself. This relationship is no example, so it is best to concentrate on what is known: the average velocity itself. The first argument we gave determines the average velocity directly. And that's it! That we can perhaps see now why we shall not in general be in all of the correct numerical coefficients in our elementary calculations.

We return now to our simplifying assumption that each collision knocks off all energy of the pair system. Let's check what is made of each collision. Suppose our S -particle is a heavy object at a background of lighter particles. Then our S -particle will not lose its "kinetic" momentum in each collision. It would take many collisions before it became this "unmovable" agent. We should assume, instead, that each collision in some sense loses the energy — in fact a certain fraction of its momentum. We shall not work out the details, but note that the result is equivalent to replacing τ_{coll} by average collision time, by a two-and-fourth τ which corresponds to the average "forgetting time," i.e., the average time to forget its previous momentum. With such an interpretation of τ_{coll} we can use the formula (43.18) for situations which are not quite as simple as we first assumed.

43-4 Tissue conductivity

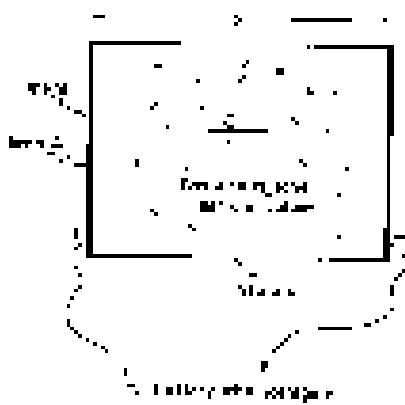

Fig. 43-7 Bedside current in ionized gas.

We now apply our results to a specific case. Suppose we have a gas in a vessel in which there are also some ions — atoms or molecules with a net electric charge. We show the situation schematically in Fig. 43-2. If two opposite walls of the container are metallic plates, we can connect them to the terminals of a battery and thereby produce an electric field in the gas. The electric field will result in motion of the ions, so they will begin to drift toward one or the other of the plates. An electric current will be induced, and the gas with its ions will become like a resistor. By computing the ion flow from the drift velocity we can compute the resistance. We ask, specifically: How does the flow of electric current depend on the voltage difference V that we apply across the two plates?

We consider the case that our container is a rectangular box of length L and cross-sectional area A (Fig. 43-2). If the potential difference in voltage from one plate to the other is V , the electric field E between the plates is V/L . (The electric potential is the work done in carrying a unit charge from one plate to the other. The force on a unit charge is E . If E is the same everywhere between the plates, which is a good enough approximation for now, the work done on a unit charge is just EV , or $V = EB$.) The electric force on an ion of rate q is qE , where q is the charge on the ion. The drift velocity of the ion is then v times this force, or

$$qE = mv^2 \quad \Rightarrow \quad qvE = mv^2 \frac{V}{L} \quad (43.19)$$

An electric current I is the flow of charge in a unit time. The electric current of one of the plates is given by the total charge of the ions which arrive at the plate in a unit of time. If the ions drift toward the plate with the velocity v_{drift} (that they which are within a distance $v_{\text{drift}}T$) are active at the plate in the time T , then, since N ions per unit volume, the number which reach the plate at the time T is $(N_A v_{\text{drift}})^2 v_{\text{drift}}^{-1} T$. Integration over the energy q , we have (43.19)

$$\text{Charge collects in } V \text{ in unit } T. \quad (43.20)$$

The current I is the charge collected in T divided by T , or

$$I = \frac{\text{charge}}{T} = \frac{qV}{L} \quad (43.21)$$

$$I = \mu d^2 n \frac{d}{2} E. \quad (43-19)$$

We find that the current is proportional to the voltage, where d is the length of the tube, and μ is a constant; it is the "value" of the proportionality constant.

$$\frac{I}{E} = \omega^2 n \frac{d}{2}. \quad (43-20)$$

We have a relation between the resistance and the molecular properties n , a , and μ , which depends on m , k , and ν . If we know n and μ from atomic measurements, a measurement of R could be used to determine a , and from a also:

43-5 Molecular diffusion

We turn now to a different kind of problem, one a different size of analysis: the theory of diffusion. Suppose that we have a container, or jar, of thermal expansion α , and that we introduce a small amount of a different kind of gas at some place in the container. We shall call the original gas the "background" gas, and the new one the "special" gas. The special gas will start to spread out through the whole container, but it will spread slowly because of the presence of the background gas. This slow spreading process is called diffusion. The diffusion is controlled mainly by the molecules of the special gas, being knocked about by the molecules of the background gas. After a large number of collisions, the special molecule will spread out more or less evenly throughout the volume of the whole volume. We must be careful not to confuse diffusion of a gas with convection transport, that may occur due to convection currents. Most commonly, the mixing of two gases occurs by a combination of convection and diffusion. We are interested here only in the case that there are no "drift" currents. The gas is spreading only by molecular motion, by diffusion. We wish to see just how fast diffusion takes place.

We now compute the average of molecules of the "special" gas due to the molecular motion. There will be a net flow only when there is some non-uniform distribution of the molecules; otherwise all of the molecular motion would average to give no net flow. Let us consider first the flow in the x -direction. To find the flow, we consider an imaginary plane surface perpendicular to the x -axis and count the number of special molecules that cross this plane. To obtain the net flow, we must count as positive those molecules that cross in the direction of positive x and subtract from this number the number which come in the negative x -direction. As we have seen many times, the number which crosses a surface area in a time Δt is given by the number σ such that the interval Δt is a volume which includes the distance ΔT from the plane. (Note that σ is the actual molecular velocity, not the drift velocity.)

We shall simplify our algebra by giving our surface one unit of area. The mean number of special molecules which pass "forward" right through the x -direction to the right is $\sigma_1 \Delta t$, where σ_1 is the number of special molecules per unit volume to the left within a factor of $\Delta x \times \Delta n$, here we are ignoring such factors). The number which cross "from right to left" is similarly, $\sigma_2 \Delta t$, where σ_2 is the number density of special molecules on the right-hand side of the plane. If we call the molecular current J by which we mean the net flow of molecules per unit area per unit time, we then

$$J = \frac{\sigma_1 + \sigma_2}{2T} \frac{\Delta x \Delta n \Delta t}{\Delta T}. \quad (43-21)$$

 ΔT

$$J = (\sigma_1 - \sigma_2) \tau. \quad (43-22)$$

What shall we use for σ_1 and σ_2 ? When we say "the density of the 'old'" molecules in the left side of the jar? We shall define the density at the place from which the molecules started their "flight," because the number which does such

mass is determined by the number present in the plume. So by the definition the density difference is the "equivalent concentration" with δn being the density at the distance r to the right of our cylinder center.

It is convenient to consider first the distribution of our special molecules in space, described by a continuous function $\rho(x, y, z)$ which we shall call ρ_0 . By $\rho_0(x, y, z)$ we mean the number density of special molecules in a small volume element centered at (x, y, z) . In terms of ρ_0 we can express the diffusion equation (41.18)

$$\partial \rho_0 / \partial r = D \cdot \frac{\partial^2 \rho_0}{\partial r^2} - \frac{\partial \rho_0}{\partial r} / \delta n. \quad (41.23)$$

Substituting this result in Eq. (41.20) and multiplying by a factor of 2, we get

$$J_x = -D \frac{\partial \rho_0}{\partial r}. \quad (41.24)$$

We have found that the flow of special molecules is proportional to the derivative of the density, or to what is sometimes called the "gradient" of the density.

This does not yet tell us how much current through approximations. Besides various factors of two we have left out, we have used a value we should have used 2, and we have assumed that ρ_0 and n refer to a plume in the perpendicular distance r from our surface; whereas for those molecules which do not travel perpendicular to the surface $\rho_0(r)$ is not equal to the density at distance r from the surface. All of these influences can be made; the results of a more careful analysis show that the right-hand side of Eq. (41.24) should be multiplied by 1/2. So a better answer is

$$J_x = -\frac{D}{2} \frac{\partial \rho_0}{\partial r}. \quad (41.25)$$

Similar equations can be written for the currents in the y and z directions.

The current J_x and resistance problem can be measured by macroscopic observations. The experimentally determined ratio is called the "diffusion coefficient" D . That is,

$$J_x = -D \frac{\partial \rho_0}{\partial r}. \quad (41.26)$$

We have been able to show that for a gas we expect

$$D = \eta k. \quad (41.27)$$

So far in this chapter we have considered two distinct processes: scattering of molecules due to "outside" forces; and diffusion by spreading determined only by the internal forces, the random collisions. There is, however, a relation between them, since they both depend basically on the incident molecules, and are zero free both of space in 1-D calculations.

With Eq. (41.27) we substitute $\rho_0 = \rho_0(r)$ and $r = \rho_0$ in the case

$$J_x = -D \rho_0^2 \frac{\partial \rho_0}{\partial r}. \quad (41.28)$$

But ρ_0 depends only on the temperature. We recall Eq.

$$k_B T^2 = 3kT. \quad (41.29)$$

so:

$$J_x = \omega D \frac{\partial \rho_0}{\partial r}. \quad (41.30)$$

We find that D , the diffusion coefficient is just ω times ρ_0 , the mobility coefficient:

$$\omega = \eta k. \quad (41.31)$$

And it turns out that the numerical coefficient in (41.31) is exactly right—no extra factors have to be chosen in order to fit our rough assumptions. We can show,

in fact, that (43.11) must always be correct, even in non-dilute situations (for example, the case of a suspension in a liquid, where the details of our simple calculation would not apply at all).

To prove that (43.11) must be correct, let's do it in a different way, using only one basic principle of statistical mechanics. Imagine a situation in which there is a gradient of "special" molecules, and we have a diffusion current proportional to the density gradient, according to Eq. (43.20). We now apply a force F in the x direction, so that the chemical potential field is $\phi = F$. According to the definition of the mobility μ , this will be a drift velocity given by

$$v_{\text{drift}} = \mu F. \quad (43.12)$$

By our usual arguments, the average number density of molecules which pass a unit of area in a unit of time is

$$J_{\text{drift}} = \mu N_A v_{\text{drift}}, \quad (43.13)$$

or

$$J_{\text{drift}} = \mu N_A F. \quad (43.14)$$

We now consider the force F so that the drift current due to F is zero. In other words, the drift current is zero for all non-special molecules. We have $J_{\text{drift}} = J_{\text{gas}} = 0$, or

$$\mu \frac{\partial \phi}{\partial x} = \nu_{\text{gas}} F. \quad (43.15)$$

This is the "modified" form of Fick's law (with the addition of density ρ in Eq. 1.29)

$$\frac{\partial \phi}{\partial x} = \frac{\nu_{\text{gas}} F}{\mu}. \quad (43.16)$$

But notice: We are describing an equilibrium condition, so our equilibrium laws of dilute ideal molecules apply. According to these laws, the probability of having n molecules at the coordinate x is proportional to e^{-nE} , where E is the potential energy. In terms of the number density n , this means that

$$n_x = n_0 e^{-\beta E(x)}. \quad (43.17)$$

If we differentiate (43.17) with respect to x , we find

$$\frac{\partial n_x}{\partial x} = -n_0 e^{-\beta E(x)} \cdot \frac{1}{kT} \frac{\partial E}{\partial x}, \quad (43.18)$$

or

$$\frac{\partial \phi}{\partial x} = -\frac{n_0}{kT} \frac{\partial E}{\partial x}. \quad (43.19)$$

In our situation, since the force F is in the x direction, the potential energy E is just $-Fx$, and $\partial E/\partial x = F$. Equation (43.19) then gives

$$\frac{\partial \phi}{\partial x} = \frac{n_0 F}{kT}. \quad (43.20)$$

(This is just exactly Eq. (10.2), from which we deduced ν_{gas} in the first place, since here n_0 is constant). Combining (43.16) with (43.19) we get exactly Eq. (43.11). We have shown that Eq. (43.11) which gives the diffusion current in terms of the mobility μ , has the correct coefficient and is very generally true. (Usually one diffusion experimentally measures μ . This relation was first deduced by Flory.)

43.4 Thermal conductivity

The methods of the kinetic theory that we have been using above can be used also to compute the thermal conductivity of a gas. If the gas at the top of a container is colder than the gas in the bottom, heat will flow from the top to the bottom. (We think of the top being "newer" because otherwise conduction would not be

set up and the problem would not keep the end of heat conduction). The transfer of heat from the hotter gas to the colder gas by the diffusion of the "heat" molecules with lower energy decreased and the addition of the "heat" molecules upward. To compute the flow of thermal energy we can ask about the energy at risk downward across an element of space by the mechanism being analyzed, and convert the energy at risk upward across the surface by the downward moving molecules. The difference will give us the net downward flow of energy.

The thermal conductivity κ is defined as the ratio of the rate of which thermal energy is carried versus the instantaneous temperature gradient.

$$\frac{1}{A} \frac{dQ}{dt} = -\kappa \frac{\Delta T}{L}. \quad (43.41)$$

Since the details of the calculations are quite similar to those we have done above at considering the flow of mass in a laminar flow, we shall leave it to the exercises for the reader to show that

$$v = \frac{k_e \sigma}{\tau}, \quad (43.42)$$

where $(\tau = 1.97)$ is the average energy of a molecule at the temperature T .

If we use the relation $(\kappa = 1/v)$, the heat conductivity can be written as

$$\kappa = \frac{1}{v} = \frac{k_e}{1.97 \sigma}. \quad (43.43)$$

We have another surprising result. We know that the average velocity of gas molecules depends on the temperature but not on the density. We know, however, that depend only on the size of the molecules. So our simple result says that the mean free path and therefore the rate of flow of heat in any particular circumstance is independent of the density of the gas! The change in the number of "carries" of energy with a change in density is just compensated by the larger distance the "carries" can go between collisions.

One may ask, "Is the heat flow independent of the gas density in the limit of low density perhaps?" When this is not true at all! One might note the formula (43.43) was derived, as were all the others in this chapter, under the assumption that the mean free path between collisions is much greater than any of the dimensions of the container. Whenever the probability exists for that a molecule has a short distance of crossing from one well of its container to the other without having a collision, none of the results given in this chapter apply. We must at such cases go back to kinetic theory and calculate again the details of what will occur.

The Laws of Thermodynamics

44-1 Heat Engines; the first law

So far we have been discussing the properties of matter from the *LJ* point of view, trying to understand why what happens if we squeeze hot things or stretch them, changing certain properties. However, there was no hope of calculating steps among the properties of substances which can be worked out without consideration of the detailed structure of the materials. The determination of the relationships among the various properties of materials, without knowing their internal structure, is the subject of thermodynamics. Historically, thermodynamics was developed before the understanding of the internal structure of matter was achieved.

As part of this, let us trace from the kinetic theory that the pressure of a gas is caused by molecular bombardment, and we know that if we heat a gas, its bombardment increases, the pressure must increase. Conversely, if the piston in a container of the gas is moved inward against the force of bombardment, the energy of the molecules bombarding the piston will increase, and consequently the temperature will increase. So, on the one hand, if we increase the temperature at a given volume we increase the pressure. On the other hand, if we compress the gas, we will find that the temperature will rise. From the kinetic theory, one can derive a quantitative relationship between these two effects, but one is likely to be right-handed that they are related in some necessary fashion which is independent of the details of the calculation.

Let us consider another example. Many people are familiar with this interesting property of rubber. If you take a rubber band and pull it a *little* more, it goes from its original length, for example, and pulls it out, he can feel a definite warning, and this warning is negligible in the sense that, if he releases the rubber band quickly while it is between his lips, it is definitely visible that occurs (i.e., when we stretch a rubber band it becomes longer when we release the tension of the band it coils). Now our instincts might suggest that if we拉伸 a band, or might pull, then the fact that pulling a band back in might imply that stretching a band should cause it to contract. And, in fact, if we apply a force to a rubber band holding its weight, we will see that the band contracts abruptly (Fig. 44-1). So it is true that when we have a rubber band it pulls, and this fact is definitely related to the fact that when we release the tension of it, it coils.

The internal machinery of rubber that causes these rather surprising complications. We will describe it from a molecular point of view to some extent although our main purpose in this chapter is to understand the relationships of these effects independently of the molecular model. In particular, we can see from the molecular model that the effects are directly related, this way to understand the behavior of rubber, it is necessary that this substance consists of an enormous tangled web of long chains of molecules, a kind of "molecular spaghetti," with one end, exemplified between the electric lamp are cross-links. The spaghetti that is sometimes welded together where it crosses and in place of spaghetti, a good example. When we pull on such a tangled network of the chains tend to pull on each other, the direction of the pull. At the same time, the chains are in their natural form, so they try and pull one firmly. It follows that such a net, if stretched, would not be like a normal stretched, because it would be held down the sides by the other chains and other electrons, and would tend to kink up again. So the real reason why a rubber band tends to contract is this: when one pulls it out, the chains are lengthened, and the thermal agitation of the molecules on the sides of the chains tend

44-2 Heat engines: the first law

44-3 The second law

44-4 Reversible engines

44-5 The thermodynamic temperature

44-6 Entropy

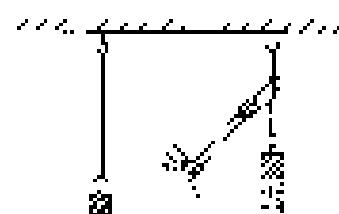

Fig. 44-1. The heated rubber band.

buckle the chains up and make them shorter. One can then appreciate that if the chains are held tautened and the temperature is increased, with the effect of the bombardment on the sides of the chains, there is an increase in the chains tends to pull in, and it is possible to put a stronger weight when loaded. In other terms, material for a time, a rubber band is allowed to relax and chain becomes soft, and the molecules walking in. You are by as they pass and from the relaxing chain. See the very good figure 1.

We have seen how these two effects, contraction when heated and stretching during relaxation, can be related by the binomial theory, but it would be a tremendous challenge to determine from the theory the precise relationship between the two. We would have to know how many different thermal expansion coefficients there are, what the chains look like, and we would have to be account of all kinds of other complications. The detailed mechanism is no example, but we can find by kinetic theory, pretty certainly exactly what happens at a definite interface between the two effects which occur to an extent without knowing anything about the internal machinery!

The whole subject of thermodynamics has already been fully up to the covering a kind of science different from another one is "stranger" to angle. Temperature is often to be at lower temperatures, it is not to be possible to lift weights, and to move them around, and thus you burn with heat. In fact, we have already seen experimentally that a twisted rubber band can lift a weight. The study of the way that one does work with heat is the beginning of the science of thermodynamics. Can we make an engine which uses the heating effect on a rubber band to work? One can cause a silly looking engine to do this, as the "Foucault's" bicycle wheel. You can make of the wheel with a lot of heat bands, then because "a longer" than the rubber bands on the other side. The center of gravity of the wheel will be pulled away from the bearing so that the wheel turns. At the same, a hot rubber band will expand the heat, and the bands move away from the heat and cool, so that the effect will be damped as long as the heat is applied. The efficiency of this engine is very nearly low. Four hundred watts of power pour into the thermometer, but it is just possible to lift 4 kg. With such an engine! An interesting question, however, is whether we can get heat to do the job more in more efficient ways.

In fact, the science of thermodynamics began with an analysis, by the great engineer Sadi Carnot, of the problem of how to built the best and most efficient engine, and this was just one of the few famous cases to which engineering has contributed significantly to physical theory. Another example that comes to mind is the more recent analysis of information theory by Claude Shannon. These two are you, interestingly, two can be closely related.

Now the way a steam engine, originally invented, is built is to pump some water, and the steam is to the engine and passes on a piston which makes a heat pressure, so the steam pushes the piston. And, the "Carnot heat" which he just a simple way to compute the cycle would be to let the steam escape into the air. If you do not stop supplying water, it is cheaper, more efficient to let the steam pass directly out, where it is combined by air, water, and then pass the water back to the boiler, or heat exchanger continuously. Heat is thus supplied to the engine and converted into work. Now would it be better to use alcohol? What property of fuel a substance have on than it makes the best possible engine? That was the question to which Carnot addressed himself, and one of his by-products was the discovery of the law of adiabaticity that we have just examined above.

The results of Carnot's engine are still considered important in certain applications, although statements called the law of thermodynamics. At the time when Carnot wrote, the first law of thermodynamics, the conservation of energy, was not known. Carnot's arguments were so carefully drawn, however, that they are said even though the first law was not known in his time. Some time later, Clausius' theory came to similar conclusions, which were understood more easily than Carnot's very elaborate reasoning. But it turned out that Clausius' work, and the famous 44-2

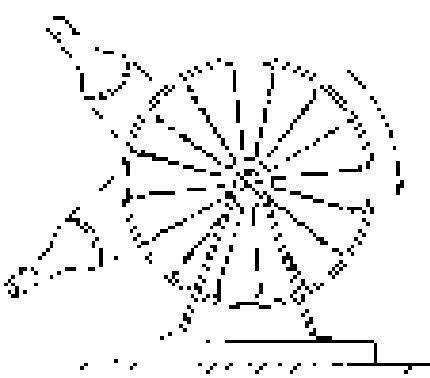

Fig. 44-2. The rubber-band bicycle.

on of energy in general, but that was not done and according to the colour theory, which was later shown to be false. So it has often been said that Carnot's logic was wrong, but his logic was quite correct. Only Carnot's simplified system, with everything read, was incorrect.

The so-called second law of thermodynamics was first discovered by Carnot before any first law. It would be interesting to give Carnot's argument, that did not use the first law, but we shall not do so because we want to be in physics, not history. What I mean by first law from the start, in spite of the fact that a great deal can be done without it,

Let us begin by stating the first law. If we increase the energy of one has a system and put heat into it, and they work out, then the energy is increased by the heat plus the work done. We can write this as follows. The heat Q put into a system plus the work W done on the system is the increase in the energy E of the system; the latter energy is sometimes called the internal energy.

$$\text{Change in } E = Q + W. \quad (44.1)$$

This change in E can be represented as taking a little heat dQ and doing a little work dW .

$$dE = dQ + dW, \quad (44.2)$$

which is a different form of the same law. We know that very well. Now to continue.

44.2 The second law

Now what about the second law of thermodynamics? We know that if we do work and the energy, the work added to us is equal to the heat added. If we do work at a constant temperature T , and we do the work slowly enough, the temperature does not change much, and the converted work and the given amount of heat will be equal. Is it possible to convert the heat back into work, at a given temperature? Is it possible to convert the heat back into work, at a given temperature? The second law of thermodynamics says that it is not. It would be very convenient to be able to convert heat into work merely by reversing a process like this. If we consider only the conservation of energy, we might think that just energy comes out in the vibrations of a molecule, might provide a good example of this. But Carnot assumed that it is impossible to extract the energy of heat at a single temperature. In other words, if the whole world were at the same temperature, one could not convert all this heat entirely into work, while the process of making work go into heat can take place at a given temperature, one cannot reverse it to get the work back again. Specifically, Carnot assumed that heat cannot be taken from a certain temperature and converted into work with no other change in the system or the surroundings.

The last point is very important. Suppose we have a lot of compressed air at certain temperature, and we let the air expand. If we do work, it can make increases in, for example, "Laws of" like in the expansion, but if we try to get the like expansion, at a given temperature, it does not do. We could warm it up again. So the heat added to the air, and we have done work with the compressed air. But Carnot was very wrong, because he did not take into this as if that, if we recompress the air, that we let expand, we will find we can do some work, and when we are finished we will discover that we can only get no work out of the system at temperature T , but we actually put some in. We must necessarily occur vibrations at which the result of the whole process is established, and we can't get more work just as the net result of the process of doing work against friction is to take work and convert it into heat. If we move a car, we will bring the system back precisely to its starting point, and the result the net work against friction and produced heat. Can we reverse the process? It is impossible, so that everything goes backwards, on the return, there won't be any, and ends the cycle. According to Carnot, no. So let us suppose that this is impossible.

If it were possible it would mean, among other things, that we could take heat out of a cold body and you "freeze" it. Only at present is it possible. Now we know it is natural that a hot thing can warm up a cold thing if we simply put a hot body and a cold one together. A discharge heating coil, our experience assures us, it is not going to happen next the hot one gets hotter, and the cold one gets colder. But if we could obtain work by extracting the heat out of the ocean, say, or from anything else at a single temperature, then that work could be converted back into heat by friction at some other temperature. For instance, the other arm of a working machine could be rubbing something that is already hot. The net result would be no work done. Thus a "heat" body, the ocean, could be put . . . into a hot body. Now, the hypothesis of Carnot, now known as of the second law, is sometimes stated as follows: heat cannot be used. Now Comte added to a hot object. But, as we have just seen, these two statements are quite different, but one cannot do what a process which only results to convert heat to work, at a single temperature, and secondly, heat can convert heat back by itself from a cold to a hot place. We shall merely use the first form.

Carnot's analysis of heat engines is quite similar to the argument that we gave above regarding engines in our discussion of the conservation of energy in Chapter 11. In fact, that argument was patterned after Carnot's argument about heat engines, and so the present lecture will follow very much the same.

Suppose we build a heat engine that takes "heat" Q_1 at a temperature T_1 . A certain heat Q_2 is taken from the boiler, the steam engine does some work W , and it then delivers some heat Q_3 into a "condenser" at another temperature T_2 (Fig. 44-3). Carnot did not say how much heat Q_2 was lost; he did not know the first law, and he did not use the first law. Heat Q_3 was equal to Q_2 , because he did not believe in it. Although everybody thought it so, according to the caloric theory, the heats Q_1 and Q_3 would have to be the same. Carnot did not say they were the same—but that is part of the weakness of his argument. If we do use the first law, we find that the net thermal Q_1 is the heat Q_3 , but we put in more heat if that was done:

$$Q_3 = Q_1 - W. \quad (44.5)$$

(If we have some kind of cyclic process where water is pumped back into the boiler after it is condensed, we will say that we have used Q_1 absorbed and sent W down. During each cycle, the a certain amount of water can goes around the cycle.)

Now we shall build another engine, and see if we cannot get more work from the same amount of heat being added at the temperature T_1 , with the condenser still at the temperature T_2 . We start out the same amount of heat, Q_1 , from the boiler, and we shall try to get more work than we did out of the steam engine—perhaps by using some new fluid, such as alcohol.

44-3 The reversible engine

Now we must analyze our engine. One thing is clear: we will not get something of the engine's power because in which there is friction. The best engine will be a frictionless engine. We assume, then, the same hypothesis that we did when we studied the conservation of energy. Let it a perfectly frictionless engine.

We must also consider the analog of free molecular motion, "frictionless" heat transfer. If we push hot object at a high temperature against a cold object, we can be heat flows, then it is not possible to make frictionless flow in opposite direction by a very small change in the temperature of either object. So when we have a heat engine operating, it can move it with a little force one way, "push hot way," and if we push it with a little force the other way, it goes the other way. We need to find the analog of molecular motion: heat transfer when direction we can move it only a little. If the difference in temperature is small, that is impossible, but if you make going the heat flows always the same two things, i.e., essentially, the same temperatures, will just not introduce any difference to make it flow in the desired direction. You, however, will be forced to heat source (Fig. 44-4). If we had

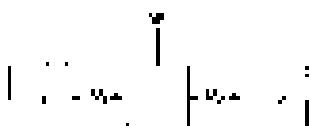

Fig. 44-3. Heat engine.

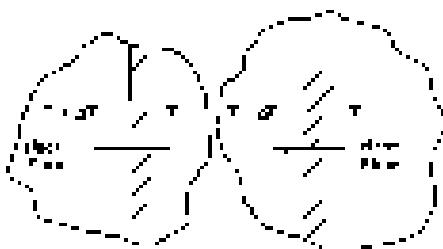

Fig. 44-4. Reversible heat engine.

The objection can be left a little, heat will flow to the gas; if we cool it a little, heat will flow out. But we find that the ideal engine is a *reversible* reversible machine, in which every process is reversible in the sense that, by minor changes, infinitesimal changes we can make the engine go in the opposite direction. This means that *nowhere* in the machine must there be any appreciable friction, and nowhere in the machine must there be any place where the heat of compression, or the flame of the boiler, is in direct contact with something definitely cooler or warmer.

Let us now consider an idealized engine in which all the processes are reversible. To show that such a thing is possible in principle, we will give an example of an engine cycle which may or may not be practical, but which is at least conceivable, in the sense of *Conceivable*. Suppose that we have a gas in a cylinder equipped with a free piston & piston. The gas is not necessarily a perfect gas. The fluid does not even have to be a gas, but to be specific let us say we have a perfect gas. Also, suppose that we have two heat pads, T_1 and T_2 , which may be things like the infinite temperature ∞ , T_1 and T_2 . We will suppose in this case that T_2 is higher than T_1 . Let's first cool the gas and then compress it, which is in contact with the heat pad at T_1 . As we do this, pushing the piston out very slowly so the heat flows from the gas, we will make sure that the temperature of the gas will be less than T_1 , and that the process will not be quite reversible, but if we pull it in slowly enough, the temperature of the gas will never depart much from T_1 . On the other hand, if we push the piston back slowly, the temperature would be more infinitesimally higher than T_1 , and the heat would flow back. We see that such an adiabatic compression is *approximately* reversible, that slowly and gently enough is a reversible process.

To make it more clear, we are doing what is called a *decompression*, or the pressure of the gas against its volume. As the gas expands, the pressure falls. The curve marked (1) tells us how the pressure and volume change if the temperature is kept fixed at the value T_1 . For an ideal gas this curve would be $PV = \text{constant}$. During the isothermal expansion the pressure falls as the volume increases until we stop at the point A. At the same time, a certain heat Q_1 enters the gas from the reservoir T_1 if the gas were insulated without a piston, it would, with the same work, it would cool off, so we *add* heat. Having continued the isothermal expansion, stopping at the point B, let us take the cylinder away from the reservoir and continue the expansion. This time we permit no heat to enter the cylinder. Again we perform the expansion slowly, so there is no reason why we cannot remove it and again it remains there, no friction. The gas continues to expand and the temperature falls since there is no heat gain/heat entering the cylinder.

We let the gas expand, following the curve marked (2), until the temperature falls to T_2 at the point C, but in this kind of expansion, made without adding heat, is called *adiabatic expansion*. Even on the gas, we find easily know that curve (2) lies below the curve $P^{\gamma} = \text{constant}$, where γ is a constant greater than 1, so that the adiabatic curve has a more negative slope than the isothermal curve. The gas cylinder has now reached the temperature T_2 , so that if we put it on the heat pad at temperature T_2 there will be no reversible change. Now we slowly compress the gas while it is in contact with the reservoir at T_2 , following the curve marked (3); (Fig. 44-2, Sec. 3). Because the cylinder is in contact with the reservoir, the temperature is constant, i.e., heat lost is flow from the cylinder into the reservoir at the temperature T_2 . Having compressed the gas adiabatically along curve (1) to the point D, we remove the cylinder from the heat pad at temperature T_2 and compress it still further without adding any heat, flow now. The temperature will rise and the pressure will follow the curve reversed (2). If we carry out each step properly, we can return to the point A at temperature T_1 where we started and repeat the cycle.

So we have, in Fig. 44-2, shown we have carried the gas through a complete cycle, and during one cycle we took up Q_1 at temperature T_1 , and have released Q_2 at temperature T_2 . Now the point is that this cycle is reversible in that we could represent it in steps the other way around. We could have gone backwards instead of forwards; we could have started at point A at temperature T_1 , expanded

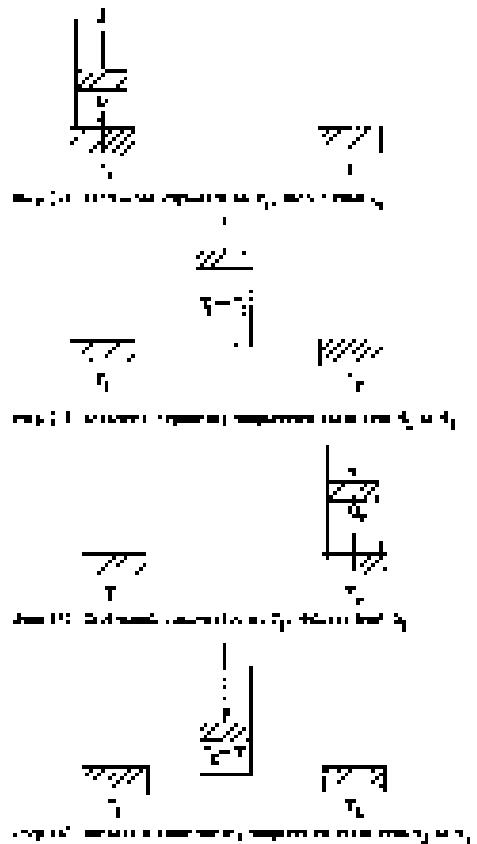

Fig. 44-3. Step in Carnot cycle.

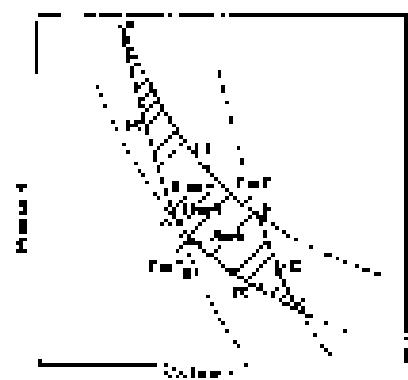

Fig. 44-4. The Carnot cycle.

along the curve. (4), expanded directly to temperature T_2 , absorbing heat Q_2 and $+W'$, along curve 4-5-6-7 along the cycle back to 1. If we run the cycle in one direction, we make the work on the gas; if in the other direction, the gas does work $+W'$.

Technically, it is easy to find out what the total amount of work is, because the work during expansion is the pressure times the change in volume, if δV . On this particular diagram, we know that P vertically and V horizontally, so if we call the vertical distance x and the horizontal distance y , that is $\int y dx$ in other words, the area under the curve. So the area under each of the numbered curves is a measure of the work done by or on the gas in the corresponding step. It is easy to see that the net work done is the signed area of the figure.

Now that we have given a single example of a reversible machine, we shall suppose that other sorts of machines also possible. That is, we assume that we have a reversible engine which takes (Q_1) at T_1 , does work W' , and delivers some heat to T_2 . Now let us suppose we have any compressor B made by means of a flywheel which is designed to absorb an amount of heat $Q_1 + W'$, and rejects the heat at the lower temperature T_2 (Fig. 44-7). Assume the engine B does no work. Then we shall show that B is acting as a heat reservoir. To see this, we can do more work than a reversible one. What? Suppose that, indeed, B works like this B' . Then we could take the heat Q_1 out of the reservoir at T_2 , and work engine B would do work W' and deliver some heat to the reservoir B . To see we do more work than a reversible one. That is, suppose that B' would do work W'' and deliver some heat to the reservoir B . Then, we do more work than B' ; we could use a part of it, W' , to drive the remainder, $W'' - W'$, for useful work. With this work W' we could run engine B backwards because it is a reversible engine. It will absorb some heat from the reservoir at T_2 and deliver Q_1 back to the reservoir at T_2 . After this double cycle, the net result would be that we would have put the system back the way it was before, and we would have done some excess work, namely $W'' - W'$, and all we would have done would be to extract energy from the reservoir at T_2 . We were careful to assume the heat Q_1 is the reservoir at T_2 . So that reservoir can be small and "instantaneous" and immobile machine A + B , whose net effect is therefore to remove a net heat $W'' - W'$ from the reservoir at T_2 , and convert it into work. But to obtain useful work from a reservoir at a single temperature with no other changes is impossible according to Carnot's principle; it cannot be done. Therefore no engine which absorbs a given amount of heat from a higher temperature T_2 and delivers it at the same temperature T_2 can do more work than a reversible engine operating under the same temperature conditions.

Now suppose that engine B is not reversible. Then, of course, not only must W' be not greater than W'' , but now we can reverse the argument and show that W' cannot be greater than W'' . So, if these engines are reversible they must both do the same amount of work, and with this come to Carnot's brilliant conclusion that A + B whose net effect is therefore to remove the net heat $W'' - W'$ from the reservoir at T_2 , and convert it into work. But to obtain useful work from a reservoir at a single temperature with no other changes is impossible according to Carnot's principle; it cannot be done. Therefore no engine which absorbs a given amount of heat from a higher temperature T_2 and delivers it at the same temperature T_2 can do more work than a reversible engine operating under the same temperature conditions.

If we could find out what the law is that determines how much work we obtain when we absorb the heat Q_1 at T_1 and we give back T_2 , this quantity would be a universal thing, independent of the substance. Of course if we knew the properties of the Coulomb interaction, we could work it out and thereby determine the substance must give the same amount of work in a reversible engine. That is the key idea, the clue by which it is possible to find the relationship between how much work is obtained when the field contracts when we heat it, and how much it costs when we let it contract. Imagine that we can turn rubber band into a reversible machine, and that we make it go around a reversible cycle. The net result, the total amount of work done, is then a universal function, that is to say, function which is independent of substance. So we see that a substance's properties must be limited in a certain way; one

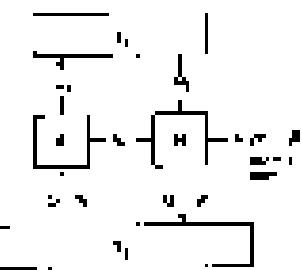

FIG. 44-7. Reversible engine A being driven backwards by engine B .

cannot make up anything he wants, or he would be able to live a life which he could use to produce more than the maximum amount of useful work when he carried it around a reversible cycle. This principle, this law, is the only law of nature that concerns us of the thermodynamics.

44.4 The efficiency of an ideal engine

Now we shall try to find the law which determines the heat \dot{Q}_1 as a function of T_1 , T_2 , and P_2 . It is clear that \dot{Q}_1 is proportional to \dot{Q}_2 , for if we consider two reversible engines in parallel, both working together and both doing the same, the combination is also a reversible engine. If each one does heat \dot{Q}_2 , the two together do $2\dot{Q}_2$, and the work done is also doubled, and so on. So it is not at all surprising that \dot{Q}_1 is proportional to \dot{Q}_2 .

Now the next important step is to find this relation law. We can, and will, do so by studying a reversible engine with the one particular substance whose laws we know, a perfect gas. It is also possible to obtain the rule by a purely logical argument, using our particular substance at ∞ . There is one of the very beautiful aspects of learning in physics and we are reluctant not to show it to you, but for those who would like to see it we said "there it is just a minute". The first we shall see the much less abstract and simpler method of direct calculation for a perfect gas.

We need only obtain formulas for \dot{Q}_1 and \dot{Q}_2 , for \dot{W} is just $\dot{Q}_2 - \dot{Q}_1$, the heat exchanged with the reservoir during the isothermal expansion or contraction. For example, how much heat \dot{Q}_1 is absorbed from the reservoir at temperature T_1 during the isothermal expansion (isentropic) from the initial point (P_1, V_1) to some point (P_2, V_2) , temperature T_2 , to point (P_2, V_2) pressure P_2 , volume V_2 , and the same temperature T_2 ? For a perfect gas each molecule has an energy that depends only on its temperature, and since the temperatures and the number of molecules are the same at (P_1, V_1) and at (P_2, V_2) , the total energy is the same. There is no change in total energy due to the work done by the gas.

$$\dot{W} = \int_{V_1}^{V_2} p dV,$$

during compression is energy \dot{W} , taken from the reservoir. During the expansion, $\dot{W} = \dot{m}RT_1$, or

$$p = \frac{\dot{m}RT_1}{V^2}$$

or

$$\dot{Q}_1 = \int_{V_1}^{V_2} p dV = \int_{V_1}^{V_2} \dot{m}RT_1 \frac{dV}{V} \quad (44.1)$$

and

$$\dot{Q}_1 = \dot{m}RT_1 \ln \frac{V_2}{V_1}$$

is the heat taken from the reservoir at T_1 . In the same way, for the compression of \dot{V}_2 (curve 12) of Fig. 44-6) the heat delivered to the reservoir at T_2 is

$$\dot{Q}_2 = \dot{m}RT_2 \ln \frac{V_2}{V_1} \quad (44.2)$$

To finish our analysis we must only find a relation between P_1/V_1 and P_2/V_2 . This we do by noting that a free, adiabatic expansion from \dot{V}_1 to \dot{V}_2 with pV^γ is a constant. Since $dV = \dot{m}RT$, we can write this as $(pV^\gamma)^{1/\gamma} = \text{constant}$, in terms of T and V , as $TV^{\gamma-1} = \text{constant}$,

$$T_1 V_1^{\gamma-1} = T_2 V_2^{\gamma-1} \quad (44.3)$$

Likewise, since $(pV)^\gamma$, the expansion from \dot{V}_2 to \dot{V}_1 , is also adiabatic, we find

$$T_1 V_1^{\gamma-1} = T_2 V_2^{\gamma-1} \quad (44.4)$$

If we divide this equation by the previous one, we find that \dot{W}_1/\dot{W}_2 , and \dot{V}_1/\dot{V}_2 , in the ratios (44.4) and (44.5) are equal, and that

$$\frac{\dot{Q}_1}{\dot{V}_1} = \frac{\dot{Q}_2}{\dot{V}_2}. \quad (44.7)$$

This is the relation we were seeking. Although proved for a perfect gas engine we know it must be true for any reversible engine at all.

Now we shall see how this reversible law could also be obtained by logical argument, without knowing the complete theory of any specific substance, as follows. Suppose that we have three engines and their temperatures, let us say T_1 , T_2 and T_3 . Let one engine absorb heat \dot{Q}_1 from the temperature T_1 and do a certain amount of work \dot{W}_{12} , and let it deliver heat \dot{Q}_2 at the temperature T_2 (Fig. 44-8). Let another engine run backwards between T_2 and T_3 . Suppose that we let the second engine be of such a size that it will absorb the same heat \dot{Q}_2 , and deliver the heat \dot{Q}_3 . We will have input exergy amount of work, \dot{W}_{23} , and its negative, because the engine is running backwards. When the first machine goes through a cycle it absorbs heat \dot{Q}_1 and delivers \dot{Q}_2 at the temperature T_2 ; then the second machine takes the same heat \dot{Q}_2 out of the reservoir at the temperature T_2 and delivers it into the reservoir at temperature T_3 . Therefore the net result of the two machines is to demand \dot{W}_{12} to take the heat \dot{Q}_1 from T_1 and deliver \dot{Q}_3 at T_3 . These two machines are thus equivalent to a third one, which absorbs \dot{Q}_1 at T_1 , does work \dot{W}_{12} , and delivers heat \dot{Q}_3 at T_3 , because $\dot{W}_{12} = \dot{W}_{12} - \dot{W}_{23}$. Let us now easily show from the first law, as follows:

$$\dot{W}_{12} - \dot{W}_{23} = (\dot{Q}_1 - \dot{Q}_2) - (\dot{Q}_2 - \dot{Q}_3) = \dot{Q}_1 - \dot{Q}_3 = \dot{W}_{13}. \quad (44.8)$$

We can now obtain the loss which enters the efficiencies of the engines, because this clearly must be some kind of relationship between the efficiencies of engines running between the temperatures T_1 and T_3 , and between T_2 and T_3 , and between T_1 and T_2 .

We can make the argument very clear in the following way. We have just seen that we can always relate the heat absorbed at T_1 to the heat delivered at T_3 by finding the heat delivered at some other temperature T_2 . Therefore we can get all the engines' properties if we know, or a standard temperature, everything with that standard temperature. In other words, if we know the efficiency of an engine running between certain temperatures T_1 and a certain arbitrary standard temperature, then we can work out the efficiency for any other difference in temperatures. Because we know, because using only reversible engines, we can work from the initial temperature down to the standard temperature and back up to the final temperature again. We can define the standard temperature arbitrarily as one degree. We shall then adopt a special symbol for the heat which is delivered at this standard temperature, which shall call it \dot{Q}_s . In other words, when a reversible engine absorbs the heat \dot{Q}_1 at temperature T_1 it will deliver, at the unit temperature, a heat \dot{Q}_s . If our engine absorbing heat \dot{Q}_1 at T_1 delivers the heat \dot{Q}_s at one degree, and if an engine absorbing heat \dot{Q}_2 at temperature T_2 will also deliver the same heat \dot{Q}_s at one degree, then it follows that an engine which absorbs heat \dot{Q}_1 at temperature T_1 will deliver heat \dot{Q}_s if it runs between T_1 and T_2 , as we have already proved by considering engines running between these temperatures. So all we really have to do is to find the standard heat \dot{Q}_s , we need to put in at the temperature of T_1 in order to deliver a certain amount of heat \dot{Q}_s at the unit temperature. If we discover that, we have everything. The heat, \dot{Q}_s , of course, is a function of the engine, i.e., T_1 . It is easy to see that the heat must increase as the temperature increases, for we know that it takes work to run an engine backwards and deliver heat at a higher temperature. It is also easy to see that the heat \dot{Q}_s must be proportional to \dot{Q}_1 . Our important law is now quite simple. For a given amount of heat \dot{Q}_s delivered at one degree from an engine running at temperature T_1 degrees, the heat \dot{Q}_s delivered must be that amount \dot{Q}_s times unity increasing linearly of the temperature:

$$\dot{Q}_s = Q_s(T). \quad (44.9)$$

44-5 The thermodynamic temperature

At this stage we are not going to try to find the formula for the above increasing function of the temperature in terms of our familiar centigrade temperature scale, but instead we shall define temperature by a new scale. At one time "the temperature" was defined empirically by dividing the expansion of water into even degrees of a certain size. But when one compares expansion with a mercury thermometer, one finds that the degrees are no longer even. But now we can make a definition of temperature which is independent of any particular substance. We can use the function $\beta(T)$ which does not depend on what substance we use, because the behavior of these reversible engines is independent of their working substances. Since the function β is constant with temperature, we will define the function $\theta(T)$ as the temperature, measured in units of the standard atmosphere temperature, as follows:

$$\theta = \beta T, \quad (44-10)$$

where

$$\theta_0 = \beta \cdot T_0. \quad (44-11)$$

This means that the heat lost on object is by forcing our standard heat, is also lost by a reversible engine working between the temperature of the object and the unit temperature (Fig. 44-6). If seven times more heat is lost out of a boiler than is delivered to a condenser, the temperature of the boiler will be only seven degrees, and so forth. By measuring how much heat is absorbed at the unit temperature, we determine the temperature. This is just what is done in this very simple absolute thermometric temperature, and it is independent of the substance. We shall use this definition exclusively from now on.¹

Now we see that when we have one engine, one working between T_1 and one degree, the odds making between T_1 and one degree defining the same heat θ_1 , or a temperature, then the heat absorbed must be called θ_1 .

$$\frac{\theta_1}{T_1} = \beta = \frac{\theta_2}{T_2}. \quad (44-12)$$

This also means that if we have a single engine running between T_1 and T_2 , then the result of the above analysis (by analogy) is that θ_1 is to T_1 as θ_2 is to T_2 . If the engine absorbs energy θ_1 at temperature T_1 and gives off heat θ_2 at temperature T_2 . Whenever the engine is reversible, the ratio between the heat absorbed to heat given off is the center of the ratios of the thermodynamic.

If this is all there is to thermodynamics, why is it considered such a difficult subject? In doing a problem involving a given mass of some substance, the condition of the substance at any moment can be described by telling what its temperature is and what its volume is. If we know the temperature and volume of a substance, and the substance is some function of the temperature and volume, then we know the internal energy. One could say, "This is not very difficult way. Tell me the temperature and the pressure, and I will tell you the volume." I can think of the volume as a function of temperature and pressure, and the internal energy is a function of temperature and pressure, and so on." That is why thermodynamics is hard, because everyone uses a different approach. If we would only sit down once and decide on our variables, and let's do here, it would be fairly easy.

Now we start to make distinctions. Just as $T = \theta_0$ is the center of the universe in mechanics, and it goes on and on and on after that, in the same way the principle just found is all there is to thermodynamics. They can one make contributions to it?

¹ We have previously defined our scale of temperature in a different way, namely by saying that the mean kinetic energy of a molecule is proportional to the temperature, and that the performance of an engine is proportional to T . Is this new definition equivalent? Yes, since the first result (44-11) derived from the first law is the same as that given here. We shall discuss this point again in the next chapter.

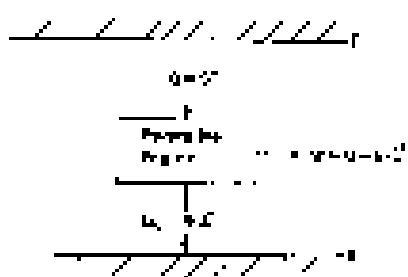

Fig. 44-6. Absolute thermodynamic temperature.

We begin. To obtain our first conclusion, we shall combine heat, law, the law of conservation of energy and this law which relates the heats Q_1 and Q_2 , and we can easily obtain the efficiency of a reversible engine. From the first law, we have $W = Q_1 - Q_2$. According to the new principle,

$$Q_1 = \frac{T_1}{T_2} Q_2$$

so the work becomes

$$W = Q_1 \left(1 - \frac{T_2}{T_1}\right) = Q_1 \frac{T_1 - T_2}{T_1} \quad (44.10)$$

which tells us the efficiency of the engine. The total work we get out of the mass, however. The efficiency of an engine is proportional to the difference in the temperatures between which the engine runs, divided by the higher temperature.

$$\text{Efficiency} = \frac{W}{Q_1} = \frac{T_1 - T_2}{T_1} \quad (44.11)$$

The efficiency of most engines at their normal operating temperatures is around 20% to 30%, absolute zero. So, since T_1 must be positive, the efficiency is always less than unity. That is our first conclusion.

4.1.6 Entropy

Equation 44.7 or 44.10 can be interpreted in a special way. Working always with reversible engines, a heat Q_1 at temperature T_1 is "reciprocated" to Q_2 at T_2 if $Q_1/T_1 = Q_2/T_2$, in the sense that one is absorbed the other is released. This suggests that if we call Q/T remaining, we can say: "a reversible process as much Q/T is associated to it liberates, there is no gain or loss of Q/T . $T_1 > Q/T$ is called entropy, and we say "heat is nothing but a change in entropy in a reversible system." If $Q/T = 0$, then the entropy is Q/T or, as we symbolize it, $Q/T^0 = S$. Actually, S is the letter usually used for entropy, and it is numerically equal to the heat (which we have called Q) of unit area. However, (entropy is not itself a heat, it's heat divided by a temperature, because it's measured in joules per degree).

Now it's interesting that besides the pressure, which is a function of the temperature and the volume, and the internal energy, which is a function of temperature and volume, we have four variables, all of which is a function of the condition, i.e., the entropy of the substance. Let us try to explain how we denote S_1 and S_2 : We mean what we call a "function of the condition." Consider the system in two different conditions, a and b , we find in the experiment where we did the adiabatic and isothermal expansions (thermodynamically, there is no need that the engine does only these processes, it could have three or four different expansions at which it takes in and delivers heat, and so on). We can move around on a $p-V$ diagram a , over the cycle, and go from one condition to $a \rightarrow b \rightarrow a$. In other words, we could do the same in a certain condition a , and then in going over to some other condition b , and we will require that this transition, made known to be reversible. Now suppose that all along the path from a to b we have to overcome at different temperatures, so that the heat dQ removed from the substance at each little step is converted to each reservoir of the temperature corresponding to that point on the path. Then let us assume all these reservoirs, by whatever means, to a range between the two temperatures. When we are finished carrying the substance from a to b , we still bring it to the case we took off their original condition. Any heat dQ that has been released from the substance at temperature T has now been converted by a reversible machine, and a certain amount of entropy dS has been added at the unit temperature as follows:

$$dS = dQ/T \quad (44.12)$$

Let us determine the total amount of entropy which has been released. The entropy difference is the entropy needed to get S out of S_1 by this path.
 44-10

reversible transformation, is the total entropy, the total of the entropy taken out of the system, minus, and different at the unit temperature:

$$S_e - S_u = \int_{T_1}^{T_2} \frac{dQ}{T}. \quad (44.16)$$

The question is, does the entropy difference depend upon the path taken? There is more than one way to go from a to b . Remember that in the Carnot cycle we could go from a to b (Fig. 44-10) by first expanding isothermally and then adiabatically, or we could first expand adiabatically and then isothermally. So the question is whether the entropy change, which occurs when we go from a to b in Fig. 44-10 in the same OR ONE CYCLE AS IT WOULD ANOTHER. It would be reasonable because if we went $a \rightarrow b$ via around the cycle, going forward then $a \rightarrow b$ and backward on another, we would have a reversible engine, and there would be no loss of heat to the reservoir at unit temperature. In a truly reversible cycle, no heat may be taken from the reservoir at the unit temperature; so the entropy needed to go from a to b is the same over one part as it is over another. It is independent of path and depends only on the endpoints. We can, therefore, say that entropy is a *state function*, which we shall mean simply by *state*, thus depending only on the condition, i.e., only on the volume and temperature.

We can find a function $S(T)$ which has this property—the “law” implies the change in entropy, as the substance is moved along any reversible path, in terms of its heat removed at unit temperature, then

$$\Delta S = \int \frac{dQ}{T}, \quad (44.17)$$

where dQ is the heat removed from the substance at temperature T . This total entropy change is the difference between the entropy calculated at the initial and final points:

$$\Delta S = S(T_2, T_1) - S(T_1, T_2) = \int_{T_1}^{T_2} \frac{dQ}{T}. \quad (44.18)$$

This expression does not completely define the entropy, but rather only the difference of entropy between two different temperatures. Only if we can calculate the entropy for one special condition can we truly define a *temperature*.

For a long time it was believed that absolute entropy meant nothing, that only differences could be defined—but finally Nernst proposed what he called the *Absolute Entropy*, which is also called the *Third Law of Thermodynamics*. It is very simple. We will see what it is, but we will not explain why it is true. Nernst's postulate states simply that the entropy of any object at zero temperature is zero. We know of one case at $T = 0$ K, namely $S = 0$, where S is zero; and so we can set the entropy at any value point.

To give an illustration of the reverse of this idea, let me take up a perfect gas. Let us isothermal (and therefore reversible) expansion, $\int dQ/T = 0/J$, since T is constant. Therefore (from 44.17) the change in entropy is

$$S(T_2, T_1) - S(T_1, T_2) = \theta R \ln \frac{V_2}{V_1}$$

so $S(T, V) = \theta R \ln V$ is some function of V only. Now does S depend on T ? We know that for a free volume adiabatic expansion, S does not increase. Thus entropy does not change even though T changes, provided that V changes such that $TV^{\gamma-1} = \text{constant}$. Can you see that this implies that

$$S(V, T) = \theta k \left[\ln T + \frac{1}{\gamma-1} \ln V \right] + c,$$

where c is a constant, independent of both V and T . θ is called the *absolute constant*. It depends on the gas in question, and may be determined experimentally. From the Carnot Cycle, by measuring the heat liberated in cooling and condensing

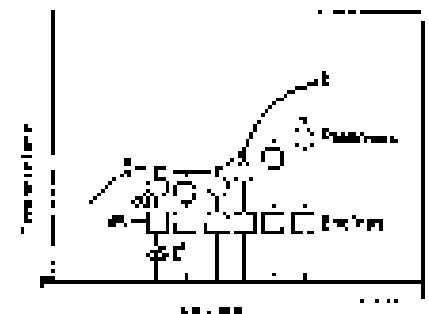

Fig. 44-10. Change in entropy during a reversible isothermal cycle.

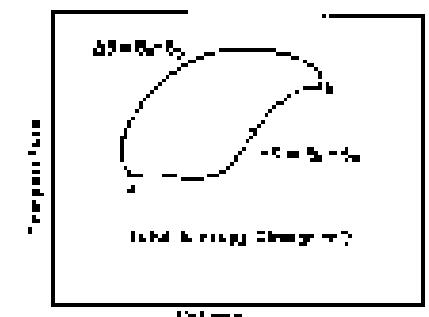

Fig. 44-11. Change in entropy in a non-reversibly reversible cycle.

the gas, and it is brought to a point (or for liquid, a liquid) at T , by expending $\delta Q/T$. It can also be demonstrated theoretically by means of Planck's constant and quantum mechanics, but we shall not study it in this course.)

Now we shall review some of the properties of the entropy of things. We first remember that if we do Q of reversible work on a system by δQ , then the entropy of the substance will change by $\Delta S = \delta Q/T$. And we remember that as we go along the path, the entropy—the heat delivered at temperature—increases according to the rule $dS = dQ/T$, where $dQ > 0$ the heat we remove from the substance when its temperature is T .

We already know that if we have a reversible cycle, the total entropy of everything is not changed, because the heat (Q) absorbed at T_1 and the heat (Q) released at T_2 correspond to equal and opposite changes in entropy, so that the net change in the entropy is zero. So for a reversible cycle there is no change in the entropy of anything, including the universe. This rule may not be the conservation of energy again, but it is odd; it applies only to reversible cycles. If we include irreversible cycles there is no law of conservation of entropy.

We shall give two examples. First, suppose that we do irreversible work on an object by friction, passing Q and Q' on some object at temperature T . The entropy is increased by Q/T . The heat Q is used in the work, and thus when we do a certain amount of work by friction against an object whose temperature is T , the entropy of the whole world increases by Q/T .

Another example of irreversibility is this: If we put together two objects that are at different temperatures, say T_1 and T_2 , a certain amount of heat will flow from one to the other by itself. Suppose, for instance, we put a hot stone in cold water. Then when a certain heat ΔQ is transferred from T_1 to T_2 , how much does the entropy of the hot stone change? It decreases by $\Delta Q/T_1$. How much does the water entropy change? It increases by $\Delta Q/T_2$. The heat will, of course, flow only from the higher temperature T_1 to the lower temperature T_2 , so that ΔQ is positive $\geq T_1 > T_2$. So the change in entropy of the whole world is positive, and it is the difference of the two first laws:

$$\Delta S = \frac{\Delta Q}{T_2} - \frac{\Delta Q}{T_1}. \quad (44.19)$$

So the following proposition is true: In any process that is irreversible, the entropy of the whole world is increased. Only in reversible processes does the entropy remain constant. Since no process is truly reversible, there is always at least a little gain to the universe, a reversible process is an idealization of which we have nothing to gain or entropy-minimal.

Unfortunately, we are not going to enter into the field of thermodynamics very far. Our purpose is only to illustrate the principal ideas involved and the reasons why it is possible to make such arguments. You will find that thermodynamics very often in this course. Thermodynamics is used very often by engineers and particularly by chemists. So we must learn some thermodynamics in physics in chemistry or engineering. Because it is not *mathematics*, complicating everything, we shall just give basic conclusions of the origin of the theory, rather than teach all the general applications.

The two laws of thermodynamics are often stated this way:

First law: the energy of the universe is always constant

Second law: the entropy of the universe is always increasing

This is not a very good statement of the second law; it does not say, for example, that in a reversible cycle the entropy stays the same, and it does not say exactly what the entropy is. It is just a close approximation to the two laws, but it does not really tell us exactly what it means. We have summarized the laws discussed in this chapter in Table 44-1. In the next chapter we shall apply these laws in disease. The relationship between the heat generated in the expansion of a rubber band, and the entropy increase when it is heated.

Table 44.1
Summary of the laws of thermodynamics

First law:

Heat added to a system \rightarrow work done on a system \rightarrow increase in internal energy of the system:

$$\delta Q + \delta W \approx dU.$$

Second law:

A common usage (and net result) is to take heat from a reservoir and convert it to work is impossible:

No heat engine taking heat Q_1 from T_1 and delivering heat Q_2, T_2 can do more work than a reversible engine, for which

$$\Delta U = Q_1 - Q_2 = Q_1 \left(\frac{T_2 - T_1}{T_1} \right).$$

The entropy of a system is often (but not always)

(a) If heat ΔQ is added reversibly to a system at temperature T , the increase in entropy of the system is $\Delta S = \Delta Q/T$.

(b) $dS = 0$ if $T = 0$ (absolute zero)

In a reversible change, the total entropy of all parts of the system (including reservoirs) does not change.

In irreversible change, the total entropy of the system always increases.

Illustrations of Thermodynamics

45-1 Internal energy

Thermodynamics is a rather difficult and complex subject when we want to apply it, and it is not appropriate for us to go very far into the applications at this time. The subject is of very great importance, however, to engineers and chemists, and those who are interested in the subject can learn about the requirements in physical chemistry or in engineering thermodynamics. There are also good reference books, such as Zemansky's *Heat and Thermodynamics*, where one can learn more about the subject. In the Encyclopedia Britannica, four volumes, one can find excellent articles on thermodynamics and thermodynamics, and in *Physical Chemistry*, there are four chapters on physical chemistry, vapor law, liquefaction of gases, and so on.

The subject of thermodynamics is complicated because there are so many different ways of describing something. If we wish to describe the behavior of a gas, we can say that the measure depends on the temperature and on the volume, or we can say that the volume depends on the temperature and the pressure. Or, were we to refer to the internal energy U , we might say that it depends on the temperature and volume, if those are the variables we have chosen. But we might also say that it depends on the temperature and the pressure, or the pressure and the volume, and so on. In the last chapter we discussed a certain function of temperature and volume, called the entropy S , and we can of course construct as many other functions of these variables as we like: T . S is a function of temperature and volume. We see here a large number of different quantities which can be functions of many different combinations of variables.

To keep the subject simple in this chapter, we shall stick at the earliest and most basic and reduce to the independent variables. Because we know, as said previously, that it is easier to measure and control in chemical experiments, here we shall use temperature and volume throughout this chapter, except in one place where we shall see how to make the transformation into the common system of variables.

We shall first then, consider only one system of independent variables: temperature and volume. Secondly, we shall discuss only two dependent functions: the internal energy and the pressure. All the other functions can be derived from these, so it is not necessary to discuss them. With these limits, however, thermodynamics is still a fairly difficult subject, but it is not quite so impossible.

First we shall review some mathematics. If a quantity is a function of two variables, the idea of the derivative of the quantity receives a little more emphasis than for the case where there is only one variable. What do we mean by the derivative of A with respect to the variable T ? The pressure changes accompanying a change in the temperature depends partly, of course, on what happens in the volume while T is changing. We must specify the change in V before the concept of a derivative with respect to T has a precise meaning. We might ask, for example, for the rate of change of P with respect to T if V is held constant. This is not just the ordinary derivative that we usually write as dA/dT . We systematically use a special symbol, $\partial A/\partial T$, to remind us that A depends on several variables P and V is on T , and that A 's other variable is held constant. We do not only use the symbol ∂ to call attention to the fact that the other variable is held constant, but we also use the notation that A held constant as a value $(\partial A/\partial T)_P$. Since we have only two independent variables, this notation is redundant, but it will help us keep our wits about us in the thermodynamic jungle of partial derivatives.

45-2 Entropy

45-2 Applications

45-3 The Clausius-Clapeyron equation

Let us suppose that the function $f(x, y)$ depends on two independent variables x and y . By $\partial f/\partial x$, we mean simply the ordinary derivative, obtained in the usual way, if we treat y as a constant:

$$\left(\frac{\partial f}{\partial x}\right)_y = \lim_{\Delta x \rightarrow 0} \frac{f(x + \Delta x, y) - f(x, y)}{\Delta x}.$$

Similarly, we define

$$\left(\frac{\partial f}{\partial y}\right)_x = \lim_{\Delta y \rightarrow 0} \frac{f(x, y + \Delta y) - f(x, y)}{\Delta y}.$$

For example, if $f(x, y) = x^2 + xy$, then $(\partial f/\partial x)_y = 2x + y$, and $(\partial f/\partial y)_x = x$. You can no longer refer to simple derivatives: $\partial^2 f/\partial x^2$ or $\partial^2 f/\partial y^2$. The latter symbol indicates that we first differentiate f with respect to x , treating y as a constant, then differentiate the result with respect to y , treating x as a constant. The overall order of differentiation is immaterial: $\partial^2 f/\partial x \partial y = \partial^2 f/\partial y \partial x$.

We will need to compute the change Δf in $f(x, y)$ when we change $x \rightarrow x + \Delta x$ and $y \rightarrow y + \Delta y$. We assume throughout the following that Δx and Δy are infinitesimally small:

$$\begin{aligned} \Delta f &= f(x + \Delta x, y + \Delta y) - f(x, y) \\ &= \underbrace{f(x + \Delta x, y + \Delta y) - f(x, y + \Delta y)}_{\Delta x \left(\frac{\partial f}{\partial x} \right)_y} + \underbrace{f(x, y + \Delta y) - f(x, y)}_{\Delta y \left(\frac{\partial f}{\partial y} \right)_x}. \end{aligned} \quad (45.1)$$

The last equation is the **differential relation** that expresses Δf in terms of Δx and Δy .

As an example of the use of this relation, let us calculate the change in the internal energy $U(T, V)$ when the temperature changes from T to $T + \Delta T$ and the volume changes from V to $V + \Delta V$. Using Eq. (45.1), we write

$$\Delta U = \Delta T \left(\frac{\partial U}{\partial T} \right)_V + \Delta V \left(\frac{\partial U}{\partial V} \right)_T. \quad (45.2)$$

In our last chapter we found a similar expression for the change ΔH in the enthalpy when a quantity of heat ΔQ was added to the gas:

$$\Delta H = \Delta T + P \Delta V. \quad (45.3)$$

In comparing Eqs. (45.2) and (45.3) one might be led to think that $P = (\partial H/\partial V)_T$, but this is not correct. To obtain the correct relation, let us first suppose that we add a quantity of heat ΔQ to the gas while keeping the volume constant, so that $\Delta V = 0$. With $\Delta V = 0$, Eqs. (45.2) and (45.3) reduce to $\Delta U = \Delta Q$, and Eqs. (45.2) and (45.3) reduce to $\Delta H = (\partial U/\partial T)_V + \Delta Q$, so that $(\partial U/\partial T)_V = \Delta Q/P$. The ratio $\Delta Q/P$, the amount of heat one must put into a substance in order to change its temperature by one degree with the volume held constant, is called the **specific heat at constant volume** and is designated by the symbol C_V . By this argument we have shown that

$$\left(\frac{\partial U}{\partial T}\right)_V = C_V. \quad (45.4)$$

Now let us again add a quantity of heat ΔQ to the gas, but this time we will hold T constant and allow the volume to change by ΔV . The analysis in this case is more complex, but we can calculate ΔH by the argument of Carnot, and find the result of the Carnot cycle we introduced in the last chapter:

The pressure-volume diagram for the Carnot cycle is shown in Fig. 45.1. As we have already seen, the total amount of work done by the gas in a reversible cycle is $\Delta Q(T_f/V_f)$, where ΔQ is the amount of heat energy added to the gas as it expands adiabatically at the temperature T from volume V_i to $V_f = \Delta V$, and $T_f = T_i$. The final temperature reached by the gas is, in accordance with the first law of thermodynamics, given by the equation

the shaded area in Fig. 45-1. In some circumstances, the work done by the gas is $P dV$, and its positive when the gas expands and negative when the gas is compressed. If we plot $P \times V$, the variation of $P \times V$ is represented by a curve which gives the value of P corresponding to a particular value of V . As the volume changes from one value to another, the work done by the gas (in ergs) in dV is the area under the curve connecting the initial and final values of P . When we apply this idea to the Carnot cycle, we see that as we go around the cycle, owing attention to the sign of the work done by the gas, the net work done by the gas is just the shaded area in Fig. 45-1.

Now we want to evaluate the shaded area geometrically. The cycle we have used in Fig. 45-1 differs from that used in the previous chapter in that we now suppose the ΔT and ΔQ are "infinitesimally small". We are working between adiabatic lines and isothermal lines that are very close together, and the "steps" described by the broken lines in Fig. 45-1 will approach a parallelogram as the increments dT and dQ approach zero. The area of this parallelogram is just $dP dV$, where dV is the change in volume as energy dQ is added to the gas at constant temperature, and dP is the change in pressure as the temperature changes by dT at constant volume. One can easily show that the shaded area in Fig. 45-1 is given by $dP dV$ by recognizing that the shaded area is equal to the area enclosed by the dashed lines in Fig. 45-2, which is just dV times the rectangle bounded by dP and dV only by the addition and subtraction of the shaded triangular areas in Fig. 45-2.

Now let us summarize the main result of the arguments we have developed so far.

$$\left. \begin{aligned} \text{Work done by the gas} &= \text{shaded area} = \Delta Q \left(\frac{\Delta T}{T} \right) \\ \text{or} \\ &= \frac{\Delta T}{T} \cdot \text{heat needed to change } V \text{ by } dV \text{ at } T \\ \text{or} \\ &= \Delta P \cdot \text{change in } T \text{ when } T \text{ changes by } dT \text{ at } V \\ \text{or} \\ &= \frac{1}{2} V \cdot \text{heat needed to change } T \text{ by } dT, \quad T \left(\frac{\partial U}{\partial T} \right)_V \end{aligned} \right\} \quad (45.7)$$

Equation (45.7) expresses the essential result of Carnot's argument. The whole of thermodynamics can be deduced from Eq. (45.7) and the First Law, which is stated in Eq. (45.3). Equation (45.7) is essentially the Second Law, although it was originally deduced by Carnot in a slightly different form, since he did not use our definition of temperature.

Now we are prepared to calculate $(\partial U / \partial T)_V$. By how much would the internal energy change if we changed the volume by dV ? First, $dU = -dQ + dW$. This is first, and second, dQ comes because work is done. The heat term is

$$dQ = T \left(\frac{\partial F}{\partial T} \right)_V dT,$$

according to Eq. (45.5), and the work done is $-F dV$. Therefore

$$dU = T \left(\frac{\partial F}{\partial T} \right)_V dT - F dV. \quad (45.8)$$

Dividing both sides by dV , we get for the rate of change of U with V at constant T

$$\left(\frac{\partial U}{\partial V} \right)_T = T \left(\frac{\partial F}{\partial V} \right)_T = P. \quad (45.9)$$

In most thermodynamics, in which F and P are the only variables and P and V are the only functions, Eqs. (45.6) and (45.9) are the basic equations from which all the rest of the subject can be deduced.

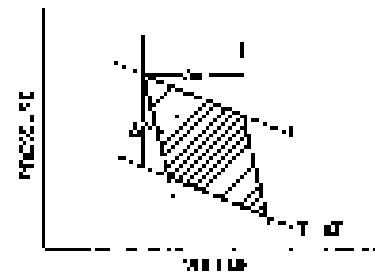

Fig. 45-1. Pressure-volume diagram for a Carnot cycle. The curve meeting T and $T - \Delta T$ are isothermal lines; the steeper curves are adiabatic lines. ΔV is the volume change at heat ΔQ is added to the gas at constant temperature T . ΔP is the pressure change in constant volume at the gas temperature is changed from T to $T - \Delta T$.

Fig. 45-2. Shaded area = area enclosed by dashed lines = area of rectangle = $dP dV$.

45.2 Applications

Now let us discuss the meaning of Eq. (45.7) and see why it answers the questions which we proposed in our last chapter. We considered the following problem: at constant density, the volume of a rubber band depends on temperature, because of the thermal movements of the atoms of a rubber. For the same pressure, suppose when we let the piston move back, that is when out of the gas and, in order to keep the temperature constant, heat will have to be put back in. The question is when it expands, and the pressure rises what is needed? There must be some connection between these two phenomena, and this connection is given explicitly by Eq. (45.7). If we hold the volume fixed and increase the temperature, the pressure rises at a rate $(\partial P / \partial T)_V$. Related to that fact is this: if we increase the volume, the gas will cool unless we put some heat in; in accordance with the temperature condition, and only ΔU tells us the amount of heat needed to raise the temperature. Equation (45.7) expresses the fundamental interrelationship between these two effects. That's where we predicted we would find when we discussed the laws of thermodynamics. Without knowing the internal mechanism of the gas, and knowing only that we cannot make perpetual motion of the second type, we can deduce the relationship between the amount of heat needed to maintain constant temperature when the gas expands, and the pressure change when the gas is cooled.

Now that we have Eq. (45.7), we want to apply it to determine the rubber band. When we stretch it, that is, when we heat it, its temperature falls, and when we heat a rubber band, we find that it pulls itself in. What is the equation that gives the same relation for a rubber band as Eq. (45.7) gives for gas? For a rubber band equilibrium will be something like this: when $\Delta U = 0$, i.e., the internal energy is changed by ΔU and ΔU is zero work is done. The only difference will be that the work done by the rubber band is $-F dL$ instead of $P dV$, where F is the force on each end, and L is the length of the band. The value F is a function of temperature and of length of the band. Replacing ΔU in Eq. (45.7) by $-F dL$, we get

$$\Delta U = -F dL + \Delta U_{\text{ext}} \quad (45.8)$$

Comparing Eqs. (45.7) and (45.8), we see that the rubber band equation is obtained by a direct substitution of one term for another. Furthermore, if we substitute $-F$ for P , and $-L$ for V , in our discussion of the Carnot cycle applies to the rubber band. We can immediately deduce, for instance, that the heat ΔU needed to stretch the band by dL is given by the expression $(\partial U / \partial L)_{T,P} dL = F(T, P, L) dL$. This equation tells us that if we keep the length of a rubber band fixed and heat the band, we can calculate how much the force will increase in terms of the heat, needed to keep the temperature constant when the band is stretched a little bit. So we see that the same equation applies to both gas and a rubber band. In fact, if one can write $\Delta U = -F dL + \Delta U_{\text{ext}}$, where F and ΔU_{ext} represent different quantities, force and length, pressure and volume, the result may apply to heat conduction. For example, substituting dA and θ for dL and T . For example, consider the electric potential ϕ between the "voltage," V in a battery and the "charge," Q , that moves through the battery. We know that the work done in passing the charge, Q , through the battery, is QV . (Since we include a QV term in the work, we require that our battery maintains a constant voltage.) Of course, what thermodynamics can tell us about the performance of a battery. If we substitute dA for dL and θ for T in Eq. (45.8), we obtain

$$\frac{\Delta U}{dA} = -F \left(\frac{\partial V}{\partial Q} \right)_A \theta \quad (45.9)$$

Equation (45.9) says that the internal energy U is changed when a charge dQ flows through the cell. What is $\Delta U/dQ$ not simply the voltage V ? In battery? The answer is that a real battery gets warm when charge moves through the cell. The internal energy of the battery is changed, first, because the battery did some work in the external circuit, and second, because the battery is heated. The nu-

workable thing is that the standard free enthalpy can be expressed in terms of the way in which the battery voltage changes with temperature. Fortunately, when the charge moves through the electron circuit, reaction $\text{A} + \text{B} \rightarrow \text{C}$, Eq. (45.9) says precisely the way of measuring the amount of energy required to produce a chemical reaction. All we need do is measure a cell that, when on the reaction, measure the voltage, and measure how much the voltage changes with temperature when we take an charge from the battery!

Now we have another! But the volume of the battery can't be an infrared constant, since we have obtained the $P\Delta V$ term when we do the work done by the battery equal to E_cell . That is not true; it is technically quite difficult to keep the volume constant. It is much easier to keep the total Δn constant. This approach is preferable. For this reason, the chemists do not use any of the equations we have written above; they prefer equations which do not contain Δn under constant pressure. We chose at the beginning of this chapter, after Eqs. 45.4 and 45.5, independent variables. The chemists prefer P and T , and we will now consider how the results we have obtained up to now are transformed into a new kind of system of variables. Remember that in the following treatment oxygen is a unity set in parentheses, so we are shifting gears from T and P to T and P .

We started in Eq. 45.9 with $\Delta H^\circ = \Delta Q - P\Delta V$; $P\Delta V$ may be replaced by $P\Delta T + P\Delta S$. If we could somehow replace the last term, $P\Delta S$, by ΔH° , then we would now interchanged P and T , and the chemists would be happy. We can do this if we notice that the difference of the terms in Eq. 45.4 is $\Delta H^\circ + P\Delta V$, and if we add this equality to Eq. 45.5, we obtain

$$\frac{\Delta H^\circ = P\Delta V + P\Delta T}{\Delta H^\circ = \Delta Q - P\Delta S} = P\Delta T$$

$$\frac{\Delta H^\circ - \Delta Q}{\Delta H^\circ - P\Delta V} = P\Delta S$$

In order that our result look like Eq. (45.5), we define $\Delta = P\Delta T$ to be something new, called the *voltage*, Δ , and we write $\Delta = \Delta Q - P\Delta V$.

Now we are ready to transform our variables into standard language with the following rules: $\text{P} \rightarrow P$, $\text{J} \rightarrow -P$, $\text{V} \rightarrow P$. For example, the fundamental relationship that chemists would use instead of Eq. (45.7) is

$$\left(\frac{\partial f}{\partial P}\right)_T = -f\left(\frac{\partial f}{\partial T}\right)_P = 1.$$

It would now be clear how one transforms to the chemists' variables P and T . We now go back to our original variables; for the remainder of this exercise, P and T are the independent variables.

Now let us apply the results we have obtained to a number of physical situations. Consider first an ideal gas. From kinetic theory we know that the internal energy of a gas depends only on the mass of the molecule and the number of molecules. The internal energy depends on T , but not on P . If we change P but keep T constant, E is not changed. Therefore in $\partial Q/\partial T = 0$, and Eq. 45.7 reduces to the, for an ideal gas,

$$-\left(\frac{\partial f}{\partial T}\right)_P = P = 0. \quad (45.10)$$

Equation 45.10 is a differential equation for f , or something about P . We take account of the partial derivatives in the following way: Since the partial derivative is to constant P , we will replace the partial derivative by an ordinary derivative and we explicitly, to remind us, constant P . Equations 45.10) then becomes

$$\frac{\Delta f}{\Delta T} = P = 0; \quad \text{constant } P. \quad (45.11)$$

which we can integrate to get

$$\ln P = \ln T + \text{const.} = \text{const. } K, \quad (45.12)$$

$$P = \text{const. } \times T = \text{const. } K. \quad (45.12)$$

We know that for an ideal gas the pressure is equal to:

$$P = \frac{RT}{V} \quad (45.13)$$

which is consistent with (45.2), since V and R are constants. Why did we bother to go through this calculation if we already knew the results? Because we have been using the "absolute" definition of temperature. At this stage we assumed that the kinetic energy of the molecules was proportional to the temperature, an assumption that defines one scale of temperature which we will call the "ideal gas scale." The T in Eq. (45.2) is based on this gas scale. We also say a temperature measured on the gas scale must be the same. Further, we defined the temperature in a way which was completely independent of the substance. From large tables based on the Simeon's law we defined T_0 . We might call the "grand thermodynamic absolute temperature" T , the T that appears in Eq. (45.13). What we learned here is that the pressure of an ideal gas (defined as one for which the internal energy does not depend on the volume) is proportional to the T and the molecular weight of the molecule. We can know that the pressure is proportional to the temperature measured on the gas scale. Therefore when we divide total molecular temperature by proportionality constant we get the "grand thermodynamic absolute temperature," that means of course, but if we were sensible we would make two scales agree. In this instance, at least, the two scales agree because chosen so that they actually are proportional by constant has been imposed to us. Most of the time man chooses himself for himself, but in this case he made them equal.

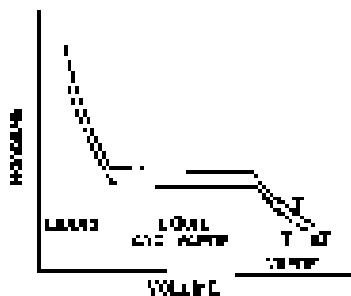

Fig. 45-9. Isothermal lines for a condensable vapor compression in a cylinder. At the left, the substance is in the liquid phase. At the right, the substance is vaporized. In the center, both liquid and vapor are present in the cylinder.

45-7 The Clausius-Clapeyron equation

The vaporization of a liquid is another application of the results we have derived. Suppose we have some liquid in a cylinder, such that we can compress it by pushing on the piston, and we ask ourselves, "If we keep the temperature constant, how does the pressure vary with volume?" In other words, we want a curve on isothermal line in the $P-V$ diagram. The substance in the cylinder is not an ideal gas but as mentioned earlier, since it may be in the liquid or the vapor phase, we both may be present. If we apply sufficient pressure, the substance will condense to a liquid. Now if we squeeze still harder, the volume changes very little, and we increase the pressure, finally with decreasing volume, as shown at the left in Fig. 45-9.

If we increase the volume, by pulling the piston out, the pressure drops until we reach the point at which the liquid starts to boil, and then vapor starts to form. If we pull the piston out further, all that happens is that more liquid evaporates while more liquid and part vapor in the cylinder. The two phases are in equilibrium. Liquid is evaporating and vapor is condensing at the same rate. If we make more room for the vapor more vapor is needed to maintain the pressure, so a little more liquid evaporates, but the pressure remains constant. On the flat part of the curve in Fig. 45-9 the pressure does not change, and the value of the press., as here is called the vapor pressure at temperature T . As we continue to increase the volume, there comes a time when there is no more liquid to evaporate. At this juncture, if we expand the cylinder further, the volume will fall as for an ordinary gas, as shown at the right of the $P-V$ diagram. The lower curve in Fig. 45-9 is the iso-enthalpic line at slightly lower temperature $T - \Delta T$. The pressure in the liquid phase is slightly reduced because liquid expands with α . Increase in temperature (for most substances, but not for water near the freezing point) and, of course, the vapor pressure is lower at the lower temperature.

We will now make a cycle out of the two isotherm lines by connecting them together by adiabatic lines between the ends of the flat sections, as shown in Fig. 45-4. The little jagged on the lower right-hand corner of the figure will indicate the difference and we will neglect. We are going to use the argument of Carnot, which tells us that the heat added to the substance is hanging it from a liquid and again is related to the work done by the substance as it goes around the cycle. Let

Fig. 45-10. Pressure-volume diagram for a Carnot cycle with a condensable vapor in the cylinder. At the left, the substance is in the liquid state. A quantity of heat Q_1 is added at temperature T_0 to vaporize the liquid. The vapor expands adiabatically as T changes to $T = T_0$.

us call L the heat needed to vaporize the substance in the cylinder. As in the experiment immediately preceding Eq. (45.13), we know that $L(2T_0) = \text{work done by the substance}$. As before, the work done by the substance is $L \times \text{vaporized area}$, which is approximately $\Delta P(T_0) \cdot V_0$, where $\Delta P(T_0)$ is the difference in vapor pressure at the two temperatures $T_0 < T < 2T_0$, V_0 is the volume of the gas, and V_0 is the volume of the liquid, both volumes measured at the vapor pressure. Setting these two expressions for the areas equal, we get $L(2T_0) = \Delta P(V_0 - V_0)$.

or

$$\frac{L}{V_0(V_0 - V_0)} = (\partial P/\partial T)_0. \quad (45.14)$$

Thus Eq. (45.14) gives the relationship between the rate of change of vapor pressure with temperature and the amount of heat required to vaporize the liquid. This relationship was deduced by Carnot, but it's called the Clausius-Clapeyron equation.

Now let us compare Eq. (45.14) with the results deduced from kinetic theory. Here T_0/V_0 is very much larger than T_0 . So $V_0 - V_0 \approx V_0 = RT/P$ per mole. If we further assume that L is a constant, independent of temperature, and if we good approximation for ΔP we have $\Delta P/T = L/V_0^2 T^2$. The solution of this differential equation is

$$P = C T e^{-L/V_0 T}, \quad (45.15)$$

Let us compare this with the power law variation with temperature that we deduced earlier from kinetic theory. Kinetic theory indicated the possibility, at least roughly, that the number of molecules of vapor above a liquid would be

$$n = \left(\frac{V}{V_0}\right) e^{-L/V_0 - 2E_0/RT}, \quad (45.16)$$

where $E_0 - V_0$ is the internal energy per mole in the liquid. Since the internal energy per mole in the gas, i.e., the energy needed to vaporize a mole of liquid. Equation (45.15) from thermodynamics and Eq. (45.16) from kinetic theory are very closely alike, because the pressures are the same, but they are not exactly the same. However, they will turn out to be exactly the same if we assume $L = T_0$, or equivalently, if $L = \text{const}$. If we ignore $L - E_0$, a constant independent of temperature, then the argument leading to Eq. (45.15) will produce Eq. (45.16).

This comparison shows the similarities and discrepancies of thermodynamics and kinetic theory. First of all, the agreement is exact, while Eq. (45.16) can only be approximated, for instance, if L is really constant and it the mole. \approx right. Second, we may not understand correctly how the gas becomes liquid, nevertheless, Eq. (45.15) is right, while (45.16) is only approximate. Third, although non-linearity applies to a gas condensing into a liquid, the argument is true for any other change of state. For instance, the solid-liquid transition has the same kind of curve as that shown in Figs. 45.3 and 45.4. Introducing the latent heat L resulting from the latent heat change in Eq. (45.14) there is $(\partial P_{\text{gas}}/\partial T)_0 = \Delta P/V_0^2 T_0 = L/V_0^2$. Although we may not understand the kinetic theory of the melting process, we nevertheless have a correct equation. However, when we compare with the kinetic theory, we have another difference. Equation (45.15) is only a *Calculus* approximation, and we have no way of obtaining the constants of integration, i.e., the kinetic theory can obtain the constants also if we have a good model that describes the phenomenon completely. So there are advantages and disadvantages to each. Why? Knowledge is weak, and the situation is complex, thermodynamical relations are only the most general. When the situation is very simple and a theoretical calculation is made, then it is better to try to go more in to mathematical theoretical analysis.

One more example: blackbody radiation. We have discussed a box containing radiation and nothing else. We have looked at the equilibrium between the radiation and the radiation. We also found that the pressure hitting the wall of the box would over the pressure P and we found $PV = U/T$, where $T > 0$.

and energy of all k -photons $\omega \in V$ is the volume of the box. If we substitute $\Omega = \partial V$ in the box Eq. (45.7), we find

$$\left(\frac{\partial \Omega}{\partial V}\right)_V = \Omega \quad \Rightarrow \quad \left(\frac{\partial \Omega}{\partial V}\right)_V = S. \quad (45.10)$$

Since the volume of our box is constant, we can replace $(\partial \Omega / \partial V)_V$ by $dV/dV = 1$ to get $S = \text{const} \propto V$. The pre-factor of V varies as the fourth power of the temperature and the energy content of the radiation, $S/V = P/V$, also varies as T^4 . It is useful to write $S/V = (4\pi/3)T^4$, where c is the speed of light and ϵ is constant. It is not possible to get ϵ from thermodynamics alone. There is a prior example of its power, and its limitations. We know that S/V goes as T^4 is a good idea, but to know how big S/V actually is at any temperature requires that we integrate the function ϵ itself. But only a complete theory can supply such backgound radiation we have since a theory and we can obtain an expression for the constant ϵ in the following manner.

Let $d\omega$ be the frequency distribution, i.e. energy flow through $\epsilon \text{ m}^2$ in one second with frequency between ω and $\omega + d\omega$. The energy density distribution = energy/volume = $E(\omega)/V$ is

$$\begin{aligned} \frac{E}{V} &= \text{total energy density} \\ &= \int_{-\infty}^{\infty} \text{energy density } \epsilon \text{ and } \omega + d\omega \\ &= \int_{-\infty}^{\infty} \frac{E(\omega) d\omega}{c}. \end{aligned}$$

From our car's discussions, we know that

$$E(\omega) = \frac{\hbar \omega^3}{\pi^2 c^3 (e^{h\omega/kT} - 1)}.$$

Substituting this expression for $E(\omega)$ in our equation for E/V , we get

$$\frac{E}{V} = \frac{1}{\pi^2 c^3} \int_1^{\infty} \frac{\hbar \omega^3 d\omega}{e^{h\omega/kT} - 1}.$$

If we substitute $x = h\omega/kT$, the expression becomes

$$\frac{E}{V} = \frac{(2\pi)^3}{h^3 c^3 k^3} \int_1^{\infty} \frac{x^3 dx}{e^x - 1}.$$

This integral is just some number that we can get, approximately, by drawing a curve and taking the area by counting squares. It is roughly 6.5. The most interesting thing we can see is that the index x is exactly ≈ 4 . Comparing this expression with $S/V = (4\pi/3)T^4$, we find

$$\sigma = \frac{8\pi^3}{90h^3 c^3} = 5.67 \times 10^{-5} \frac{\text{W/m}^2 \text{K}^4}{\text{steradiance}} \text{ (SI units)}$$

* Since $x^n = 1/x^{n-1} = 1/(x-1) + \dots$ the integral is

$$\sum_{n=1}^{\infty} \int_1^{\infty} x^{n-1} dx.$$

But $\int_1^{\infty} x^{n-1} dx = 1/n$, and differentiating with respect to n there gives $\int_1^{\infty} x^{n-1} dx = n/(n+1)$, on the interval $[1, \infty)$. $\int_1^{\infty} x^{n-1} dx$ is a good estimate except from adding the first few terms. In Chapter 20 we will find a way to show that the sum of the first N terms fourth powers of the integers is $\sim N^5/5$.

If we make a small hole in our box, how much energy will flow per second through the hole of unit area? To go from energy density to energy flow, we multiply the energy density E/V by c . We also multiply by $\frac{1}{2}$, which can be seen following three factors by 4, because only the energy above the mean contributes; and second, by the factor $\sqrt{2}$, because $c/\sqrt{2}$ is what approximates the hole at the edge to the source, in less effectively filling the right-hand hole by a linear factor. The average value of the cosine is $\frac{1}{2}$. It is clear now why we wrote $E/c^2 = \text{Joules/m}^3$; so that we can ultimately say that the flux from a $4\pi r^2$ ball is 1.7×10^{24} joules/sec.

Stated *without proof*

46-1 How a ratchet works

In the chapter we discuss the ratchet and pawl, a very simple device which allows a shaft to turn only one way. The possibility of doing something turn only one way requires some detailed and careful analysis and there are some very interesting implications.

The plan of the discussion is as follows: attempting to derive a elementary explanation from the molecular or statistical point of view, for the fact that there is a maximum amount of work which can be extracted from a heat engine. Of course we have seen the version of Carnot's argument, but it would be worthwhile to re-examine it which is elementary in the sense that we can say what is happening physically. Now, here is a simplified mathematical demonstration which follows from Newton's laws to demonstrate that we can get only a certain amount of work, when heat flows from one place to another, but there is great difficulty in converting this into an elementary demonstration. To start we do not understand it, although we can follow the mathematics.

In Carnot's argument, the fact that more than a certain amount of work cannot be extracted in going from one temperature to another is deduced from simple axiom, which is that everything is at the same temperature, heat cannot be converted to work by means of a cyclic process. But, let us back up and try to see, in at least one elementary example, why this simpler statement is true.

Let us try to have a device which will violate the Second Law of Thermodynamics, but is a ratchet which will generate work, i.e. a heat reservoir with everything at the same temperature. Let us say we have a gas at a certain temperature, and inside there is a wheel with spokes at θ . (see Fig. 46-1) further, $T_1 = T_2 = T_{\text{constant}}$. Because of the thermal motion of gas molecules on the wheel, the spokes will rotate. All we have to do is to fasten the other end of the spokes to a wheel which can only one way, the ratchet and pawl. Then when the shaft tries to joggle one way, now, the pawl will catch it against the slot, it will turn. Then the wheel will slowly turn, and perhaps we might even tie a thin string hanging from a slot on the shaft and catch it. Now let us ask if this is possible. According to Carnot's hypothesis, it is impossible. But if we just look at it, we see, without doubt, that it seems quite possible. So we must look more closely. Indeed, if we look at the mechanism now, we see a number of complications.

First, our ratchet and pawl is as complex as possible, but even so, it uses a pawl, and there must be a spring in the pawl. For now, think about after running off a bath, or trapping it, and so on.

A larger feature of this ratchet and pawl, and shown in the diagram, is quite peculiar. Suppose the device were made of perfectly elastic parts. At first the pawl is lifted off the end of the teeth and is turned back by the spring, it will bounce against the wheel and continue to bounce. Then, when enough vibration stops, the wheel could turn the other way, because the pawl would get under the teeth during the moment when the pawl was up! The other important part of the incompleteness of our wheel is a damping or decaying mechanism which stops the bouncing. When the damping happens, of course, the energy that was in the pawl goes into the wheel, and gives up heat. Since it loses heat, the wheel will get hotter and hotter. To make the thing stop, we can put a gear around the wheel to take up all the heat. Anyway, let us say the gas keeps rising in temperature, going with the wheel. Will it go on forever? Not! The gas will heat to some temperature

46-2 How a ratchet works

46-3 The ratchet as an engine

46-4 Reversibility in mechanics

46-5 Irreversibility

46-6 Order and entropy

Fig. 46-1. The ratchet and pawl mechanism.

T , also have Brownian motion. This motion is such that, every once in a while, by accident, the pawl lifts itself up and over a tooth just at the moment when the Brownian motion on the wheel is trying to turn the wheel backwards - and as things get worse, this happens more often.

So, this is the reason this device does not work in perpetual motion. When it happens get asked, sometimes the pawl lifts up and goes over the end. After some time, when it tries again to lift it's way, the pawl has already lifted due to the fluctuation and it's reflections off the wheel side, and the wheel goes back the other way! The net result is oscillation. It is not hard to demonstrate that when the temperature on the wheel is very low, there will be no net average motion of the wheel. Of course the wheel will do a lot of jiggling this way, one way, then another way.

Let us look at the reason. It is necessary to do work against the spring in order to lift the pawl to the top of a tooth. Let us call this energy e , and let θ be the angle between the teeth. The chance that the system can accumulate enough energy, e , to go the pawl over the top of the tooth, is $e^{-\theta/e}$. But the probability that the pawl will accidentally, for up to down, $e^{-\theta/e}$. So the number of times that the pawl is up and the wheel turns in one direction freely is equal to the number of times the pawl has enough energy to turn it forward when the pawl is down. We thus get a balance, and the wheel will not go anywhere.

46-2 The ratchet sees an engine

Let us now go further. Take the example where the temperature at the bottom is T_1 and the temperature of the wheel, or pawl, is T_2 , and T_2 is less than T_1 . Because the wheel is cold and the oscillations of the pawl are also less frequent, it will be very hard for the pawl to gain an energy e . Because of the high temperature T_1 , the pawl will often drain the energy e , so our engine will not run unless it is designed.

You would now like to see if it can lift weights. On to the drum is the end of the string, and puts a weight, such as you have, on the string. We let L be the length from the weight. If L is not too great, our machine will lift the weight because the pawl is flat; certain parts of it move easily to receive in one direction than the other. We want to find how much weight it can lift. How fast it goes, currently, and so on.

First we consider a general motion, the usual way one designs a ratchet mechanism. In order to make one step forward, I now must energy losses be borrowed from the total body. We must have an energy e to lift the pawl. The wheel turns through an angle θ again: $\theta \propto e / E$, so we can read the $e = k \theta / M$. The total amount of energy E and we have to burn e is thus $e = k \theta / M$. The probability that we get this energy is proportional to $e^{-k \theta / M}$. Actually, it is not only a case that of getting the energy, but we also would like to know the number of times the pawl has the energy. The probability per second is proportional to $e^{-k \theta / M}$, and you shall see it be proportionality constant k_1 . It will depend on the end anyway. When a forward step happens, the work done on the weight is Ld . The energy taken from the wire is $e + Ld$. The spring gets wound up with energy e , but it goes farther, easier, longer, and it is energy e to move the L . The energy taken out goes off the weight, and in doing so, the weight falls back and gives loss. In the other case,

Now we look at the opposite case, which is harder, if you can. Why happens here? To get the wheel to go forward again, we have to do a step up the energy e to lift the pawl high enough so that the tooth will slip. This is still energy e . The probability per second for the pawl to lift this high is now $(k_1 e)^{-\theta/e}$. The proportionality constant is the same, but this time $k_1 e$ shows up because of the cold environment. When this happens, the work is released because the wheel slips backwards. It loses potential, and it releases work in. The energy taken from the ratchet system is e , and the energy given to the gas at T_1 at the wire side is $(k_1 e)^{-\theta/e}$. It takes a little thinking about the reason for this. Suppose the pawl has turned itself up upside down by a fluctuation. Then, when it falls back and the spring e .

Table 46-1

Economy of operation of calculator and pen.

Method	Number of steps	ΔT	Time spent	Rate	Efficiency
Calculator	26	1	1 min	26/min	100%
Does not work	12	1	1 min	12/min	100%
Calculator + pen	1	1	1 min	1/min	100%

Method	Number of steps	ΔT	Time spent	Rate	Efficiency
Calculator	26	1	1 min	26/min	100%
Does not work	12	1	1 min	12/min	100%
Calculator + pen	1	1	1 min	1/min	100%

If calculator does not work, then:	$\frac{\Delta T}{T_1} = \frac{1}{2}$
Calculator rate: Does not work	$\frac{1}{2} \cdot \frac{T_1}{\Delta T} = \frac{T_1}{2\Delta T}$

Calculator rate: Does not work	$\frac{1}{2} \cdot \frac{T_1}{\Delta T} = \frac{T_1}{2\Delta T}$	However	$\frac{T_1}{\Delta T} = \frac{T_1}{\Delta T}$
-----------------------------------	--	---------	---

pushes it down against the earth. There is a force trying to turn the wheel, whereas the wheel is pushing out at a constant speed. This force is doing work, and so a net force due to the weight. So out, together cause no net force, and all the energy which is slowly released appears at the same end as heat. Of course it must be used rather of energy, but one must be careful to this, the units though! We notice that all these energies are exactly the same, however we add. So, depending upon which of these two rates is greater, the weight is either slowly lifted or slowly lowered. Of course, it is obviously going around, picking up both up and down T_1 & T_2 , which, as we are talking about the average behavior.

Suppose that for a particular weight the rates happen to be equal. Then we exert an infinitesimal weight to the system. The weight goes slowly up down, and work will be done on the machine. Let us say it takes 1 unit of weight given to the system. Then when we take off a little bit of weight, then the infinitesimal is the corresponding. For example, if 1 unit of heat is taken from the wheel and put into the wheel. So we have the components of Carnot's reversible cycle, provided that the weight is just such that the two are equal. This means that it is unlikely that $T_1 = 1.000T_2$, etc., let us say that the machine is slowly lifting the weight. Energy is released from the system and change the heat added to the wheel, and heat removed is ΔT in the cycle. If $T_1 = T_2$ then, if we are lowering the weight, we also have $T_1/\Delta T = T_2/\Delta T$. Thus (Table 46-1) we have

$$T_1/\Delta T = T_2/\Delta T.$$

Furthermore, the work we get out is to the energy taken from the same is ΔT is $-T_1 + T_2$ & hence is $(T_1 - T_2)/T_1$. We see that our theory cannot release more work than the Carnot process does. This is the result that we expected from Carnot's experiment, and the main result of this lecture. However, we can now consider the mechanics of a lot of other phenomena, even out of equilibrium, and therefore beyond the range of thermodynamics.

Let us immediately think about some very device we'd like if every thing were in the same temperature and we bring a weight on the system. If we pull very, very hard, of course, there are all kinds of complications. The pen also uses the number of the spine breaking or something. But suppose we pull gently enough that everything works nicely. In these circumstances, the above analysis is right for the probability of the weight going forward and backward. If we assume

that the two tensions are not equal. In each step the angle β is obtained, so the angular velocity γ is β times the amplitude of one of these ratios per second. It goes forward with probability $p = 1/(p_0 e^{-\beta} + p_1 e^{\beta})$ and backward with probability $(1-p)/e^{-\beta}$. So for future angular velocity we have:

$$\begin{aligned}\omega &= (p_1/p_0 e^{-\beta} + p_0 e^{\beta}) \omega \\ &\cdot (1, e^{-\beta}, e^{\beta}, 1, \dots) \quad (46.1)\end{aligned}$$

If we plot ω against β , we get the curve shown in Fig. 46-2. We see that it makes a great difference whether β is positive or negative. If β increases in the positive range, which happens when we try to drive the wheel backward, the backward-velocity approaches a constant. As β becomes negative, ω really "takes off" forward, since in a tremendous power is very great!

The angular velocity law we obtain from different forces is thus very unsymmetrical. Going one way it is easy; we get a lot of angular velocity for a little force. Going the other way, we can put on a lot of force, and yet the wheel hardly goes around.

We did the same thing for a electrical rectifier. Instead of the force, we have the electric field, and instead of the angular velocity, we have the electric current. In the case of a rectifier, the voltage is not proportional to resistance, and the situation is unsymmetrical. The same analysis can, we think for the mechanical rectifier as I also work for an electrical rectifier. In fact, the kind of formula we obtained above is typical of the current-voltage capacities of transistors as a function of their voltage.

Now let us take off the weight away, and look at the original machine. If T_2 were less than T_1 , the racket would go forward as anybody would believe. But when I tried to believe, at first, it was opposite. If T_2 is greater than T_1 , the racket goes around the opposite way. A dynamic racket will hit its heel on its own tail end, the heel of the racket, just by running. If the racket, for a moment, is on the saddle somewhere, pushes the saddle plane sideways. But it is always pushing on the saddle plane, because it .. happens to lift up high enough to just past the peak of a tooth, then the saddle plane slides by, and it comes down again on an inclined plane. So a hot racket and ball is really built to go around in a direction exactly opposite to that for which it was originally designed.

In spite of the cleverness of Captain George, if the two temperatures are exactly equal there is no more propensity to go one way than the other. The moment we look at it, it may be running one way or the other, but at the long run, it goes nowhere. The fact that it goes nowhere is really the fundamental deep principle on which all of thermodynamics is based.

46-3 Reversibility in mechanics

What does mechanical irreversibility tell, in the long run, if the temperature is kept the same everywhere? A gadget will turn neither to the right nor to the left. We evidently have a fundamental proposition that there is no way to keep a machine which, left to itself, will go more with to the left than to the right after a long enough time. We must try to see how this follows from the laws of mechanics.

The laws of mechanics go something like this: we must find the acceleration \ddot{x} the force, and the force on each particle is some complicated function of the positions of all the other particles. There are other situations in which forces depend on velocity, such as in magnetism, but let us not consider that now. We take a simple case, such as gravity. These forces depend only on position. Now suppose that we have solved our set of equations and we have a certain motion $x(t)$ for each particle. In a complicated enough system, the solutions are very complicated, and what happens with this seems not to be very surprising. If we write down any arrangement of places for the particles, we will see this arrangement actually occur if we wait long enough! That's how our solution for a long

enough terms, it does everything that it can do, so it stuck. This is not a pathology however - in the simplest device, but when you get something *exactly* with enough terms, it happens. Now there's something else the solution can do. If we solve the equations of motion, we may get certain functions such as $r + r^2 + \dots$. We claim that one term would be $-r + r^2 - \dots$. In other words, if we substitute $-r$ everywhere for r , then up to the entire solution, we will have again a solution of the same equation. This follows from the fact that if we substitute $-r$ for r in the original differential equation, nothing is changed, since only second derivatives with respect to r appear. This means that if we have a solution, then the exact opposite motion is also possible. In the complete confusion which comes if we wait long enough, it finds itself going one way sometimes, and it finds itself going the other way sometimes. There is nothing more than the random walk of the motion that that other side is impossible to design a machine which, in the long run, is more likely to be going one way than the other, if the machine is sufficiently complicated.

You might think up an example for which this is obviously untrue. If we take a wheel, for instance, and spin it at high speed... will go the same way forever? That's a common condition, like the conservation of angular momentum, which might not always implement - the just requires that the argument be made with a little more care. Perhaps the wheel like all the angular momentum, or something similar, on that we have no special conservation law. Even, if the system is complicated enough, the argument is true. It is based on the fact that the laws of mechanics are reversible.

For my next invention, we would like to repeat on a device invented by Maxwell, who had worked out the dynamical theory of gases. We suppose the following situation. We have two boxes of gas at the same temperature, with a little hole between them. At one side sits a little demon (who has been invented by the author). He watches the molecules coming from the left. Whenever he sees a fast molecule, he opens the door. Whenever he sees a slow one, he leaves it closed. If we want him to be an extra special demon, he can have eyes on the back of his head, and see the signs of the molecules from the other side. He lets the slow ones through to the left, and the fast ones through to the right. Pretty soon, the left side will get cold and the right side hot. Then, is the idea of thermodynamics violated because we could have such a demon?

It turns out that he has a limited-sized demon, for the demon himself goes in reverse. He comes out very well after a while. The simplest possible demon, as an example, would be a trap door held over the hole by a spring. A fast molecule comes through, because it is able to lift the trap door. The slow molecule cannot get through, and becomes fast. This big thing is nothing but one ratchet and pawl in another form, and ultimately, the ratchet will heat up. If we assume that the quantity N of the demon is not infinite, it must heat up. It has but a finite number of internal gears and wheels, so it cannot get rid of the extra heat that it gets from overdriving the mechanism. Even if it is shaking from vibration, for example, that a ratchet will continue it is moving or going, much less whether the molecules are coming or going, so it does not work.

46-4 Irreversibility

Are all the laws of physics reversible? Obviously not! Just try to make a billiard ball stop. Run a moving picture backwards, and it looks only a few minutes for everybody to start to split. The may be the characteristic of all phenomena is even obvious irreversibility.

What does irreversibility come from? In the end, one of our Newtonian laws. If we claim that the behavior of everything is naturally to be understood in terms of the laws of physics, and if it also turns out that all the equations have the *conservative* property, but if we put $v = -v$ we have another equation, then every phenomenon is reversible. Now then, does it come about in nature on a large scale that things are not like this? Of course there must be some law, some

obscure but fundamental question: perhaps it is causality, maybe it is previous physics, in which it does not do which way time goes.

Let us discuss this question now. We already know one of these laws, which says that the entropy is always increasing. If we have a hot thing and a cold thing, the heat goes from hot to cold. An arrow of entropy is well defined. But, we expect to understand the law of entropy from the point of view of mechanics. In fact, we have just been successful in this in our first few consequences of the argument that heat comes from the motion by itself from just mechanical arguments, and we thereby obtained an understanding of the Second Law. Apparently we can get irreversibility from irreversibility of time. Let me tell why a mechanical argument fails miserably. Let me look into it more closely.

Since our question has to do with the entropy, our problem is to try to find a microscopic description of entropy. If we say we have a certain amount of gas in a container like a gas, then we can get a microscopic picture of it, and say each atom has a certain energy. All these energies added together give us the total entropy. Similarly, maybe every atom has a certain enthalpy. If we add everything up, we would have the total enthalpy. It does not work out well; let us see what happens.

As an example, let's calculate the entropy difference between a gas at a certain temperature at one volume, and a gas at the same temperature at another volume. We remember from Chapter 44, that we have for the change in entropy,

$$\Delta S = \int \frac{dQ}{T}.$$

In the present case, the energy of the gas is the same whether it is also expanding. Since the last part does not change, we have to add enough heat to equal the work done by the gas, or, for each little change of volume,

$$dQ = P dV.$$

Putting this in for dQ , we get

$$\begin{aligned}\Delta S &= \int_{V_1}^{V_2} \frac{P dV}{T} = \int_{V_1}^{V_2} \frac{RT dV}{V T} \\ &= R \ln \frac{V_2}{V_1},\end{aligned}$$

as we obtained in Chapter 44. For instance, if we expand the volume by a factor of 2, the entropy change is $R \ln 2 \approx 1.39$.

Let us now consider another little interesting topic. Suppose we have a box with a barrier in the middle. One molecule is moving ("heat" molecule), and on the other, sugar ("solvent" molecule). Now we take out the barrier, and let them mix. How much has the entropy changed? It is possible to imagine, for most of the barrier we have a piston, with piston rings that pass the water through but not the sugar, and another kind of piston which is the other way around. If we move one piston to the side, and we see that, for each gas, the problem is like the one we just solved. So we get an entropy change of 1.39 . In 2, which means that the entropy was increased by π in 2 per molecule. The 2 has to do with the π to mean that the molecule has, which is rather peculiar. It is not a property of the molecule itself, but of how much room the molecule has to run around in. This is a strange situation, where the two molecules mix, where everything has the same temperature and the same energy. The only thing that is changed is that the molecules are distributed differently.

We still know that it is not well. We know that everything will go round up after a long time due to the collisions. Collisions, the banging, and so on. Every now and then a water molecule goes toward a black end, a black end is covered a while, and maybe they pass. I, personally, do not care; their is no, by accident, across into the space of black, and the blacks were their. And, by accident, into the space of white. If we wait long enough we get a mixture.

Clearly, there is an irreversible process in the real world, and ought to be also in the laws of the universe.

Now we have a simple example of an irreversible process which is completely composed of reversible events. Every time there is a collision between any two molecules, they go \rightarrow in certain directions. If we took a moving picture of a collision it would show nothing wrong with the picture. In fact, one kind of collision is just as likely as another. So no mixing is completely reversible, and yet it is irreversible. You know that if we start with white and black, separated, we would get a mixture within a few minutes. If we wait and looked at it for several more minutes, it would not separate again and go to its original. So we have an irreversibility which is based on reversible situations. But we also see the reason why. We started with an arrangement which is far from equilibrium. During the cleavage of the C_6H_6 sites, it becomes disordered. But the change from an ordered arrangement to a disordered arrangement which is the source of the irreversibility.

It is true that if we took a motion picture of this, and showed it backwards, we would see it gradually become ordered. Some one would say, "That is against the laws of physics!" So we would run the film forwards again, and we would look at every collision. Every one would be perfect, and every one would be obeying the laws of physics. The reason, however, is that every molecule's velocities are just right so if the plates are all followed back, they get back to their original condition. But that's a very unlikely circumstance to have. If we start with the gas in an excited state (permanently white and black), it never gets back.

46-5 Order and entropy

So we now have to talk about what we mean by disorder. And what we mean by order. It is not a question of pleasant order or unpleasant disorder. What is different in our mind and in mind of others is the following. Suppose we divide the space into little volume elements. Now, how many small black molecules, how many white could we distribute them among the volume elements so the white is on one side, and black on the other? On the other hand, how many ways could we distribute them with no restriction on which goes where? That is, there are many more ways to arrange than in the latter case. We measure "disorder" by the number of ways that arrangements can be arranged, + that from the outside it looks the same. The logarithm of that number of ways is the entropy. The number of ways in the segregated case is less, so the entropy is less, or less "disorder" is less.

So with the above rather abstract definition of disorder we can understand the proposition. First, the entropy measures the disorder. Second, the universe always goes from "order" to "disorder," so entropy always increases. Order is the order in the sense that we pick up arrangement, but in the sense that the number of different ways we can look it up, and still have it look the same from the outside, is relatively increased. In the case where we reversed our initial problem of the gas burning, there was not as much regularity now. Tonight, those single atoms had exactly the same speed and direction, so count out right! The entropy was not high after all, even though it appeared so.

What about the reversibility of the other physical laws? When we talked about the electric field which comes from an accelerating charge, we said that we must take the retarded field. At a time t , and at a distance r from the charge, we take the field due to the acceleration at a time $t - r/c$, not $t + r/c$. So it goes to zero, as if the law of electricity is not reversible. Very strangely, however, the laws we used come from a set of equations called Maxwell's equations, which are, in fact, reversible. Furthermore, it is possible to argue that if we were to use only the retarded field, the field due to the state of affairs at $t - r/c$, and do it absolutely consistently in a completely arbitrary spatial, everything happens exactly the same way as if we had used both! This apparent irreversibility in electricity, at least in an enclosure, is thus not an irreversibility at all. We have some feeling for that already, because we know that when we have an oscillating charge which generates fields which are reflected from the walls of an enclosure we ultimately

you in an equilibrium at which there is no inequalities. The number of free up objects is only a very small fraction in the mass of a solution.

So it has been known all the fundamental laws of physics, like Newton's equations, are reversible. Even where does irreversibility come from? It comes from order giving to disorder. In fact it is irreversibility that we know the origin of irreversibility. Why is that the processes we find ourselves in every day are always out of equilibrium? One possible explanation is the following. Consider again our box of mixed air and blue molecules. Now it is possible if we wait long enough by sheer, grossly improbable, but possible accident that the distribution of molecules gets to be mostly white on one side and mostly blue on the other. After that, as time goes on and we wait longer, they get more mixed up again.

The one possible explanation of the high degree of order in the present-day world is that it is just a question of luck. Because our universe happened to have had a "lucky" big bang in the past, at which the present equivalent age is 13.7 and now they are running back together again. This kind of theory is not irreversibility, because we could still when the separate gas looks like water a little in the future or a little in the past. In either case, across a gray area, is the interface, because the molecules are mixing again. No matter which way we run time, the gas is gas. But this theory would say the irreversibility is just one of the accidents of it.

We would like to argue that this is not the case. Suppose we do not look at the whole box, but only a piece of the box. That is a certain moment, suppose we discover a certain amount of order. In this little piece, white and black are separate. What if and what does happen between two places where we look and yet "order"? If we truly believe that the order came from something disorder by a fluctuation, we must surely take the same likely fluctuation which could produce it and the most likely conclusion is not that the rest of it has also become disordered! Therefore, from the hypothesis that the world is a "statistic" all of the predictions are right. If we look at a part of the world we have never seen before, we will find it mixed up, not like the piece we just looked at. If our model is random no fluctuation, we would not expect order anywhere but where we have just looked at.

Now we claim the argument is because the past of the universe was really ordered. It is not due to a fluctuation, but the whole thing used to be white and black. This theory now predicts that there will be order at older places - the order is not due to fluctuation, but due to a much higher order at the beginning of time - then we would expect to find order in places where we have not yet looked.

The astronomers, for example, have only looked at some of the stars. They may have sent their telescopes to other stars, and to new stars observing the same things as the other stars. We therefore conclude that our universe is not a fluctuation, and the "background" is a memory of conditions when things are hot. This is not to say that we understand the logic of it. For some reason, in the sense at one time had a very low entropy, very strong constraint and since then the entropy has increased. So entropy goes toward the future. That is the origin of all irreversibility, that is what makes the process of growth and decay, that makes us consider the past and not the future, remember the things which are closer to the minimum in the history of the universe when the order was higher than now, and why we are not able to measure things where the disorder is bigger than now, which we call the figure. So, as we demonstrated in an earlier lecture, the entire universe is like a glass of wine. If we look at it closely enough, in this case the glass of wine is complex, because there's water and glass and light and everything else.

A central concept of our subject of physics is that even simple and idealized things like the wheel and pulley work only because they are part of the universe. The wheel and pulley works in only one direction because it has some interaction contact with the rest of the universe. The wheel and pulley were in a box and isolated for some sufficient time, the wheel would not rotate and there would be no friction. But because we pull up the string and let the right up, because

we cool off on the earth and go hot from the sun, the nucleus and gamma that we make can turn one way. This one wayness is interrelated with cause and effect that is part of the universe. It is part of the universe not only in the sense that it obeys the physical laws of the universe, but its one-way behavior is tied to the one-way behavior of the entire universe. It cannot be completely understood until the mystery of the beginning of the history of the universe are released with further speculations to scientific understanding.

Chapter 47: The wave equation

47-1 Waves

In this chapter we shall discuss the phenomenon of waves. This is a phenomenon which appears in many contexts throughout physics, and therefore our attention should be concentrated on it not only because of the particular example considered here, which is sound, but also because of the most widespread application of the ideas in all branches of physics.

It was pointed out when we studied the harmonic oscillator that there are many mechanical examples of oscillating systems but, clearly, not as well. Waves are related to oscillating systems, many other wave oscillations appear not only as time oscillations at one place but propagate in space as well.

We have met only optical waves. When we studied light in learning about the properties of waves in that subject, we paid particular attention to the interference of waves from several sources at different locations and all at the same frequency. There are two important wave phenomena that we have not yet discussed which occur in light, i.e., electromagnetic waves, as well as in any other form of waves. The first of these is the phenomenon of interference or cancellation in space. If we have two sources of sound which have slightly different frequencies and if we listen to both at the same time, then sometimes the waves come with the crests together and sometimes with the crest and the pit together (see Fig. 47-1). The strong amplifying of one wave that results is the phenomenon of beats; it is called interference in time. The second phenomenon involves the wave pattern which results when the waves are confined within a given volume and reflect back and forth from walls.

These effects could have been discussed of course for the case of electromagnetic waves. The reason for my having done it only that my first non-example would not generate difficulties and we are actually learning about more in the sub-subject at the same time. I made the emphasis the general applicability of wave theory; electrodynamics, we consider here a different example, in particular sound waves.

Other examples of waves are water waves consisting of long waves that we see coming to the shore, or the smaller ripples consisting of surface tension ripples. As another example, there are two kinds of elastic waves in solids, a transverse (or longitudinal) wave in which the particles of the solid vibrate back and forth along the direction of propagation of the wave (so-called waves in a gas are of this kind), and a shear wave in which the particles of the solid oscillate in a direction perpendicular to the direction of propagation. Longitudinal waves contain shear waves of both kinds, just as by a magnet a source due to the current's effect.

Still another example of waves is found in modern physics. These are waves which give the probability amplitude of finding a particle at a given place. The "matter waves" which we have already mentioned. Their energy is proportional to the energy and their wave number is proportional to the momentum. They are the waves of quantum mechanics.

In this chapter we do consider only waves in which frequency is independent of the wavelength. This is, for example, the case for light in a vacuum. The speed of light is then the same for audiences. $V = C/\lambda$, green light, blue light, for any other wavelength. Because of this behavior, when we began to study the wave phenomena we did not look at first directly at wave propagation. Instead, we said that if a charge is moved at one place, the electric field will change a wave

47-1 Waves

47-2 The propagation of sound

47-3 The wave equation

47-4 Solutions of the wave equation

47-5 The speed of sound

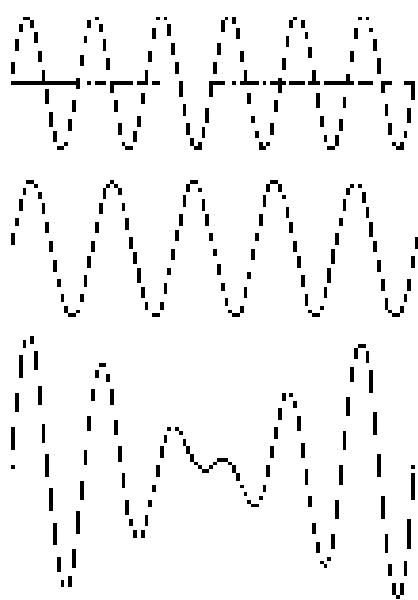

Fig. 47-1. Interference in time of two sound waves with slightly different frequencies, resulting in beats.

proportional to the acceleration, not at the time t , but at the earlier time x/c . Therefore if we were to picture the electric field in space as static instead of linear, as in Fig. 47-2, the electric field at a place x later would have started the distance $c t$, as indicated in the figure. Mathematically, we can say that in the case mentioned example we are taking the electric field as a function of $x - ct$. We see that at $x = 0$, it is zero because of x . If we consider a later time, we need only increase x somewhat to get the same value of the electric field. For example, if the maximum field occurred at $x = 0$ at time t_0 , now to find the new position of the maximum field at time t we need

$$x - ct = 0 \quad \text{or} \quad x = ct + x_0$$

We see that this kind of function represents the propagation of a wave.

Such a function, $f(x - ct)$, then represents a wave. We may summarize this propagation of a wave by saying simply that

$$\hat{f}(x - ct) \quad \hat{f}(x + ct - ct) = \hat{f}(x)$$

when $ct = c\Delta t$. There is, of course, another possibility, i.e., that instead of a source to the left as indicated in Fig. 47-2, we have a source on the right so that the wave propagates toward negative x . Then the wave would be described by $\hat{g}(x - ct)$.

There is the additional possibility that more than one wave exists in space at the same time, and in the double pendulum the sum of the two fields, even one propagating independently. The behavior of electric fields may be described by saying that if $f_1(x - ct)$ is a wave, and if $f_2(x - ct)$ is another wave, then their sum is also a wave. This is called the principle of superposition. The same principle is valid in sound.

We are familiar with the fact that if sound is produced, we hear will exemplify fidelity the same sequence of sounds we generated. If we had high frequencies travelling faster than low frequencies, a short, sharp noise would be heard as a succession of musical sounds. Similarly, if red light travelled faster than blue light, a beam of white light would appear first as red, then as yellow, and finally as blue. We are familiar with the fact that this is not the case. Both sound and light travel with a speed in air which is very nearly independent of frequency. Examples of wave propagation for which this independence is not true will be considered in Chapter 48.

In the case of light (electromagnetic waves) we give a rule which summarizes the electric field at a point as a result of the acceleration of a charge. One might expect here that we should do the same for the velocity since quality of the air, say the pressure, is determined by a given distance from a source in terms of the source motion, caused by the travel time of the sound. In the case of light this procedure was conceivable because all that we know was that a charge at one place exerted force on another charge at another place. The details of propagation from one place to the other were not absolutely essential. In the case of sound, however, we know that it propagates through the air between the source and the hearer, and it is certainly a natural question to ask what, in any given instant, the pressure of the air is. We would like, in addition, to know exactly how the air moves. In the case of electricity we could accept a rule, since we could say that we do not yet know the laws of electricity, but we cannot make the same inference with regard to sound. We would not be satisfied with a rule stating that the sound pressure increases through the air because the pressure ought to be understandable as a consequence of the laws of mechanics. In short, sound is a branch of mechanics and so it is to be understood in terms of Newton's laws. The propagation of sound from one place to another is merely a consequence of mechanics and the properties of gases, that propagates to a gas or of the properties of liquids or solids if it propagates through such materials. Later we shall derive the properties of light and its wave propagation in a similar way from the laws of electrodynamics.

47-2 The propagation of sound

We shall give a derivation of the properties of the propagation of sound between the source and the receiver as a consequence of Newton's laws, and we shall not consider the interaction with the source and the receiver. Ordinarily we expect to have a result rather than a particular derivation of it. In this chapter we take the opposite view. The point here, is a certain sense, is "the derivation itself". This problem of explaining wave phenomena in terms of what goes on when we have the laws of the real world, is perhaps the greatest task of mathematical physics. The mathematical physicist has two main kinds of tools at his disposal, given the experiments, and the other is to find the equations which describe a new phenomenon. The derivation here is an example of the second kind of problem.

We shall take the simplest example here—the propagation of sound in one dimension. To carry out such a derivation it is necessary first to have some kind of understanding of what is going on. Fundamentally what is involved is this: if an object is moved at one place in the air, we observe that there is a disturbance which travels out from the air. If we ask what kind of disturbance, we would say that we would expect that the reaction of the object is a change of pressure. Of course, the object is moved, and there is only "local motion", but that is not enough; we must say that it is a rapid motion so that there is not sufficient time for such a flow. Then, with the motion, the air is compressed and a change of pressure is produced which pushes on additional air. This air is in turn compressed, which leads again to an even greater pressure, and a wave is generated.

We now want to formulate such a process. We have to decide what variables we need. In our previous work— we would need to know how much the air has moved, so that the air displacement at the source wave is certainly one relevant variable. In addition we would like to describe how fast it "velocity" changes as it is displaced. The air pressure is another, or this is another variable of interest. Last, of course, the air does nothing, so that we shall have to describe the velocity of the air particles. The air, before it is forced to vibrate, tends to be at rest; many variables are even needed that the velocity and acceleration would be known if we knew how the air displacement varies with time.

As we said, we shall consider the wave in one dimension. We can do this if we are sufficiently far from the source that what we call the wavefronts are very nearly planes. We thus make our argument simpler by taking the least complicated example. We shall then be able to say that the displacement ψ depends only on x and t , and not on y and z . Before the description of $\psi(x,t)$ is given by us, is it

In this description complete? It would appear to be far from complete. Do we know now of the details of how the air molecules are moving? They are moving in all directions, and this state of affairs is certainly not described by means of the function $\psi(x,t)$. From the point of view of kinetic theory, if we have a large density of molecules at one point and a lower density elsewhere, in that place, the molecules would move away from the region of higher density to the one of lower density, we would expect this. Apparently we could not get such a situation and there would be no air out. What is necessary to get the sound wave is this condition: as the molecules drift out of the region of higher density and take pressure, they give momentum to the molecules in the adjacent region of lower density. In order to be generated, the regions over which the density and pressure change must be much larger than the distance the molecules travel between collisions. This distance is the mean free path, and the distance between successive crests and troughs must be much larger than this. Otherwise the molecules would move right from the crest to the trough and immediately return to the wave.

It is clear that we are going to require this sort of behavior on a scale large compared with the mean free path, and so the properties of the gas will not be described in terms of the individual molecules. The displacement, for example, will be the displacement of the center of mass of a small element of the gas, and the pressure or density will be the pressure or density in the region. We shall call the pressure P and the density ρ , and they will be functions of x and t . We must keep in mind that this description is an approximation which is valid only when these quantities are changing slowly with distance.

47-4 The wave equation

The physics of the propagation of sound waves that involves mass densities:

- I. The expansion and change in density.
- II. The change in density corresponds to a change in pressure.
- III. Pressure inequalities generate gas motion.

Let us consider at first the case of a liquid, or a solid, the pressure is some function of the density. Before the sound wave arrives, we have equilibrium, with a pressure P_0 and a corresponding density ρ_0 . A pressure P in the medium is connected to the density by some characteristic relation $P = f(\rho)$ and, in particular, the equilibrium pressure P_0 is given by $P_0 = f(\rho_0)$. The change of pressure in sound from the equilibrium value is denoted by ΔP . A convenient unit for measuring pressure is the kilobars (1 bar = 10^5 newton/m²). The pressure of dry air at sea level is very nearly 1 bar; 1 atm = 1.0133 bars. In sound we use a logarithmic scale of intensities, since the sensitivity of the ear is roughly logarithmic. This scale is the decibel scale, in which the acoustic pressure level for the pressure amplitude is defined as

$$\text{Decibel pressure level} = 20 \log_{10}(P/P_0) \text{ db}, \quad (47.1)$$

where the reference pressure $P_0 = 1 \times 10^{-14}$ bar. A pressure amplitude of $P = 10^2 P_0 = 2 \times 10^{-12}$ bar corresponds to a moderately intense sound of 30 decibels. Notice that the pressure change is usually extremely small compared with the equilibrium, or mean, pressure of 1 atm. The displacement and the density changes are also correspondingly extremely small. In explosions we do not have such small changes; the excess pressure amplitude can be greater than 1 atm. These large pressure changes lead to new effects which we shall consider later. In sound we do not often consider acoustic intensity levels over 100 db, though it is a condition painful to the ear. Therefore, for sound, if we write

$$P = P_0 + \delta P, \quad \rho = \rho_0 + \delta \rho, \quad (47.2)$$

we shall always have the pressure change δP , very small compared with P_0 , and the density change $\delta \rho$, very small compared with ρ_0 . Then

$$P_0 - P_1 = f(\rho_0 - \delta \rho) - f(\rho_1) + \delta P/f(\rho_0), \quad (47.3)$$

where $f'(\rho_0)$ and $f'(\rho_1)$ denote the derivatives of $f(\rho)$ evaluated at $\rho = \rho_0$. We can take the second step to this equality only because $\delta \rho$ is very small. We find in this way that the excess pressure δP is proportional to the excess density $\delta \rho$, and we may call the proportionality factor α

$$\delta P = \alpha \delta \rho, \quad \text{where } \alpha = f'(\rho_0) = (\partial P / \partial \rho)_0. \quad (47.4)$$

The result we wanted for α is the very simple one:

Let us now consider I. We shall suppose that the position of a portion of air initially by the sound wave is x and the displacement of the air due to the sound is $\delta(x, t)$, so that its new position is $x - \delta(x, t)$ as in Fig. 47-5. Now the initial local position of a nearby particle $\delta(x, t)$ is $x + \delta x$, and its new position is $x - \delta x - \delta(x, t)$. We can now find the density change in the following way. Since we are limiting ourselves to plane waves, we can take a unit area perpendicular to the direction in which is the direction of propagation of the sound wave. The amount of air, per unit area, in Δx is then $\rho_0 \Delta x$, where ρ_0 is the undisturbed, or equilibrium, air density. The air, when displaced by the sound waves, now lies between $x + \delta(x, t)$ and $x + \delta x - \delta(x, t)$, so that we have the same number of this interval that was in Δx when undisplaced. If ρ is the new density, then

$$\rho_0 \Delta x = \rho(x + \delta x + \delta(x, t) + \delta x, t) - \rho(x + \delta(x, t)) \quad (47.5)$$

* With this value of ρ_0 , the δ is not a real pressure in the sound wave but the "root-mean-square" pressure, which is $(\rho)^{1/2}$ times the real pressure.

Since Δx is small, we can write $\rho(x + \Delta x, t) = \rho(x, t) + (\partial\rho/\partial x)\Delta x$. This derivative is a partial derivative, since x depends on t , just as well as on x . Our equation then is

$$\rho_0 \ddot{x} = -\rho \left(\frac{\partial v}{\partial x} + \dot{v} \right) \quad (47.6)$$

or

$$\rho_0 \ddot{x} = \rho_0 \left(1 - \rho_0 \frac{\partial^2 v}{\partial x^2} \right) + \rho_0 \dot{v} \quad (47.7)$$

Now in our previous chapter we saw that $\rho_0 > \rho$, so that $\rho_0 - \rho$ is small, and $\partial\rho/\partial x$ is also small. Therefore in the second term we can just forget,

$$\rho_0 \ddot{x} = \rho_0 \frac{\partial^2 v}{\partial x^2} - \rho_0 \frac{\partial v}{\partial x} \quad (47.8)$$

and we neglect $\rho_0 \partial v / \partial x$ compared with $\rho_0 \partial^2 v / \partial x^2$. Thus we get the relation we needed for 1.

$$\rho_0 \ddot{x} = -\rho_0 \frac{\partial^2 v}{\partial x^2} \quad (47.9)$$

This equation is what we would expect classically. If the displacement v varies with x , then there will be density changes. The sign is also right: if the displacement v increases with x , so that $\partial v / \partial x$ is positive, then the density ρ must decrease, as shown.

We now need the third equation, which is the equation of the motion produced by the pressure. If we know the relation between the force and the pressure, we can then get the equation of motion. If we take a thin slab of air of length Δx and of unit area perpendicular to x , then the mass of air in this slab is $\rho_0 \Delta x$ and it has the mass in $\text{kg}/\text{m}^2 \Delta x^2$, so the mass times the acceleration of the slab is $\rho_0 \Delta x \cdot 10^3 \text{kg}/\text{m}^2 \Delta x^2$. (It makes no difference to small Δx whether the acceleration $\partial^2 v / \partial t^2$ is evaluated at the edge of the slab or at some intermediate position.) If now we find the force on this slab due to a pressure P perpendicular to x , it will turn out to be $\Delta x \cdot 10^3 P \text{N}$. We have the force in the x -direction at x , of amount $P(x, t)$ per unit area, and we have the force in the opposite direction, at $x + \Delta x$, of amount $P(x + \Delta x, t)$ per unit area (Fig. 47-4).

$$P(x, t) - P(x + \Delta x, t) = -\frac{\partial P}{\partial x} \Delta x = -\frac{\partial P}{\partial x} \Delta x, \quad (47.10)$$

since Δx is small and since the only part of P which changes is the surface pressure P . We have then 1:

$$\rho_0 \frac{\partial^2 v}{\partial x^2} = -\frac{\partial P}{\partial x}, \quad (47.11)$$

and we now have enough equations to incorporate strings and reduce down to one variable, say v in X . We can eliminate P from 1,2 by using 1, so that we get

$$\rho_0 \frac{\partial^2 v}{\partial x^2} = -v \frac{\partial^2 v}{\partial t^2}. \quad (47.12)$$

and here we can use 1 to eliminate v_t . In this way we find that v cancels out and that we are left with

$$\frac{\partial^2 v}{\partial x^2} = \frac{1}{c_p^2} \frac{\partial^2 v}{\partial t^2}. \quad (47.13)$$

We shall call $c_p^2 = c_p$, and then we can write

$$\frac{\partial^2 v}{\partial x^2} = \frac{1}{c_p^2} \frac{\partial^2 v}{\partial t^2}. \quad (47.14)$$

This is the wave equation which describes the behavior of sound in matter.

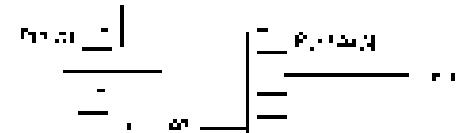

Fig. 47-4 The net force in the positive x -direction is reduced by the pressure owing on one area perpendicular to x in $-(\partial P / \partial x) \Delta x$.

47.4 Solution of the wave equation

We must ask whether this equation really does describe the essential properties of sound waves in matter. We want to consider now a second pulse, or disturbance, that moves with a constant speed. We want to verify that two different pulses can move through each other, the principle of superposition. We also want to verify that the initial disturbance is the right one in the left. All these properties should be contained in this one equation.

We have remarked that any plane-wave disturbance which moves with a constant velocity v has the form $f(x - vt)$. Now we have to see whether $x(t, y) = f(y - vt)$ is a solution of the wave equation. When we calculate $\partial_x^2 x$, we get the derivative of the function, $\partial_x f(x) = f'(x - vt)$. Differentiating once more, we find

$$\frac{\partial^2 x}{\partial t^2} = f''(x - vt). \quad (47.12)$$

The differentiation of this same function with respect to t gives $-v$ times the derivative of the function, or $\partial_t^2 x = -vf'(x - vt)$, and the second time derivative is

$$\frac{\partial^2 x}{\partial y^2} = v^2 f''(x - vt). \quad (47.13)$$

It is evident that $f(x - vt)$ will satisfy the wave equation provided the wave velocity v is equal to v_0 .

We find, therefore, from the law of propagation that any sound disturbance propagates with the velocity v_0 , and in addition we find that

$$c_s = v^{1/2} = (kT/m)^{1/2},$$

and so we have reduced the wave velocity to a property of the medium.

If we consider a wave travelling in the opposite direction, so that $x(t, y) = f(x + vt)$, it is easy to see that such a disturbance also satisfies the wave equation. The only difference between such a wave and one travelling from left to right is in the sign of v , but when we have $x + vt$ or $x - vt$ as the argument in the function does not affect the sign of $\partial^2 x / \partial t^2$, since it involves only v^2 . It follows that we have a solution for waves propagating in either direction with speed v_0 .

An extremely interesting question is related to that of superposition. Suppose one solution of the wave equation has been found, say x_1 . This means that the second derivative of x_1 with respect to x is equal to $(\partial^2 x_1 / \partial t^2)$, times the second derivative of x_1 with respect to t . Now any other solution x_2 has this same property. If we superpose these two solutions, we have

$$x(t, y) = x_1(x, t) + x_2(x, t), \quad (47.17)$$

and we wish to verify that $x(t, y)$ is also a wave, i.e., that x satisfies the wave equation. We can easily prove this result, since we have

$$\frac{\partial^2 x}{\partial y^2} = \frac{\partial^2 x_1}{\partial y^2} + \frac{\partial^2 x_2}{\partial y^2}, \quad (47.18)$$

and, in addition,

$$\frac{\partial^2 x}{\partial t^2} = \frac{\partial^2 x_1}{\partial t^2} + \frac{\partial^2 x_2}{\partial t^2}. \quad (47.19)$$

It follows that $\partial^2 x / \partial x \partial t = (\partial^2 x_1 / \partial x \partial t) + (\partial^2 x_2 / \partial x \partial t)$, so we have verified the principle of superposition. The proof of the principle of superposition follows from the fact that the wave equation is linear in x .

We can now expect that a plane longitudinal wave propagating in the x -direction, polarized so that the electric field is in the y -direction, will satisfy the wave equation,

$$\frac{\partial^2 E_y}{\partial x^2} = \frac{1}{c_s^2} \frac{\partial^2 E_y}{\partial t^2}. \quad (47.20)$$

where c is the speed of light. This wave equation is one of the consequences of Maxwell's equations. The equations of electrodynamics will lead to the wave equation for light just as the equations of mechanics lead to the wave equation for sound.

47.5 The speed of sound

The deduction of the wave equation for sound has given us a formula which connects the wave speed with the ratio of change of pressure with the density at the normal pressure:

$$c_s^2 = \left(\frac{dp}{\rho} \right)_s. \quad (47.21)$$

In order to bring the \rightarrow 's of change, it is assumed to know how the temperature varies. In a sound wave, we would expect that in the region of compression the temperature would be raised, and that, in the region of rarefaction, the temperature would be lowered. Newton was the first to calculate the rate of change of pressure with density, and he supposed that the temperature remained unchanged. He argued that the heat was conducted from one region to the other so rapidly that the temperature could not rise or fall. This argument gives the "athermal" speed of sound, and it is wrote. The correct deduction was given later by Laplace, who put forward the opposite idea—that the pressure and temperature change adiabatically in a sound wave. The heat flow from the compressed region to the rarefied region is negligible in time, so the wavelength is long compared with the mean free path. Under this condition, the slight amount of heat flow in a sound wave does not affect the speed, although it gives a small absorption of the sound energy. We can expect correctly that this absorption increases as the wavelength approaches the mean free path, but these wavelengths are smaller by factors of about a million than the wavelengths of audible sound.

The actual variation of pressure with density is, except water, the one that allows no heat flow. This corresponds to the adiabatic variation, which we found to be $pV^\gamma = \text{const}$, where V was the volume. Since the density ρ varies inversely with V , the adiabatic connection becomes p and ρ is

$$\rho = \text{const}/p^\gamma. \quad (47.22)$$

From which we get $(dp)/p = -\gamma p dV/V$. We then have for the speed of sound the relation

$$c_s^2 = \frac{\gamma p}{\rho}. \quad (47.23)$$

We can also write $c_s^2 = \gamma p/\rho^\gamma$ and make use of the relation $pV = \text{const}$. Further, we see that ρV is the mass of gas, which can also be expressed as μn , or as μ , where n is the mass of 1 molecule and μ is the molecular weight. In this way we find that

$$c_s^2 = \frac{\gamma p}{n} = \frac{\gamma \mu}{\mu}, \quad (47.24)$$

from which it is evident that the speed of sound depends only on the gas temperature and not on the pressure or the density. We also have observed that

$$\delta V = \beta n (\bar{v}^2), \quad (47.25)$$

where \bar{v}^2 is the mean square of the speed of the molecules. It follows that $c_s^2 = (\delta V/\delta p) \bar{v}^2$, or

$$c_s = \left(\frac{\delta V}{\delta p} \right)^{1/2} \bar{v}_{\text{av}}. \quad (47.26)$$

This equation states that the speed of sound is some number which is roughly $1/(\beta)^{1/2}$ times some average speed, \bar{v}_{av} , of the分子 of the square root of the

and negative velocity. In other words, the speed of sound is of the same order as the mean free path of the molecules, and is normally somewhat less than this average speed.

Of course we could expect such a result, because a disturbance like a change in pressure is after all propagated by the motion of the molecules. However, such an argument does not tell us the precise propagation speed; it could have turned out that sound was carried primarily by the fastest molecules, or by the slowest molecules. It is reasonable and satisfying that the speed of sound is roughly $\frac{1}{2}$ of the average molecular speed v_{av} .

Beats

45-1 Adding two waves

Some time ago we discussed in considerable detail the properties of light waves and their interference. There, the effects of the superposition of two waves from different sources. In all those days we assumed that the frequencies of the sources were *not* the same. In this chapter we shall discuss some of the phenomena which result from the interference of two sources which have different freq. ratios.

It is very easy to see what is going on here. Proceeding in the same way as we have done previously, suppose we have two equal oscillating sources of the same frequency whose phase is unadjusted, i.e., that the signals arrive in phase at some point P . At the point of P is light, the light is very strong, E_H is small. It is very low; or if it is electrons, none of them arrive. On the other hand, if the amplitudes were 100% out of phase, we would get no signal at P , because the two amplitudes there is then a minimum. Now suppose that one source has the "phase shift" α of one of the sources and change the phase. A look and for the eye, this making it 2π and then 180° , and so on. Of course, we would then have variations in the net signal strength. Now we also see that if one phase of one source is slowly changing relative to that of the other it is possible, with our source, starting at zero, going up to ten, twenty, thirty, forty degrees, and so on, then what we would measure is it would be a series of strong and weak "permutations." Because when the phase shifts through 360° the amplitude returns to a maximum. Of course, to say that one source is shifting its phase relative to another is a uniform way of thinking by saying that the number of oscillations per second is slightly different for the two.

Now, however, if we have two sources of slightly different frequencies we should find, as a net result, an oscillation with a slowly oscillating intensity. That is, of course, is the subject.

It is very easy to formulate this in mathematics also. Suppose, for example, that we have two waves, and that we do not work for the moment about all the specific relations but simply analyze who, or how, in P . For convenience let us say we want to assume, one from the other source, one, say, where the two ω 's are not exactly the same. Of course the amplitudes may not be the same either, but we can solve the general problem later. Let us first take the case where the amplitudes are equal. Then the total amplitude A is the sum of the two changes. If we plot the amplitudes of the waves against the time, as in Fig. 45-1, we see that

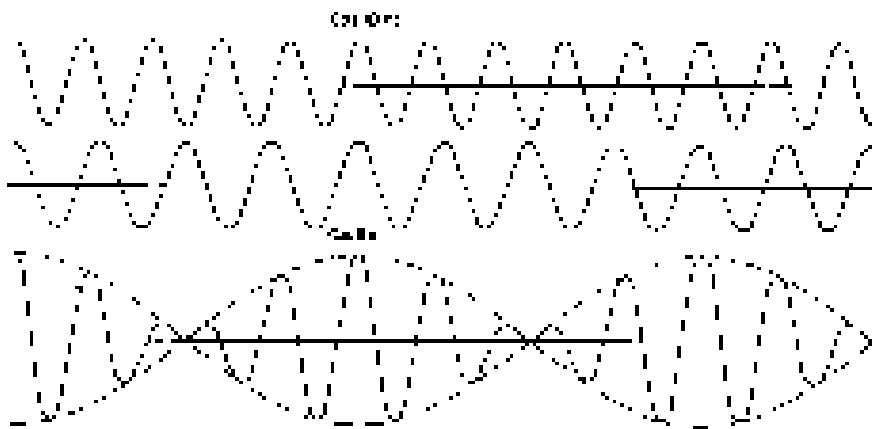

Fig. 45-1. The superposition of two acoustic waves with frequencies in the ratio 8:10. The periodic repetition of the pattern within each "beat" is not typical of the general case.

45-2 Adding two waves

45-2 Beat notes and modulation

45-3 Side bands

45-4 Localized wave zones

45-5 Probability amplitudes for particles

45-6 Waves in three dimensions

45-7 Normal modes

where the waves interfere we get a strong wave, and where a trough and crest coincide we get practically zero, and then when the waves interfere again we get a strong wave again.

Mathematically, we need only to add two cosines and determine the result somehow. There exist a number of useful relations among cosine which is not difficult to derive. Of course we know that

$$e^{i(\omega_1 t + \phi_1)} = \cos \omega_1 t + i \sin \omega_1 t, \quad (48.1)$$

and that $e^{i\theta}$ has a real part, $\cos \theta$, and an imaginary part, $\sin \theta$. If we take the real part of $e^{i(\omega_1 t + \phi_1)}$, we get $\cos(\omega_1 t + \phi_1)$. If we multiply out:

$$e^{i\theta_1} e^{i\theta_2} = (\cos \theta_1 + i \sin \theta_1)(\cos \theta_2 + i \sin \theta_2),$$

we get $\cos \theta_1 \cos \theta_2 - \sin \theta_1 \sin \theta_2$, plus some imaginary parts. But we now need only the real part, so we have

$$\cos(\theta_1 + \theta_2) = \cos \theta_1 \cos \theta_2 - \sin \theta_1 \sin \theta_2. \quad (48.2)$$

Now if we change the sign of θ_2 , since the cosine does not change sign while the sine does, the same equation, for negative θ_2 , is

$$\cos(\theta_1 - \theta_2) = \cos \theta_1 \cos \theta_2 + \sin \theta_1 \sin \theta_2. \quad (48.3)$$

If we add these two equations together, we see the signs and we learn that the product of two cosines is half the cosine of the sum, plus half the cosine of the difference:

$$\cos \theta_1 \cos \theta_2 = \frac{1}{2} \cos(\theta_1 - \theta_2) + \frac{1}{2} \cos(\theta_1 + \theta_2). \quad (48.4)$$

Now we can also reverse the formula and find a formula for $\cos \theta_1 + \cos \theta_2$ if we simply let $a = \theta_1 + \theta_2$ and $b = \theta_1 - \theta_2$. That is, $a = 2(\theta_1 + \theta_2)$ and $b = 2(\theta_1 - \theta_2)$, so that

$$\cos \theta_1 + \cos \theta_2 = \frac{1}{2} \cos \frac{a}{2} (\theta_1 + \theta_2) + \frac{1}{2} \cos \frac{b}{2} (\theta_1 - \theta_2). \quad (48.5)$$

Now we can analyze our problem. The sum of $\cos \omega_1 t$ and $\cos \omega_2 t$ is

$$\cos \omega_1 t + \cos \omega_2 t = 2 \cos \frac{1}{2}(\omega_1 + \omega_2) t \cos \frac{1}{2}(\omega_1 - \omega_2) t. \quad (48.6)$$

Now let us suppose that the two frequencies are nearly the same, so that $\frac{1}{2}(\omega_1 + \omega_2)$ is the average frequency, and is more or less the same as either ω_1 or ω_2 if ω_1 is much smaller than ω_2 , or ω_2 because, as we suppose, ω_1 and ω_2 are really equal. That means that we can ignore the evolution by saying that there is a high-frequency noise or the more or less like the ones we started with, but that its "size" is slowly changing. Its "size" is pulsating with a frequency which appears to be $\frac{1}{2}(\omega_1 - \omega_2)$. But is this the frequency at which the beats are heard? Although (48.6) says that the amplitude goes as $\cos \frac{1}{2}(\omega_1 - \omega_2) t$, what it is really telling us is that the high-frequency oscillations contained between two opposed cosine curves is shown dotted in Fig. 48-1. On this basis one could say that the amplitude varies at the frequency $\frac{1}{2}(\omega_1 - \omega_2)$, but if we are talking about the intensity of the wave we must think of it as having twice this frequency. That is, the pulsation of the amplitude, in the sense of the strength of its intensity, is at frequency $\omega_1 - \omega_2$, although the formula tells us that we multiply by a cosine wave at half that frequency. The technical basis for this difference is that the high-frequency wave has a little different phase relationship to the second harmonic.

Ignoring this small complication, we may conclude that if we add two waves at frequency ω_1 and ω_2 we will get a resulting wave of average frequency $\frac{1}{2}(\omega_1 + \omega_2)$ which oscillates in strength with a frequency $\omega_1 - \omega_2$.

If the two amplitudes are different, we can do, all over again, by multiplying the cosine by different amplitudes A_1 and A_2 , and do a lot of mathematics, rearranging, and so on, using equations like (48.2)-(48.5). However, there are other, easier ways of doing the same analysis. For example, we know that it is much

easier to work with exponents than with sines and cosines and we can represent it, however, in real part of $A_1 e^{i\omega t}$. The other sum would similarly be the real part of $A_2 e^{i\omega t}$. If we add the two, we get $A_1 e^{i\omega t} + A_2 e^{i\omega t}$. If we then factor out the average frequency, we have

$$A_1 e^{i\omega t} + A_2 e^{i\omega t} = e^{i\omega t}(A_1 \cos(\omega t) + A_2) = A_0 \cos(\omega t - \phi) \quad (45.7)$$

Again we have the high frequency wave with an oscillation of the direct intensity.

45.2 Beat notes and modulation

If we are now asked for the intensity of the wave of (45.7), we can either take the sum of the squares of the left side, or of the right side. That is to say, the left side. The frequency then is:

$$\nu = A_1^2 + A_2^2 + 2A_1 A_2 \cos(\phi) = \nu_0 \nu \quad (45.8)$$

We see that the intensity grows and falls at a frequency $\omega_0 = \pi/\tau$, varying between the limits $(A_1 + A_2)^2$ and $(A_1 - A_2)^2$. If $A_1 > A_2$, the maximum intensity is not zero.

One might try to represent this idea by means of a drawing, like Fig. 45-2. We draw a vector of length A_1 , rotating at a frequency ω_0 , to represent one of the waves in the complex plane. We draw another vector of length A_2 , going around at a frequency ω_0 , to represent the same wave. If the two frequencies are exactly equal, their resultant is of fixed length ν_0 and keeps revolving, and we get a definite fixed intensity from the two. But if the frequencies are slightly different, the two complex vectors go around at different speeds. Fig. 45-3 shows what the situation looks like relative to the moving object. We see that A_1 is moving slowly away from A_2 , and so the amplitude ν_0 is not big, because the two vectors are getting farther apart. As it gets to the left extreme position the resultant ν_0 goes to zero. At the right extreme position the two vectors go around, the amplitude of the sum wave gets exaggerated bigger, and the intensity is a pulsator. It is a relatively simple idea, and there are many different ways to represent the same thing.

The effect is very easy to observe experimentally. In the case of sound, we may arrange two oscillators driven by two separate oscillators, one for each loudspeaker, so that they never make a tone. We can receive one note from one source and a different note from the other source. If we make the frequencies exactly the same, the resulting effect will have a constant strength of a given square location. If we then change them a little bit, we have some variation in the intensity. The further they are detuned, the more rapid are the variations of sound. The ear has been built following analogous more solid rules than we are now aware.

We may also see the effect on an oscilloscope which simply displays the sum of the currents to the two speakers. If the frequency of passing is relatively low, we simply see a sinusoidal wave that wave amplitude pulsates, but as we make the oscillations more rapid we see the kind of wave shown in Fig. 45-3. As we go to greater frequency differences, the "beams" move closer together. Also, if the amplitudes are not equal and we take one signal a range than the other, even we get a wave whose amplitude does not go because zero, just as we expect. Even though it works the way it should both acoustically and electrically.

The opposite phenomenon occurs in radio transmission using so called amplitude modulation (AM). The sound is broadcast by the station as follows: the same transmitter sends an electromagnetic wave which is at a very high frequency, for example 400 kHz/cycles per second, in the broadcast band. If this carrier signal is turned over, it can generate across a wave which is of uniform amplitude of 800,000 times its a second. If it was the "information" is transmitted, the address and of information about what kind of car to buy, is that when someone talks into a microphone, the amplitude of the car in sight is changing then along with the vibrations of sound entering the microphone.

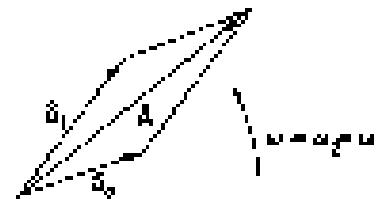

Fig. 45-2. The resultant of two complex vectors of equal frequency.

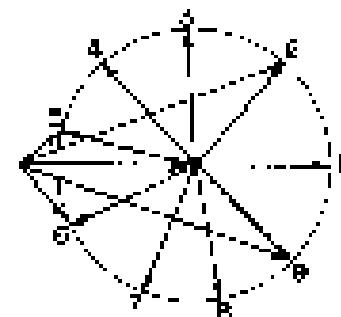

Fig. 45-3. The resultant of two complex vectors of unequal frequency, as seen in the rotating frame of reference of one vector. Note successive positions of the slowly rotating vector A_1 , above.

If we take as the simplest mathematical case the situation where a siren is singing a perfect note, with perfect sinusoidal oscillations of the vocal cords, then we get a signal whose strength is changing as shown in Fig. 4B-4. The instantaneous information is then recovered at the receiver, we get rid of the noise wave and just look at the envelope which represents the oscillations of the vocal cords, or the sound of the singer. For the speaker, then makes an oscillating vibration at the same frequency as the siren, and the listener is then sensitive enough to feel the difference in frequency. Because of a number of formidable and often subtle effects it is in fact impossible to tell whether we are listening to a siren or to a note, except; otherwise the idea is as ridiculous above.

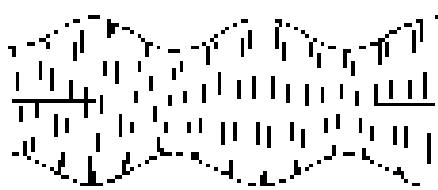

Fig. 4B-4. A modulated carrier wave. In the schematic notation, ω_0/T is the signal frequency, $\omega_0/\omega_m = 100$.

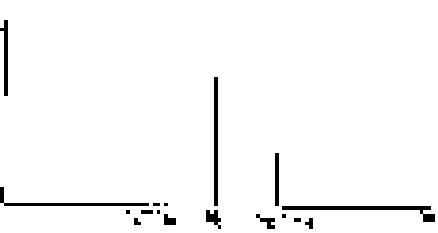

Fig. 4B-5. The frequency spectrum of a carrier wave as modulated by a single side wave ω_m .

4B-3 Side bands.

Mathematically, the modulated wave described above would be expressed as

$$S = C + \text{modulation} \quad (4B-9)$$

where C , represents the frequency of the carrier wave, ω_0 , the frequency of the modulating wave. Again we use all the theorems about the sounds, or we can use $e^{j\theta}$; it makes no difference as to how with ω_0' , but it is the same thing. We can get

$$S = \cos \omega_0 t + j \sin \omega_0 t \omega_m (\omega_0) \quad \text{given } (\omega_0 - \omega_m) \quad (4B-10)$$

From another point of view, we can say that the output wave of the system consists of three waves added in superposition: first, the original wave at the frequency ω_0 , that is, a carrier frequency, and then two new waves at two new frequencies. One is the carrier frequency plus the modulation frequency and the other is the carrier frequency minus the modulation frequency. In therefore, we make some kind of pair of the frequency being generated by the wave due to a function of frequency, as we wanted a low intensity at the frequency of the carrier, naturally, but when a signal starts having we want to have also the intensity proportional to the strength of the carrier, S , at frequencies $\omega_0 + \omega_m$ and $\omega_0 - \omega_m$ as shown in Fig. 4B-5. These are called side bands when there is a modulated signal here, the carrier, or, then, the side bands. If there is more than one tone at two different frequency ω_0 and ω_1 , there are two instances of passing, or if there is any other complicated wave here, then, of course, we can see from the mathematics that we get some more waves that correspond to the frequencies $\omega_0 + \omega_1$, etc.

Therefore, when there is a demodulated amplitude, this can be represented as the sum of many waves. That is, that the detector is measuring out, a range of frequencies, namely the carrier frequency plus or minus the modulation frequency that are modulated signal components.

Although at first we might believe that a radio transmitter transmits only at the one frequency of the carrier, since there are big, super stable crystal oscillators in there, and everything is allowed to be at precisely 500 K cycles, the moment someone measures the radio set, it 3.0 hertzcycles, he modulates the 500 kilocycles, and so they can no longer precisely at 500 kilocycles. Suppose the transmitters are so built that they are able to transmit over a good range of the radio's sensitivity (that is, from up to 20,000 cycles per second, but usually radio transmitters and receivers do not work very at 10,000), so we do not have the highest part, that is, when the main signals are within very narrow frequencies running up, etc., to 10,000 cycles, so the transmitted is modulating frequencies ...

* A different remark: In what circumstances can a curve be approximated by a lot of straight segments. In all ordinary circumstances except for certain cases the mathematics are difficult. Of course, if you must have only one value at a given point, you may not be able to draw a curve which joins an infinite number of lines, or informed curves, or something like that. But inside them such continuous approximation can be done that a siren is going to be able to make by sketching on one family of curves or compounded by adding others more together.

which may range from 790 to 810 megacycles per second. Now if we have another station at 795 because there would be a lot of interference. And, if we make our receiver so sensitive that it picks up only 800, one did not pick up the 795 megacycles on either side, we would not hear what the man was saying, because the information would be on the side which frequencies. Therefore it is absolutely essential to stop the picture at certain intermediate points, so that the side bands do not overlap and, also, the receiver must not be so selective that it does not permit reception of the side bands as well as of the radio central frequency. In the case of sound, the problem does not really come much into play. We can hear over a 20 kilocycle range, and we have usually from 300 to 1000 kilocycles in the broadcast band, so there is plenty of room for lots of stations.

The reception problem is more difficult. As the electron beam goes across the face of the picture tube, there are various little spots of light and dark. Let "light" and "dark" be the "signal." Now suddenly the beam scans over the whole picture. Suppose, approximately, in a vertical column. Let us assume that the resolution of the picture vertically and horizontally is more or less the same, so that there are the same number of dots per inch along a scan line. We want to be able to distinguish dark from light, dark from light, dark from light, etc., 300 lines. In order to be able to do this with colors we have the choice a wavelength needed that corresponds to a wavelength, from ~~maximum to minimum~~, of one 750th of the green wave. So we have $300 \times 300 \times 30$ pieces of information per second. The highest frequency that we are going to carry, therefore, is thus: 4 megacycles per second. Actually, to keep the television stations apart, we have to use 3 bits of information from this, a total of 12 bits; part of it is used to carry the sound signal. And other information. So, resolution demands are 6 megacycles per second with. It certainly would not be possible to transmit TV on the 400 kilocycles center, since we cannot measure at a higher frequency than the carrier.

At any rate, the television wave starts at 4 megacycles. The first transmission channel, which is channel 2 (U), has a frequency range from 51 to 60 megacycles, which is 9 megacycles wide. "But," one might say, "we have just proved that there were side bands on both sides, and therefore it is 18 megacycles wide." I think not. Just the radio engineers are rather clever. If we realize the modulation signal using only sine waves, but having nothing to do with the physical mechanics, we can see that there is a definite, invariant relationship between the side band on the high-frequency side and the side band on the low-frequency side. What we prove is that there is no new information on that other side band. So what is done is to suppress one side band, and the receiver is fitted with that the information which is missing is reconstructed by looking at the single side band and the carrier. Single-side-band transmission is a clever scheme for decreasing the band width needed to transmit information.

4.4 Identified wave forms

The next subject we'd like discuss is the waveforms of waves in both space and time. Suppose that we have two waves travelling in space. We know, of course, that we can represent a wave travelling in space by $e^{i(kx-\omega t)}$. This might be, for example, the displacement in a sound wave. This is a solution of the wave equation provided $\omega^2 = k^2 c^2$, where c is the speed of propagation of the wave. In this case we can write it as $e^{i(kx-\omega t)}$, modulus of the general form $f(x - ct)$. Therefore this must be a wave which is travelling at this velocity, with, and that is all right.

Now we want to add two such waves together. Suppose we have a wave that is travelling with one frequency, and another wave travelling with another frequency. We have to remember to consider the case where the amplitudes are different; it makes no real difference. Let us write it as $A_1 e^{i(k_1 x - \omega_1 t)}$. We can add this by the same kind of mathematics we used when we added signal waves. Of course, if ω_1 is the same as ω_2 , this is easy, since it is the sum of what we had before:

$$e^{i(k_1 x - \omega_1 t)} + e^{i(k_2 x - \omega_2 t)} = e^{ik_1 x} [e^{i\omega_1 t} + e^{i\omega_2 t}] \quad (15.11)$$

except that $\phi = \omega_0 t$ is the variable instead of t . So we get the same kind of wavefunctions, naturally, but we see, of course, that these modulations are moving along $\rho \neq 0$. In other words, if we added two waves, but these waves were not just oscillating but a moving in space, then the resultant wave would move along also, at the same speed.

Now we would like to generalize this to the case of waves in which the relationship between the frequency and the wave number is not so simple. For example, consider using an index of refraction. We have already studied the theory of the index of refraction in Chapter 11, where we found that we could write $k = n\omega/c$, where n is the index of refraction. As an interesting example, let us say we know that the index is

$$n = 1 + \frac{\partial \phi^2}{2c_0 \omega^2}. \quad (48.10)$$

We actually derived a more complicated formula in Chapter 11, but this one is good enough for our example.

Incidentally, we note that even when n and k are not linearly proportional, the ratio n/k is constant, the speed of propagation for the particular frequency and wave number. When it is the speed of propagation, the speed at which the phase, or the nodes of a sinusoidal wave, would move. Let us

$$v_p = \frac{\omega}{k}. \quad (48.11)$$

This phase velocity, for the case of waves in glass, is given by the speed of light in vacuum ($c = 3 \times 10^8$ cm/sec) times n (as from Eq. 1), and that is a bit higher, because we do not think we can send speeds faster than the speed of light.

What we are going to determine is the interference of two waves in which ω_1 and ω_2 have a definite formula relating them. Use above formula for v_p , Eq. 1, is given as a definite function of ω . This quantity in this particular problem—the formula for k in terms of ω is

$$k = \frac{\omega}{c} - \frac{n}{v_p}, \quad (48.12)$$

where $n = \omega_0^2/(\omega_0 + \omega_1 + \omega_2)$. At any rate, for each frequency there is a definite wave number, and we want to add two such waves together.

Let us do it just as we did in Eq. (48.9);

$$\begin{aligned} e^{i(\omega_1 t + k_1 x)} &= e^{i(\omega_0 t + k_0 x)} + e^{i(\omega_0 t + k_0 x + \omega_1 t + \omega_1 x)} \\ &\times \{e^{i(\omega_0 t + \omega_1 t + k_0 x + k_1 x)} - e^{i(\omega_0 t + \omega_1 t + k_0 x + k_1 x + 2\pi)}\}. \end{aligned} \quad (48.13)$$

So we have a modulated wave again, a wave which travels with the mean frequency and the mean wave number, but whose k and ω is varying with x in which the amplitude of the difference frequency is $\omega_1 = \omega_1 - \omega_0$ wave number.

Now let us make the case that the difference between the two waves is relatively small. Let us suppose that we are adding ω_1 to ω_0 where ω_0 and ω_1 are nearly equal; then $(\omega_1 + \omega_0)/2$ is probably the same as either one of the ω 's, but certainly for $(\omega_1 + \omega_0)/2$. Thus the speed of the wave, the "group velocity," the index is not necessarily n . But back to the point of propagation where modulation is not the same! How to reduce we have to change k to account for a certain constant of ω . The speed of this modulation wave is the rule:

$$v_g = \frac{\omega_1 - \omega_0}{k_1 - k_0}. \quad (48.14)$$

The speed of modulation is sometimes called the group velocity. If we take the case that the difference in frequency is relatively small, and the difference in wave number is also relatively small, then this expression approaches us, in the limit,

$$v_g = \frac{\omega_1}{k_1}. \quad (48.15)$$

In other words, for one source, modulation, the signal beats, there is a definite speed at which they travel which is not the same as the phase speed of the waves—what a mysterious thing!

The group velocity is the derivative of ω with respect to k , and the phase velocity is v/c .

Let us see if we can understand why. Consider two waves, again of slightly different wavelength λ , as in Fig. 45-1. They are out of phase, $\pi/2$ phase, out of phase, and so on. Now these waves represent, really, the waves in space travelling with slightly different frequencies also. Now because the phase velocity, the velocity of the crests of these two waves, is not necessarily the same, something new happens. Suppose we ride along with one of the waves and look at the other one; if they both travel at the same speed, then the other wave would stay right where it was relative to us, as we ride along on this wave. We find, in fact, that now and right opposite us we see a beat. If the two velocities are equal the crests stay on top of each other but if it is not we find the two velocities are really equal. There is only a small difference in frequency and therefore only a $\sim \frac{1}{\lambda}$ difference in velocity, but because of that difference in velocity, as we ride along the other wave moves slightly forward, say, or nothing, relative to our wave. So as in a guitar, what happens? If we move one wave just a shade forward, the wave travels forward (or backward) considerably distance. That is, the sum of these two waves has an envelope, and as the waves travel along the envelope rises or falls at a different speed. The group velocity is the speed at which modulated signals would be transmitted.

If we move a signal, i.e., some kind of charge in the wave that one could recognize when he listened to it, a kind of modulation, then this would then travel at the group velocity, provided that the amplitudes were relatively small. (When they are large, it is much more difficult to analyze.)

Now we may show (not long ago), that the speed of propagation of γ -rays in a block of carbon is very greater than the speed of light, although the phase velocity is greater than the speed of light. In order to do that we must find $d\omega/dk$, which we get by differentiating (45.14) $d\omega/dk = v/c - n\omega/c$. The group velocity, therefore, is the reciprocal of this quantity,

$$v_g = \frac{c}{1 + \omega^2 n^2} . \quad (45.18)$$

which is smaller than c . So although the phases are travel faster than the speed of light, the modulating signals travel slower, and that is the result of the apparent paradox. Of course, if we have the simple case that $n = 1$, then v_g will be also c . So when all the photons have the same velocity, certainly the group has the same velocity.

46-5 Probability amplitudes for particles

Let us now consider one more example of the phase velocity which is extremely interesting. It has to do with quantum mechanics. We know that the amplitude to find a particle at a place and, in some circumstances, vary in space and time, let us say in one dimension, in the manner:

$$\psi = A e^{i(kx-\omega t)} , \quad (46.19)$$

where ω is the frequency, which is related to the charge, e , of the charge through $E = Pv$, and k is the wave number, which is related to the momentum through $p = \hbar k$. We should say that you could not find a definite momentum p if the wave number were exactly k , but it is k plus more which goes on with the same amplitude everywhere. Equation (46.19) gives the amplitude, and if we take the absolute square, we get the relative probability for finding the particle as a function of position and time. This is a constant, which means that the probability is always the same a particle anywhere. Now suppose, instead, that we have a situation where we know that the particle is more likely to be at one place than at another. We would

represented more accurately by a wave which has a maximum and decays on either side (Fig. 48-6). It is more realistic than a wave-like (48.7) which has a series of maxima, but it is possible, by adding several waves of nearly the same ω and k together, to get rid of all but one maximum.

Now at different instants, since the square of (48.19), m^2/c^2 , is the square of having a particle somewhere, we know that at a given instant the particle is most likely to be near the center of the "lump," where the amplitude of the wave is maximum. If we wait a few moments, the waves will interact, and after some time the "lump" will reseparate like Fig. 48.7. If we know that the particle originally was scattered somewhere, obviously we can expect that it would later be elsewhere as a matter of fact, because it has moved, after all, with some velocity. The quantum theory, then, will go into the correct classical theory for the relationship of momentum, energy, and velocity only if the group velocity, the velocity of propagation, is equal to the velocity that the particle drifts classically for a particle of the same momentum.

It is very necessary, when discussing this subject, to note the case. According to the classical theory, the energy is related to the velocity through an equation like

$$E = \frac{mv^2}{\sqrt{1 - v^2/c^2}}. \quad (48.19)$$

Similarly, the momentum is

$$p = \frac{mv}{\sqrt{1 - v^2/c^2}}. \quad (48.20)$$

To get the classical theory, one does a very simple part of the classical theory by eliminating v ; we can show that

$$E^2 - p^2c^2 = m^2c^4.$$

This is the four-dimensional general result that we have talked and talked about, that $p_{\mu}p^{\mu} = m^2$; that is the relation between energy and momentum in the classical theory. Note that again, since (48.19) is the group velocity, we must add E^2 , by substitution, $E^2 = E^2 + p^2c^2$. So that for quantum mechanics it is no mystery that

$$\frac{E^2c^2}{c^2} = p^2c^2 + m^2c^2. \quad (48.21)$$

This then is the relationship between the frequency and the wave number of a quantized longitudinal amplitude wave representing a particle of mass m . From this equation we can deduce that ω is

$$\omega = c\sqrt{k^2 + m^2/c^2}.$$

The group velocity, $c\sqrt{k^2}$, is necessarily larger than the speed of light.

Now let us look at the group velocity. The group velocity equals $c\sqrt{k^2}$, or the speed to which the modulations move. We have to differentiate a square root, *i.e.*, a square root times a square root, which is not very difficult. The derivative is

$$\frac{dk}{dt} = \frac{\partial k}{\partial t} = \frac{\partial k}{\partial \omega} \frac{\partial \omega}{\partial t} = \frac{\partial k}{\partial \omega} \frac{\partial}{\partial t} \left(\sqrt{\omega^2 - p^2c^2} \right).$$

Now the square root is, after all, ω , so we could write this as $d\omega/dt = \pm k/m$. In other words, ω/E is

$$\omega = \frac{ck}{E}.$$

In both (48.20) and (48.21), $c\sqrt{k^2}$ is the velocity of the particle, according to classical mechanics. So we see that whereas the fundamental quantum-mechanical relationship $E = h\nu$ and $p = \hbar k$, for the combination of ω and k with the classical E and p , only produces the equation $\omega^2 - p^2c^2 = m^2/c^2$, now we also understand the relationships (48.20) and (48.21) which connect E and ω to k .

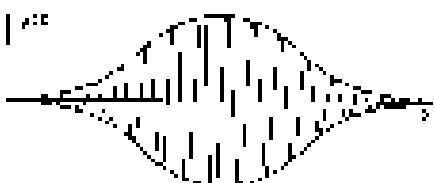

Fig. 48-6. A localized wave train.

to the velocity. Of course the group velocity must be the value v_g of the particle if the interpretation is going to make sense. If we think the particle is moving at constant speed, and then the particle has to think it is over there, as the quantum mechanics said, the distance traversed by the "lump," caused by the disturbance, can't be classically the velocity of the particle.

48.6 Waves in three dimensions

We start now in our discussion of waves to a third with a few general remarks about the wave equation. These remarks are intended to give some idea of the future, and that we can understand something much later on, but rather to see what things are going to look like when we get to waves in three dimensions. Fig. 48.17, the wave equation for waves in one dimension was

$$\frac{\partial^2 \psi}{\partial x^2} = \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2},$$

where c is interpreted as above, the wave to run in the case of sound, is the sound speed, in the case of light, is the speed of light. We showed that for a forced wave the displacement would propagate through space at a certain speed. But the excess pressure also propagates at a certain speed and so does the excess density. So we should expect that the pressure would satisfy the same equation, or indeed it does. We shall revert to the basic wave picture again. First, ρ is proportional to the rate of change of ψ with respect to x . Therefore if we differentiate the wave equation with respect to x , we will immediately discover that $\delta\rho/\delta x$ satisfies the same equation. That is, we can multiply the same equation. If ψ is proportional to ρ , and therefore $\delta\rho/\delta x$ does too. So the pressure, the displacement, everything, satisfy the same wave equation.

Usually one sees the wave equation for sound written in terms of pressure instead of in terms of displacement. This is because pressure is a scalar and has no direction. But the displacement is a vector and has direction, and it is easier to analyze the pressure.

The next problem we discuss is to do with the wave equation in three dimensions. We know that the sound wave solution in one dimension is $e^{i(kx-\omega t)}$, and $\omega = kc_n$, but we also know that in three dimensions a wave would be represented by $e^{i(\sqrt{k^2 + \omega^2}x - \omega t)}$, where, in this case, $k^2 = k_x^2$, which is, of course, $(\partial/\partial x)^2 + (\partial/\partial y)^2 + (\partial/\partial z)^2$. Now what we want to do is to guess what the correct wave equation in three dimensions is. Naively, for the case of sound this can be obtained by going through the same dynamic argument in three dimensions that we made in one dimension. But we shall not do that; instead we just write down what comes out, the equations for the pressure (or displacement, ψ , according) x

$$\frac{\partial^2 \psi}{\partial x^2} = \frac{\partial^2 \rho}{\partial x^2} = \frac{\partial^2 P}{\partial x^2} = \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2}. \quad (48.23)$$

That this is correct can be verified by differentiating $e^{i(\sqrt{k^2 + \omega^2}x - \omega t)}$. Clearly, every time we differentiate with respect to x , we multiply by $-ik_x$. If we differentiate twice, we require first to multiply by $-k_x^2$, so the first term would become $-k_x^2 e^{i(\sqrt{k^2 + \omega^2}x - \omega t)}$; the second term becomes $-k_x^2 e^{i(\sqrt{k^2 + \omega^2}x - \omega t)}$, and the third term becomes $-k_x^2 e^{i(\sqrt{k^2 + \omega^2}x - \omega t)}$. On the right, we get $-(\omega^2/c^2)e^{i(\sqrt{k^2 + \omega^2}x - \omega t)}$. Then, if we take away the first and change the sign, we get all the relation, and between variables is however it is wanted.

Moving to quantum theory, we can start writing down the general equation which corresponds to the dispersion equation (48.12) for quantized mechanical waves. If ψ represents the amplitude for finding a particle's position x, y, z , at the time t , then the great equation $\psi_{n,k}$ is given again, its for 2D particles is this

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} = \frac{\omega^2 \psi}{c^2} - \frac{m^2 \psi^2}{E^2} x. \quad (48.24)$$

In other words, the only difference with this expression is suppressed by the appearance

of x , y , z and t of the nice combination continuity wave improves. Second, it's a wave equation which, if we try a plane wave, would produce an expression that $-k^2 + \omega_0^2 k^2 = m^2 c^2 / N$, which is the right relationship for quantum mechanics. There is still another great thing contained in the wave equation: the fact that any superposition of waves is also a solution. So this equation contains all of the quantum mechanics and the relativity that we have been discussing so far, at least so long as it deals with a single particle in empty space with no external potentials in there at all.

46-7 Normal modes

Now let's do another example of the phenomenon of beats, which is rather curious and a little different. Imagine two equal pendulums which have, between them, a rather weak spring connection. They are made as nearly as possible the same length. If we put one with some energy it moves back and forth, and it pulls on the connecting spring so it moves back and forth, and even more is a machine for generating a force which has the natural frequency of the other pendulum. Therefore, is a consequence of the theory of resonance, which we studied before: when we put a force of something at just the right frequency, it will drive it. So, sure enough, one pendulum moving back and forth drives the other. However, is this the circumstance? This is a new thing *suppose*, because the total energy of the system is finite, so when one pendulum takes its energy out of the other to drive it, it finds itself gradually losing energy until, if the driving is just right along with the speed, it loses all its energy and is reduced to a stationary condition. There, of course, is the other pendulum but that has all the energy and the first one which has more and as time goes on we can see it works also in the opposite direction, until finally the energy is passed back into the first self: this is a very interesting and amusing phenomenon. We said, however, for this is related to the theory of beats, and we must now explain how we can analyze this motion from the point of view of the theory of beats.

We note that the motion of either of the two bobs is an oscillation which has an amplitude which changes steadily. Therefore the motion of one of the bobs is approximately analytic in a different way, in that it is the sum of two oscillations, present at the same time but having two slightly different frequencies. The idea is again to be possible to find two other motions in this system and to claim that what we saw was a superposition of the two motions, because this is of course a linear system. Indeed, it is easy to find two ways that we could start the motion, each one of which is a perfect single-frequency motion—absolutely periodic. The motion that we started with before was not strictly periodic, since it did not last, since one bob was passing energy to the other and so it's going to oscillate but there are ways of starting the motion so that nothing happens and, of course, as soon as we see it we understand why. For example, if we made both pendulums go together, then, since they are of the same length and the spring is not carrying anything, they will of course continue to swing like that for all time, according to Hooke and that everything is perfect. On the other hand, there is another possible motion which also has a definite frequency, that is, if we made the pendulums approach, pulling them with exactly equal distances, then again they would be in absolutely periodic motion. We can imagine that the spring just adds little to the restoring force that the spring supplies the overall and the system just keeps oscillating at a slightly higher frequency than in the first case. Why? Because the spring is pulling, in addition to the gravitation, and it makes the system a little "tighter," so that the frequency of this motion is just a shade higher than the other.

Thus this system has two ways in which it can oscillate with undamping amplitude: it can either oscillate in a manner in which both pendulums go the same way and neither all the time at one frequency, or they could go in opposite directions at a slightly higher frequency.

Now the actual motion of the ring, because the system is linear, can be represented as a superposition of the two. (This is left as an exercise, remember, at 1b.)

(- the effect of adding two motions with different frequencies.) So think what would happen if we considered these two motions. First - if the two motions were to start with equal amplitude and in the same phase, the sum of the two motions means that one half, having been increased one way by the first motion and the other way by the second motion, is zero while the other half, having been displaced the same way in both motions, has a large amplitude. As time goes on, however, the two halves remain "independent," and a plateau like the top of the wave is slowly shifting. Then comes, even though a sufficiently long time, when the time is enough that one motion could have gone "180°" oscillations, while the other were only "90°." The relative phase would be just reversed with respect to what it was before. That is, the large amplitude section will have fallen to zero and in the meantime, of course, the initially stationary half will have acquired full strength.

So we see that we could analyze this complicated motion either by the law that there is a transient and that one gains energy at the other, or else by the superposition of two counter-amplitude motions at two coherent frequencies.

Waves

49-1 The reflection of waves

This chapter will consider some of the remarkable phenomena which may result in conflicting waves in some finite regions. We will be led to the subject by particular facts about vibrating strings, for example, and then the generalization of these facts will give us a principle which is probably the most far-reaching selectable of mechanics and physics.

Our first example of conflicting waves will be to consider waves at one boundary. Let's take the simple example of a one-dimensional wave on a string. One could equally well consider waves in one dimension against a wall, or the situation is similar nature, but the example of a string will be sufficient for our present purposes. Suppose the string is held at one end, for example by fastening it in an "indefinitely solid" wall. Then we can visualise mathematically by saying that the displacement y of the string at the position $x = 0$ must be zero, because the end does not move. Now if it were not for the wall, we know that the general solution for the string is the sum of two vibrations, $y(t) = y_1 + y_2$, the first representing a wave travelling to the left in the string, and the second a wave travelling the other way in the string:

$$y = F(x - ct) + G(x + ct) \quad (49-1)$$

is the general solution for any string. If we have now to satisfy the condition that the string does not move at one end, if we put $x = 0$ in Eq. (49-1), and consequently setting y to zero of t we get $y = F(0 - ct) + G(0 + ct)$. Now this is to be zero for all time, it means that the function y must be $-F(-ct) - G(ct)$. In other words, if we multiply y by $e^{i\omega t}$, F and G are the same thing. If this result is put back into Eq. (49-1), we find that the solution for the problem is

$$y = F(x - ct) - F(x + ct). \quad (49-2)$$

It is easy to check that we still get $y = 0$ if we set $x = 0$.

Fig. 49-1 shows a wave travelling to the right at speed c near $x = 0$, and a hypothetical wave travelling in the other direction, also set in motion on the other side of the origin. The string is fixed at the side of the origin. The total motion of the string is to be regarded as the sum of these two waves in the region of zero x . As they reach the origin, they will always meet at $x = 0$, and truly *cancel each other* (destructively interfere) by the time one has gone positive x and it will, of course, be travelling in the negative x region. These results are analogous to the following statement: if a wave meets a rigid wall and reflects off, it will be reflected with a change in sign. Since a reflection can always be understood by inverting that part of the motion of the string comes out upside down from behind the wall. In short, if we assume that the string is infinite and that we have one wave going one way we have another one going the other way with the same amplitude, the displacement at $x = 0$ will always be zero and it would make no difference if we compact the string there.

The next point to be discussed is the reflection of a periodic wave. Suppose that the wave represented by $F(x - ct)$ is a sine wave and has been reflected; then the reflected wave $-F(x + ct)$ is also a sine wave of the same frequency, but travelling in the opposite direction. This requires F to have simple exponential behaviour, since the complex function relation: $F(x - ct) = e^{i\omega(x-ct)}$ and

49-4 Coupled pendulums

49-5 Linear systems

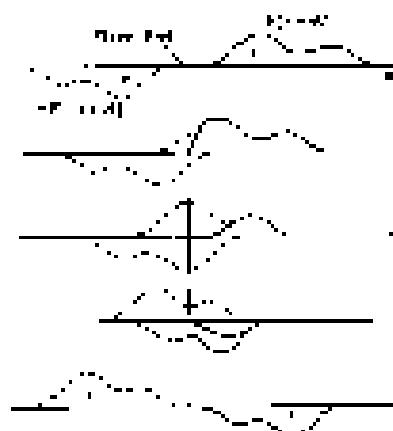

Fig. 49-1. Reflection of a wave and superposition of two travelling waves.

$\delta t = \pi - \alpha$ — *condition*. It can be seen that if these two values are in (49.2) and Δx is set equal to 0, then $\alpha = 0$ for all $\omega > \omega_0$, so it satisfies the *second condition*. Because of the properties of exponentials, this can be written in a simpler form:

$$x = e^{i\omega_0 t} (e^{-i\omega_0 t} + e^{i\omega_0 t}) = e^{i\omega_0 t} \sin(\omega_0 t/2) \quad (49.3)$$

There is something interesting and new here in the displacement that we look at any fixed x on the string's rest frequency. No matter where this point is, the frequency is the same! But does the same place, in particular whatever site $\Delta x = 0$, where there is no displacement \Rightarrow all? Furthermore, if at any time we take a snapshot of the string's string, the picture will be like waves. However, the displacement of this wave x will depend upon the time t . From inspection of Eq. (49.3) we can see that the length of one cycle of the sine wave is equal to the wavelength of either of the superimposed waves.

$$\lambda = 2\pi/\omega_0. \quad (49.4)$$

The points where there is no motion satisfy the condition $\sin(\omega_0 t) = 0$, which means that $\omega_0 t = 0, \pi, 2\pi, \dots, m\pi$. These points are called nodes. Between any two successive nodes, every point moves up and down sinusoidally, but the position of center stays fixed \pm nodes. This is the characteristic of standing waves on a string. One can find a pattern of nodes where are the present. Just at any point the object moves perfectly sinusoidally, and that all points move at the same frequency (though some will move more than others), when we have what is called a mode.

49-2 Standing waves, Mathematical Considerations

The next interesting problem is to consider what happens if the string is held at different, say sites. Assume $\alpha \neq 0$. We can begin with the idea of the reflection of waves coming from some kind of a boundary in one direction. As time goes on, we would expect the string to go back and forth, and as time goes still farther it will become a kind of little wobba, because it is combining with the reversed image wave which is coming from the other side. Finally the string's wavy will disappear and the string's energy will move in the other direction to repeat the process in the other end. This problem has an easy solution, but an interesting question is whether we can have continuous standing waves. Theory of diffraction is possible, but of course it is not necessarily periodic. Let us try to get a sinusoidally periodic wave on a string. If the string is tied at one end, we know it cannot look like our corner solution (49.3). If it is tied in the other end, it has to look like sum of the other end. So the only possibility for periodic waves is when the string is tied at both ends. When the string is tied at both ends, the only possibility is that $\sin(\omega_0 t) = 0$, however this is the only condition that will keep the ends fixed. Now to order the strings to be zero, the angle must be either $0, \pi/2, \pi$, or some other integer, k multiple of π . The condition

$$\delta t = \pi \quad (49.5)$$

will therefore give only one of the possible λ 's, depending on which integer is put in. For each of the λ 's there is a certain frequency ω which according to (49.3) is simple:

$$\omega = \Delta x \pi \omega_0 / \lambda. \quad (49.6)$$

We have found the following: that a string has a property that it can have sinusoidal motions, say with constant frequencies. This is the most important characteristic of confined waves. No matter how complicated the system is, it always turns out that there are some patterns of motion which have a perfect sinusoidal time dependence, but with frequencies that are a property of the particular system and the nature of boundaries. In the case of the string we have many different possible frequencies, such as, by definition, corresponding to a mode, because a mode is a pattern of motion which repeats itself sinusoidally. Figure 49-2 shows the first three modes for a string. For the first mode the wavelength is $\lambda = 2L$. This must be zero if one continues the wave out to $x = L$ to obtain one complete cycle of the sine wave. The angular frequency ω is then divided by the wavelength, in general, one in this case, exactly in 2π . The frequency is $\omega/2\pi$, which is in agreement with (49.2) with $v = 1$. Let us call the first mode frequency ω_1 . Now the next mode has two loops in the middle. For this mode the wavelength, then, is simply L . The corresponding value of ω is twice as great and the frequency is twice as large, $2\omega_1$. For the third mode, it is $3\omega_1$, and so on. So all the different frequencies of the string are multiples, 1, 2, 3, 4, and so on, of the lowest frequency ω_1 .

Returning now to the general method of the string, let us consider any possible motion can always be analyzed by adding the more than harmonic in operating at the same time. In fact, for general motion the actual number of modes must be excited at the same time. To get some idea of this, let us illustrate what happens when there are two modes oscillating at the same time. Suppose that we have the first mode oscillating as shown by the sequence of pictures of Fig. 49-3, which illustrates the deflection of the string for equally spaced time intervals, starting through one cycle of the lowest frequency.

Now, at the same time, we suppose that there is an oscillation of the second mode also. Figure 49-3 also shows a sequence of pictures of this mode, which at the start is 90° out of phase with the first mode. This means just or the start it has no displacement, but the two halves of the string have oppositely directed velocities. Now we recall a general principle relating to linear systems: if there are only two solutions, then their sum is also a solution. Therefore a third possible motion of the string would be a displacement which will be adding the two solutions shown in Fig. 49-3. The result, also shown in the figure, begins to suggest the idea of a bump running back and forth between the ends of the string, although with only two modes we cannot make a very good picture of its motion unless we extend. The result is, in fact, a special case of a great principle for waves generally.

Any motion at all can be analyzed by adding them it is the "principle of superposition" of all the different modes, combined with appropriate amplitudes and phases.

The importance of this principle derives from the fact that each mode is very simple—it is nothing but a sinusoidal function of time. It is true that now, the general motion of the string is not really very complicated, but there are other systems, for example the whipping of an airplane wing, in which the motion is a lot more complicated. Nevertheless, even with an airplane wing, we find cases in a certain particular way of twirling which has one frequency, and other ways of twirling may have other frequencies. If these modes can be found, then the complete motion can always be analyzed as a superposition of harmonic oscillations (except when the whipping is of such degree that the system can no longer be considered as linear).

49-3 Modes in one dimension

The best example to be considered is the interesting situation of modes in two dimensions. Up to this point we have talked only about one-dimensional situations—a stretched string or spring moving in a tube. Let's try to think of two dimensions, but an easier step will be due to two dimensions. Consider for definite a rectangular elastic membrane which is confined to a box; that is, it displaces only anywhere on the two angular edges, and let the dimensions of the rectangle

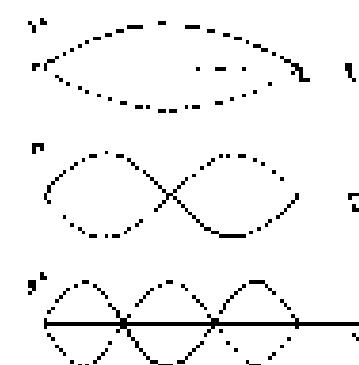

Fig. 49-2. The first three modes of a vibrating string

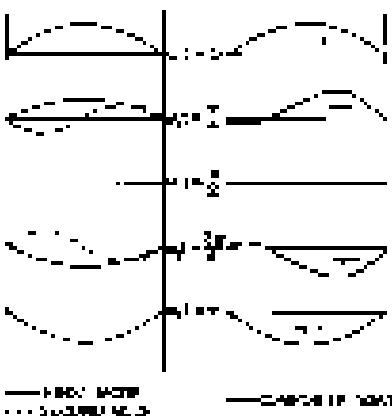

Fig. 49-3. Two modes combine to give a travelling wave.

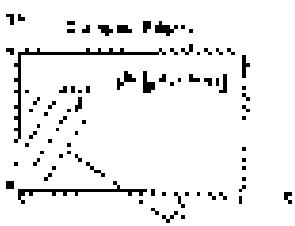

Fig. 19-4. Vibrating rectangular plate.

harmonic, as shown in Fig. 19-4. Now the question is, what are the characteristics of the possible modes? We consider as before the procedure easier for the x -mode. If we had no information at all, we would expect waves traveling along all paths that fit our mirror. For example, $(x^2)(y^2)(e^{i\omega t})$ would represent a wave traveling in some direction which depends on the relative values of x and y , and also has axes parallel to the x -axis, that is, the $\partial u/\partial y = 0$, $\partial v/\partial y = 0$. Using the ideas developed for the one-dimensional string, we can imagine another wave represented by the complex function $(-x^2)(y^2)(e^{i\omega t})$. The superposition of these waves will give us a displacement at $y = 0$ equal to the values of u and v (although these functions are defined for $y \neq 0$, let y where there is no displacement to $y = 0$, this can be ignored, since the displacement is only zero at $y = 0$). In this case we can look upon the second function as the reflected wave.

However, we want a nodal line at $y = b$ as well as at $y = 0$. How do we do this? The solution is similar to scattering, we did when studying reflection from crystals. These waves reflect off either at $y = 0$ or at $y = b$, only if the surface index of refraction is the same at $y = b$ (although it is not necessarily the same at $y = 0$), as shown in Fig. 19-5:

$$n_0 = 2n \sin \theta, \quad n = n_0 / k, \quad (19.7)$$

Now in the same way we can take the previous procedure by adding two more functions $-(x^2)(y^2)(e^{i\omega t})$ and $-(y^2)(y^2)(e^{i\omega t})$, each representing a reflection of one of the other two waves from the $y = b$ line. The condition for a nodal line at $y = b$ is similar to the one for $y = 0$. It is that $2k$ and $n_0 k$ be an integral multiple of π :

$$\pi n = 2k(b - a) \quad (19.8)$$

To conclude I recall that the waves forming a nodal line produce a standing-wave pattern, that is, a definite mode.

So we must satisfy the above two conditions if we want to have a mode. Let us find the wavelength. This can be done by eliminating the angle θ from (19.7) and (19.8) to obtain the wavelength in terms of a , b , n and ω . To easiest way to do this is to divide both sides of the relevant equations by $2k$ and $2n$, multiply them, and add the two equations together. The result is $\sin^2 \theta + \cos^2 \theta = 1 = (a/b)^2 - (n_0/n)^2$, which can be solved for λ :

$$\lambda = \frac{a^2}{\sqrt{1 + (n_0/n)^2}} + \frac{b^2}{\sqrt{1 + (n_0/n)^2}}. \quad (19.9)$$

In this way we have determined the wavelength in terms of the edges, and from the wavelength we immediately get the frequency ω . However, as we know, the frequency is equal to $2\pi f$ divided by the wavelength.

This result is interesting, and important enough that we should discuss it by a purely mathematical analysis instead of by an argument about the reflections. Let me repeat: we vibrated by a superposition of two waves chosen so that the four lines $x = 0$, $x = a$, $y = 0$, and $y = b$ are all nodes. In addition we shall require that all waves have the same frequency, and if f is the resulting motion with respect to a mode, f will be called the sum of light reflection; we know that $(y^2)(y^2)(e^{i\omega t})$ represents a wave traveling in the direction $\tan^{-1}(\omega/k) = \tan^{-1}(a/b)$. Equations (19.6) and (19.7) tell us $k = \omega/c$, and this provides

$$\lambda^2 = a^2 + b^2. \quad (19.10)$$

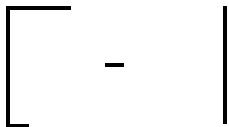

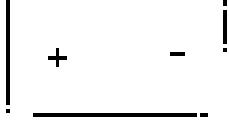

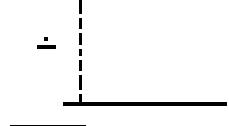

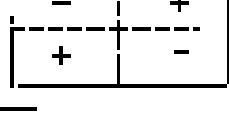

It is clear from this that $k_x = k$ and $k_y = k$.

Now our equation for the displacement, say u , of the rectangular membrane takes on the general form

$$u = [e^{i\omega t} V^{(1)} e^{i k_x x} e^{i k_y y} + e^{i\omega t} V^{(2)} e^{-i k_x x} e^{i k_y y} - e^{i\omega t} V^{(3)} e^{i k_x x} e^{-i k_y y} - e^{i\omega t} V^{(4)} e^{-i k_x x} e^{-i k_y y}], \quad (19.11)$$

Although this looks rather a mess, the sum of these things now is not very hard. D-4

Table 48-1

Mode shape	m	n	$\omega_{n,\text{expt}}$	$\omega_{n,\text{cal}}$
	1	1	1.9	1.82
	1	2	2.00	1.41
	1	1	1.9	.92
	2	1	1.74	-1.4
	2	2	3.00	2.24

The ω_n constants can be combined to give the functions $\psi_m(x)$ of the displacement form and $\psi_n(y)$:

$$\psi_n = (-1)^m \sin k_n x \sinh k_n y \quad (48-13)$$

In other words, it is a sinusoidal excitation, all right, with a position func. is also sinusoidal in both the x - and the y -direction. Our boundary conditions are of course satisfied at $x = 0$ and $y = 0$. You can easily verify as we did at $x = a$ and when $y = b$. Therefore we have to satisfy two other conditions: ψ_m must be an integer multiple of π , and ψ_n must be another integer k_n multiple of π . (Remember we have seen that $k_n = \lambda_n / a$; see 3 and $\lambda_n = 2\pi n$.) We immediately get equations (48-7) and (48-8) and from these the final result (48-9).

Now let us take as an example a rectangle whose width is twice the height. If we take $a = 2b$ and use Eqs. (48-7) and (48-8), we get the frequencies of all of the modes:

$$\omega_n^2 = \left(\frac{\pi n}{b}\right)^2 \frac{4\pi^2}{3} + m^2 \quad (48-14)$$

Table 48-1 gives some of the simple modes and can show other shapes in qualitative form.

The most important point to be emphasized about this part is the note "Ex.: the frequencies are not multiples of each other," or are they multiples of any number. The idea that the natural frequencies are harmonically related is not generally true. This is true for a system of one dimension, *i.e.* if it has no mass-dissipative systems which are more complicated than a string with uniform density and tension. A simple example of the latter is a hanging string; its natural frequencies are proportional to the length. It is also true if, in its mode oscillation, there are various masses and "springs," but the frequencies are not simple multiples of one another, nor are the mass-springs constant.

The modes of more complicated systems are *not* necessarily harmonic. For example, make the moves we have a long y above the x -axis, and by moving the x -axis and the y -axis, and so forth, we make an open-end pipe in a closed tube; types of different diameters and shapes; it is a terribly complicated oscillator, but

it is evident nevertheless. Now when one talks with gut vocal cords, they are made to produce some kind of tone. The tone is rather complicated and there are many sounds coming out, but the cavity of the mouth further modifies that tone because of the various resonant frequencies of the cavity. For instance, a singer can sing various vowels, e., i, oo or ee, and so forth, in the same pitch, but they sound different, because the various conditions are in resonance at this cavity to different degrees. The very great importance of the resonant frequencies of a cavity in modifying the voice sounds can be demonstrated by a simple experiment. Since the speed of sound goes as the reciprocal of the square root of the density, the speed of sound may be varied by using different gases. If one uses helium instead of air, since the density is lower, the speed of sound is much higher, and all the frequencies of a cavity will be raised. Consequently if one fills one's lungs with helium before speaking, the character of his voice will be drastically altered, even though the vocal cords may still be vibrating at the same frequency.

40-4 Coupled pendulums

Finally we should emphasize that not only do modes exist for consolidated oscillating systems, but also for very simple linear-like systems. A good example is the system of two coupled pendulums discussed in the preceding chapter. In that chapter it was shown that the motion could be analyzed as a superposition of two harmonic motions with different frequencies. So even this system can be analyzed in terms of harmonic motions or modes. The string has an infinite number of modes and the two-dimensional surface also has an infinite number of modes. In a sense it is analogous really. If we know how to count identities. But a simple "pendulum," which has only two degrees of freedom, and requires only two variables to describe it, has only two modes.

Let us make a mathematical analysis of the two modes for the case where the pendulums are of equal length. Let the displacement of mass be x , and the displacement of the other be y , as shown in Fig. 40.5. Without a spring, the force on the first mass is proportional to the displacement of that mass, times of gravity. There would be, if there were no spring, a certain natural frequency ω_0 for this one alone. The equation of motion would be

$$m \frac{d^2x}{dt^2} = -\omega_0^2 x \quad (40.13)$$

The other pendulum would swing in the same way if there were no spring. In addition to the force of restoration due to gravitation, there is an additional force pulling the first mass. That force depends upon the excess of displacement of the second mass, and is proportional to that difference, so it is a restoring force which depends on the symmetry, times $(x - y)$. The same force in reverse sense acts on the second mass. The equations of motion then have to be solved like this:

$$m \frac{d^2x}{dt^2} = -\omega_0^2 x - k(x - y), \quad m \frac{d^2y}{dt^2} = -\omega_0^2 y - k(y - x). \quad (40.14)$$

In order to find a motion in which both of the masses move at the same frequency, we must determine how much each mass moves. In other words, pendulum x and pendulum y will oscillate at the same frequency, but their amplitudes must have certain values, A and B , whose relation is fixed. Let us try this solution:

$$x = A e^{i\omega t}, \quad y = B e^{i\omega t}. \quad (40.15)$$

If these are substituted into Eqs. (40.14) and like terms are collected, the result is:

$$\begin{aligned} \left(\omega^2 - \omega_0^2 - \frac{k}{m}\right) A + \frac{k}{m} B &= 0, \\ \left(\omega^2 - \omega_0^2 - \frac{k}{m}\right) B - \frac{k}{m} A &= 0. \end{aligned} \quad (40.16)$$

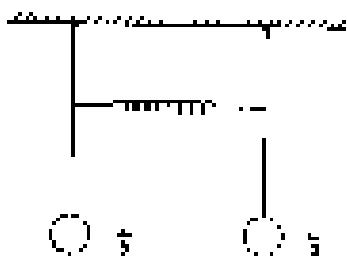

Fig. 40.5. Two coupled pendulums.

The equations we have have had the constant factor ω^2 removed and have been divided by m .

Now we see that we have two equations for what looks like two unknowns. For there can be no two unknowns because the whole idea of the motion is something that we cannot determine from these two alone. The above equations can relate one only the ratio $\omega_1^2/\omega_2^2 = k_1/k_2$, but they *never* both give the same result. The necessity for both of these equations to be consistent is a requirement that the frequency be something very special.

In this particular case this can be worked out rather easily. If the two equations are multiplied together, the result is

$$\left(\frac{\omega_1^2}{\omega_2^2} - \frac{k_1}{k_2}\right) \cdot k_2 = \left(\frac{k_1}{k_2}\right)^2 \cdot k_2 \quad (49.17)$$

The term k_2 can be removed from both sides unless k_2 is 0 or ∞ , which means there is no motion at all. If that's not true, then the two terms must be equal, giving a quadratic equation to solve. The result is that there are two possible frequencies:

$$\omega_1^2 - \omega_2^2 = \omega_2^2 - \omega_0^2 + \frac{2k_1}{m}. \quad (49.18)$$

Furthermore, if other values of frequency are substituted back into Eq. (49.16), we find that for the first frequency $\omega = \omega_1$, and the second frequency $\omega = \omega_2$. These are the "natural" shapes, as can be readily verified by experiment.

It is clear that in the first mode, where $\omega = \omega_1$, the spring is never stretched and both masses oscillate at the frequency ω_1 , as though the spring were absent. In the other situation, where $\omega = \omega_2$, the spring contributes a restoring force and raises the frequency. A more interesting case results if the pendulums have different lengths. The analysis is very similar to that given above, and is left as an exercise for the reader.

49-5 Linear systems

Now let us summarize the ideas discussed above, which are all expected to be probably the most general and wonderful principle of mathematical physics. If we have a linear system whose character is independent of the time, then the motion does not have to have any particular simplicity, and it fact may be exceedingly complex, but there are still special motions, usually a series of modes, motions, in which the whole position of motion varies exponentially with the time. For the vibrating systems that we are talking about now, the exponential is imaginary, and instead of saying "exponentially" we might prefer to say "sinusoidally" with time. However, on some higher level we may say that the motion will vary exponentially with the time in very special modes, with very special shapes. The next general motion of the system can always be represented as a superposition of motions involving each of the different frequencies.

This is worth stating again for the case of sinusoidal motion: a linear system need not be moving in a purely sinusoidal motion, i.e., at a definite single frequency. But no matter how it does move, this motion can be represented as a superposition of pure sinusoidal motions. The frequency of each of these motions is a characteristic of the system and the form or waveform of each motion is also a characteristic of the system. The general motion in any such system can be determined by giving the strength and the phase of each of these modes, and adding them all together. Another way of saying this is, letting linear vibration system be equivalent to a set of independent harmonic oscillators, just the natural frequency is corresponding to the modes.

We conclude the chapter by remarking on the connection of waves with quantum mechanics. In quantum mechanics the vibrating object, or the drop test particle, is again, the amplitude of a probability function that gives the probability of finding an electron, or system of electrons, in a given configuration. This amplitude function can vary in space and time, and satisfies, in fact, a linear equation

But in quantum mechanics there is a fundamental, in-between state, in which we will find some of the probability amplitude is equal, in the classical idea, to energy. Therefore we can consider the principle of least action to also be holding the word frequency and replacing it with energy. It becomes one of the like this a quantum mechanical system, for example an atom, need not have a definite energy, just as a simple mechanical system does not have a definite frequency; but consider how the system behaves, its behavior can always be represented as a superposition of states of definite energy. The energy of each state is a definite value of the sum, and so is the sum of amplitude which determine the probability of finding particles in different places. The general motion can be described by adding the amplitude of each of these different energy states. This is the origin of energy levels in quantum mechanics, since quantum mechanics is represented by waves in the wavefunction in which the electron does not have enough energy to ultimately escape from the proton, they are confined waves. For the quantized states of existing, there are definite frequencies, as the solution of the wave equation, as given in mechanics. The quantum-mechanical interpretation is that there are definite energies. The above quantum-mechanical system, because it is represented by waves, can have definite states of fixed energy; its amplitudes are the energy levels of definite states.

Musical tones

50.1 Musical tones

Pythagoras is said to have discovered the fact that two similar strings under the same tension are in tune only if their length ratio is such that it is a ratio of small integers. If the length ratio is 1 to 2, they will correspond to the octave interval. If the lengths are in the ratio of 2 to 3, they will correspond to the interval between C and G, which is called a 5th. These intervals are generally recognized as "pleasant" sounding chords.

Pythagoras was so interested by his discovery that he made it the basis of a school. Pythagoreans they were really—where real mystic beliefs in the great powers of numbers. It was believed that something similar would be found in about the planets, or "aphorae." We sometimes hear this expression "the music of the spheres." The idea was that there would be some kind of relationship between the orbits of the planets or between other things in nature. Pythagoreans think that this is in a kind of a way "inherited" from the Greeks, who is also different from our own scientific interest in quantitative relationships. Pythagoras' discovery was the first example, outside geometry, of any numerical relationship in nature. It must have been very surprising to suddenly discover that there was a law of nature that involved a simple geometrical regularity. Simple measurements of lengths give a prediction about something which has no apparent connection to geometry—the production of pleasant sounds. This discovery led to the extension that perhaps a general law for understanding nature could be found in mathematical regularities. The results of modern science justify that point of view.

Pythagoras would only have made his discovery by making an experimental observation. Yet this important aspect does not seem to have impressed him. It is hard, despite all the literature that has been written about it, to imagine why he did not decide simply have had a much earlier start. (It is always easy to look back at what someone else has done and to decide what he should have done.)

We might remark on a third aspect of this very interesting discovery: the discovery had to do with two issues that are significant in the ear. We may question whether we are any better off than Pythagoras in understanding why such certain sounds are pleasant to our ear. The general theory of aesthetics is probably an entirely different issue from a theory of Pythagoras' or the first discovery of the Greeks. There are, however, aspects: experiment, mathematical relationships and aesthetics. Physics has made great progress on only the last two parts. This chapter will deal with our present-day understanding of the discovery of Pythagoras.

Among the sounds that we hear, there is one kind that we call tone. It corresponds to a sort of inharmonic vibration of the continuum that is produced by the irregular vibration of some string in the neighbourhood. If we make a drumskin to indicate the pressure of the air on the ear-drum, such, however, the displacement of the drum, is a function of time, the graph which corresponds to a twice night such like that shown in Fig. 50-1(a). (Such a noise might correspond roughly to the sound of a cracked pot.) The sound of music has different characteristics. Music is characterized by the presence of more-or-less sustained regular or musical "tones." Musical instruments may produce notes as short as this tone, but for a relatively short time, as when a key is pressed on a piano, or it may be sustained almost indefinitely, as when a flute player holds a long note.

What are the special characters of a musical note from the point of view of the pressure in the ear? A musical note differs from a noise in that there is a periodicity in its graph. There is some uneven shape to the variation of the air pressure with

time, and the shape repeats itself over and over again. An example of a pressure-time function that would correspond to a musical note is shown in Fig. 30-1(b).

Musical notes usually consist of a musical note in terms of their characteristic tones: the loudness, the pitch, and the "quality." The "loudness" corresponds to the amplitude of the note or changes. The "pitch" corresponds to the period of time between repetition of the basic waveform. ("Low" notes have longer periods than "high" notes.) The "quality" of a tone has to do with the difference of "overtones" between two notes of the same loudness and pitch. An oboe, a violin, or a soprano will distinguishable even when they sound notes of the same pitch. The quality has to do with the structure of the note during pitch.

Let us consider, for a moment, the sound produced by a vibrating string. If we pluck the string, by pulling it to one side and releasing it, the subsequent motion will be determined by the motions of the waves we have generated. We know that these waves will travel in both directions, and will be reflected at the ends. They will reflect back and forth for a long time. We realize how complicated the wave is, however, if we repeat itself. The period of repetition is just the time required for the wave to travel the full length of the string. The result is just the same as general for any wave, once started. It reflects at each end and returns to its starting position, and so proceeding in the original direction. The time it becomes tor waves to stabilize is either dimension. Touching on the string will, therefore, return to its starting position after one period, and again one period later, etc. The sound wave produced... we also have the same repetition. We see why a plucking produces a musical note.

30-1 The Fourier series

We have discussed in the preceding chapter another way of looking at the motion of a vibrating system. We have seen that a simple harmonic motion, modes of oscillation, and that any particular kind of vibration that may be set up by the initial conditions can be thought of as a combination of multiple proportions—of several of the natural modes, oscillating together. For a string we found that the natural modes of oscillation had the frequencies $\omega_0, 2\omega_0, 3\omega_0, \dots$. The most general motion of a plucked string, therefore, is composed of the sum of a sinusoidal oscillation at the fundamental frequency ω_0 , and at the second harmonic frequency $2\omega_0$, and the third harmonic $3\omega_0$, etc. Now the fundamental mode repeats itself every period $T_0 = 2\pi/\omega_0$. The second harmonic mode repeats itself every $T_0/2 = \pi/\omega_0$, i.e., it repeats itself every $T_0/2$, also, i.e., it is periodic. Similarly, the third harmonic mode repeats itself after a time $T_0/3$, which is 1/3 of its periods. We see again why a plucked string, repeats its whole pattern with a periodicity of T_0 . It produces a periodic wave.

We have been talking about the motion of the spring. On the spring, which is a conductor of tension, is produced by the motion of the string, so its vibrations too must be composed of the same manner as though we were changing the ring about the center of mass of the ring. As on, the relative strengths of the amplitudes may be different in the various parts of the string, particularly if the string is "tautened" to one end and left free at the other. The efficiency of the coupling to the ring is different for different harmonics.

If we let $f(t)$ represent the air pressure as a function of time for a mono-harmonic case (as in Fig. 30-1(c)) then we expect the $f(t)$ can be written as the sum of two simple harmonic oscillations of time. Like cosine. As such, it has two inharmonic frequencies. If the period of the vibration is T_0 , the fundamental angular frequency will be $\omega = 2\pi/T_0$, and the harmonics will be $2\omega, 3\omega$, etc.

There is one slight complication. For each frequency we now expect that the various phases will not necessarily be the same for all frequencies. We should, therefore, use functions like $\cos(\omega_0 t + \phi)$. It is, however, simpler to use instead both the sine and cosine functions for each frequency. We recall that

$$\cos(\omega_0 t + \phi) = (\cos \omega_0 t) \cos \phi - (\sin \omega_0 t) \sin \phi \quad (30.1)$$

and since ω is a constant, any sinusoidal oscillation ω , the frequency ω can be written as the sum of a term $\omega_1 \cos \omega t$ and another term with an ω :

We conclude then, that any function $f(t)$ that is periodic with the period T can be written mathematically as

$$\begin{aligned} f(t) &= a_0 \\ &\quad + a_1 \cos \omega t + b_1 \sin \omega t \\ &\quad + a_2 \cos 2\omega t + b_2 \sin 2\omega t \\ &\quad + \dots = \dots \end{aligned} \quad (30.2)$$

where $\omega = 2\pi/T$ and the a_i 's and b_i 's are numerical constants which tell us how much of each component oscillation is present in the oscillation $f(t)$. We have called the "harmonics" terms a_i , so that the formula will be completely general, although it is usually used for a musical tone. It represents a start of the analysis called about ω , the "fundamental" term, of the sound pressure. With ω , our formula can take care of any case. The equality of Eq. (30.2) is represented schematically in Fig. 30-2. (The amplitudes, a_i , and b_i , of the harmonic fractions must be suitably chosen. They are drawn schematically and without any particular scale in the figure.) The series (30.2) is called the Fourier series for $f(t)$.

We have said that any periodic function can be made up in this way. We should even go back and say that any sound wave, or any function we ordinarily encounter in physics, can be made up of such ω 's. The mathematical equivalent functions which cannot be made up of simple harmonic functions—for instance, a function that has a "twelve-twist" so that it has two values for some values of t . We need not worry about such functions here.

30-3 Quality and consonance

Now we are able to answer the question: what is the "character" or "quality" of a musical tone? It is the relative amplitudes of the various harmonics. The ratios of the a_i 's are f_i 's. A tone with only one harmonic is a "pure" tone. A tone with many strong harmonics is a "rich" tone. A violin produces a different proportion of harmonics than does an oboe.

We can "manufacture" various musical tones if we connect several "resonators" to a loudspeaker. (An oscillator usually produces a nearly pure single harmonic function.) We could choose the frequencies of the oscillators to be ω , 2ω , 3ω , etc. Then by adjusting the volume control on each oscillator, we can add in, say, a_{10} , a_{15} , etc., of each harmonic, thereby producing tones of different quality. An oboe soprano does it in such this way. The "keys" select the frequency of the fundamental note, and the "keys" also switches that control the relative amplitudes of the harmonics. By throwing, these switches, the organ can be made to sound like a flute, or like a violin.

It is interesting that to produce such "artificial" tones we need only one oscillator for each frequency—we do not need separate oscillators for the different harmonic components. The ear is not very sensitive to the relative phases of the harmonics. It pays attention mainly to the ratio of the amplitudes of each frequency. Our "ear" is more accurate than is necessary to explain the subjective aspect of music. The response of a microphone or other physical instrument does depend on the phases, however, and one complete analysis may be needed in these cases.

The "quality" of a spoken word also determines the novel sounds that we recognize in speech. The shape of the mouth determines the frequencies of the natural modes of vibration of the air in the mouth. Some of these modes are set into vibration by the sound waves from the vocal cords. In this way, the amplitudes of some of the harmonics of the sound are increased with respect to others. When we change the shape of our mouth, harmonics of different frequencies are given preference. These effects account for the differences between an "o-o-o" sound and an "e-e-e" sound.

Fig. 30-2. Any periodic function $f(t)$ is equal to a sum of simple harmonic oscillations.

We know that a particular vowel sound, say "ee-eh", will sounds slightly the same vowel whether we say it in singing at a high or a low note. From the evidence we describe, we would expect that the voice frequency to increase linearly when we change our mouth so that "ee-eh" could have different changes in range the pitch of our voice. So the relation of the important harmonics to the fundamental tone is, that is, the "tonality" changes as we change pitch. Apparently the mechanism by which we recognize speech is not based on specific frequency relationships.

What should we say now about Pythagoras' discovery? We understand that two similar strings with length λ in the ratio $\sqrt{2} : 1$ will have frequencies in the ratio $\sqrt{2} : 1$. But why should they "sound pleasant" together? Perhaps we should take out clue from the frequencies of the instruments. The second harmonic of the lower string's song will have the same frequency as the fundamental of the longer song. (It is easy to show or to believe that a plucked string produces strongly the second lowest harmonic.)

Because we cannot make the "dissonant" rules. Not because compound waves they have harmonics with too many frequency. Notes sound dissonant if their upper harmonics have frequencies near to each other but "harmonious" agent that it is no rapids beats between the two. Why beats do not come possible, and why union of the upper harmonics were called consonant, is something that we do not know how to reason or describe. We can not say true this knowledge of what sounds good, who, say, is enough to say good. In other words, our understanding of it is not anything more general than the statement that when they sound in unison they sound good. It does not permit us to deduce anything more than the properties of consonances in music.

It is easy to check on the harmonic relationships we have discussed by some simple experiments with a piano. Let us take the piano C note near the middle of the keyboard by C, C', and C'', the note C'' just above by C, C', and C''. Then the fundamental will have effective frequencies as follows:

$$\begin{array}{ll} C = 2 & C = 3 \\ C' = 4 & C' = 6 \\ C'' = 6 & C'' = 12 \end{array}$$

These harmonic relationships can be demonstrated in the following way: Suppose we press C sharply—so that it does not sound, but we cause the damper to be lifted. If we then sound C, it will produce its own fundamental and some second harmonics. The second harmonic of C is the same as the C of C'' is a vibration. If we now release C, leaving C' pressed the damper will stop the vibration of the C strings, and we can hear (only) the note C'' as it dies away. In similar way, the third harmonic of C is the same as the C of C'. Or the note of C'' after getting released is the same as a vibration in the fundamental of C''.

A somewhat different result is obtained if we press C sharply and then sound C''. The third harmonic of C will correspond to the fourth harmonic of C, so only the fourth harmonic of C will be excited. We can hear (if we strain hard) the sound of C'', while, of course, nevertheless the C and "the piano". It is easy to think up more interesting combinations for this game.

We may remark by analogy that the major scale can be defined just by the condition that the three major chords (C-A-G, F-A-D, and G-B-E) each consist four consecutive notes in frequency ratio of 3:5:6. These ratios plus the fact that an octave (C-C', B-B') has the ratio 1:2 determine the whole scale for the "Major" mode, or for what is called "just intonation." A keyboard instrument like the piano are not usually tuned in this manner, but a flute "tuning" is done so that the frequencies of a soprano vocal range fall on "just" intonation points. For this tuning, which is called "tempered," the octave (still C-C') is divided into 12 equal intervals for which the frequency ratio is $(2)^{1/12}$. A fifth no longer has the frequency ratio 3/2, but 2^{1/5} ≈ 1.199 which is apparently close enough for most uses.

We have stated now for consonance differences at the considered time the meaning. Is this coincidence perhaps the reason that we make no statement? One reason for this is that we just cannot really expect it to be free of harmonics—the only way of consonance & dissonance as the relative frequencies are placed one after the other, the expected ratio. Such experiments are difficult because it is difficult to measure the pitch ratios, for reasons that we will see later. We cannot say for certain whether the ear is perceiving harmonics or being attracted when we decide that we like a sound.

5.4 The Fourier coefficients

For us to know in the Fourier synthesis theorem, a periodic signal $x(t)$ can be represented by a suitable combination of harmonics. We would like to show how we can find out what numbers of each harmonic are required. This, of course, does not apply to $f(t)$, using Eq. (50.2), if we are given all the coefficients a_n and b_n . The question now is, if we are given $f(t)$ how can we know what the coefficients of the various harmonic terms should be? (It is very suitable to take this recipe, but first we write down the recipe to we also get a cake!)

Fourier discovered that it was not really very difficult. The answer is certainly yes. We know already that it is $f(t)$ the average value $\bar{x}(t)$ of $x(t)$ over one full cycle $T = 2\pi/\omega = 1/f$. We can easily see that this is indeed so. The average value of a sinusoidal function over one period is zero. Thus two, three, or any whole number of periods, it is also zero. So the average value of all of the terms on the right hand side of Eq. (50.2) is zero, except for a_0 , unless—that we must remember $\omega = 2\pi/T$.

Now the average of a sum is the sum of the averages. So the average $\bar{f}(t)$ is just the average of a_0 . But a_0 is a constant, so its average is just the same as its value. Recalling the definition of an average, we have

$$a_0 = \frac{1}{T} \int_{-\frac{T}{2}}^{\frac{T}{2}} f(t) dt. \quad (50.3)$$

The other coefficients are much more difficult. To find them we can use a trick discovered by Fourier. Suppose we multiply both sides of Eq. (50.2) by some harmonic function—say by $\cos 2\omega t$. We then have

$$\begin{aligned} f(t) \cos 2\omega t &= a_0 \cdot \cos 2\omega t \\ &\quad + a_1 \cos \omega t \cdot \cos 2\omega t + b_1 \sin \omega t \cdot \cos 2\omega t \\ &\quad + a_2 \cos 2\omega t \cdot \cos 2\omega t + b_2 \sin 2\omega t \cdot \cos 2\omega t \\ &\quad \cdots \quad + \cdots \\ &\quad + a_n \cos n\omega t \cdot \cos 2\omega t + b_n \sin n\omega t \cdot \cos 2\omega t \\ &\quad \cdots \quad + \cdots \end{aligned} \quad (50.4)$$

Now let us average both sides. The average of $a_n \cos n\omega t$ over the time T is proportional to the average of $\cos^2 n\omega t$ over T whole periods. But that is just zero. The average of $b_n \sin n\omega t$ of the left of the terms is also zero. That is back to the a_n terms. We know, in general, that

$$\cos n(2\omega t) = 1/2(a_n + A_n) + 1/2a_n(A_n - B_n). \quad (50.5)$$

5.4.1 Amplitudes

$$a_n = 1/2(a_n + A_n). \quad (50.6)$$

We thus have two terms to deal with with $2\omega t$ periods in T and the others with ω . Their total average is zero. The average of the a_n terms is therefore zero.

By the same token, we would find a_n to be the total average, each of which also has to be zero. For the A_n term we would find a_n after multiplying $(-A_n)$. That multiplication is the same as $\cos 2\omega t$, so both of these have zero averages. It is clear

that all of the n terms will have a zero average except one. And that one is the a_0 term. For this one we have

$$\langle \cos(\omega t + \pi/2) \rangle = 0. \quad (30.7)$$

The cosine of zero is one, and its average, of course, is one. So we know the result that the average of $\langle \cos^2 \theta \rangle$ of the n terms of Ψ_0 (30.4) equals to unity.

Two terms are even easier. When we multiply by any cosine term, like $\cos \omega t$, we can show by the same method that all of the n terms have the same $\langle \cos^2 \theta \rangle$ value zero.

We see that Fourier's "trick" has acted here to zero. When we multiply by $\cos^2 \theta$ and average, all terms drop out except one, and we find that

$$\text{Average } \langle (\cos \omega t)^2 \rangle = a_0^2/2, \quad (30.8)$$

or

$$a_0 = \frac{2}{T} \int_{-T/2}^{T/2} f(t) \cdot \cos \omega t dt. \quad (30.9)$$

We shall leave it for the reader to show that the coefficients b_n can be obtained by multiplying Eq. (30.2) by $\sin \omega t$ and averaging over sides. The result is

$$b_n = \frac{2}{T} \int_{-T/2}^{T/2} f(t) \cdot \sin \omega t dt. \quad (30.10)$$

Now what is true for T we expect is true for any integer. So we can summarize our proof and result in the following more elegant mathematical form. If n is odd (an integer other than zero), and if $\omega = 2\pi/T$, then

$$\text{I. } \int_0^T \sin n \omega t dt = 0 \quad (30.11)$$

$$\text{II. } \int_0^T \cos n \omega t dt = \begin{cases} 0 & \text{if } n \neq m \\ 1/2 & \text{if } n = m \end{cases} \quad (30.12)$$

$$\text{III. } \int_0^T \sin m \omega t \cos n \omega t dt = \begin{cases} 0 & \text{if } n \neq m \\ 1/2 & \text{if } n = m \end{cases} \quad (30.13)$$

$$\text{IV. } f(t) = a_0 + \sum_{n=1}^{\infty} a_n \cos n \omega t + \sum_{n=1}^{\infty} b_n \sin n \omega t. \quad (30.14)$$

$$\text{V. } a_0 = \frac{1}{T} \int_{-T/2}^{T/2} f(t) dt. \quad (30.15)$$

$$a_n = \frac{2}{T} \int_{-T/2}^{T/2} f(t) \cdot \cos n \omega t dt. \quad (30.16)$$

$$b_n = \frac{2}{T} \int_{-T/2}^{T/2} f(t) \cdot \sin n \omega t dt. \quad (30.17)$$

In earlier chapters it was convenient to use the exponential notation for representing simple harmonic motion. Instead of this we used $\cos \omega t$, the real part of the exponential function. We have used cosine and sine functions in this chapter because it made the derivations parallel with elements. Our final result of Eq. (30.17) can, however, be written in a more compact form

$$f(t) = R e \sum_{n=-\infty}^{\infty} A_n e^{i n \omega t}, \quad (30.18)$$

where A_n is the complex number $a_n - i b_n$ (with $b_0 = 0$). If we wish to use the same notation throughout, we can write also

$$a_n = \frac{1}{T} \int_{-T/2}^{T/2} f(t) e^{-i n \omega t} dt \quad (n \geq 1) \quad (30.19)$$

We now know how to "analyze" a periodic wave into its harmonic components. The procedure is called Fourier analysis, and the resulting series is called Fourier components. We have said, however, that since we find all of the Fourier components and add them together we do indeed get back our $f(t)$. The corresponding area shown, for a wide class of functions, is that for ψ . Just one of interest to visualize that if we can do the integral ψ we will get back $f(t)$. There is one minor exception. If the function $f(t)$ is discontinuous, e.g., it jumps suddenly from one value to another, the Fourier sum will give a value at the midpoint to "average between the jumps" and never reaches the discontinuity. So if we have the strange discontinuity $f(t) = 0.0 \leq t < t_0$, and $f(t) = 1.0 \text{ for } t_0 \leq t \leq T$, the Fourier sum will give the right value everywhere except at t_0 , where it will have the value $\frac{1}{2} \text{ instead of } 1$. This rather unpleasant ambiguity in integral that is fraction should be brought to t_0 , but I neglect it. So perhaps we should make the "rule" for discontinuous or very discontinuous function $f(t)$ that only be a singularity for a real physical function that it be differentiable halfway between all the discontinuities. Then any such function within any finite number of such jumps, as well as other physically interesting functions, are given exactly by the Fourier sum.

As an exercise, we suggest that one reader determine the Fourier series for the function shown in Fig. 20-3. Since the function cannot be written in an explicit algebraic form, you will not be able to do the integrals from zero to T in the usual way. The integrals are easy, however, if we separate them into two parts. The integral from zero to $T/2$ over which $f(t) = 0$ and the integral from $T/2$ to T (over which $f(t) = -1$). The result should be

$$f(t) = \frac{4}{\pi} \left[\sin \omega t + \frac{1}{3} \sin 3\omega t + \frac{1}{5} \sin 5\omega t + \dots \right] \quad (20.19)$$

where $\omega = 2\pi/T$. We thus see that our square wave (with the particular phase chosen) has odd harmonics and their amplitudes are in inverse proportion to their frequencies.

Let us check that Eq. (20.19) does indeed give us back $f(t)$ for some value of t . Let us choose $t = T/4$, or $\omega t = \pi/2$. We find

$$f(t) = \frac{4}{\pi} \left(\sin \frac{\pi}{2} + \frac{1}{3} \sin \frac{3\pi}{2} + \frac{1}{5} \sin \frac{5\pi}{2} + \dots \right) \quad (20.20)$$

$$= \frac{4}{\pi} \left(1 - \frac{1}{3} - \frac{1}{5} - \frac{1}{7} + \dots \right) \quad (20.21)$$

The series¹¹ has the value $\pi/4$, and we find $\text{Max}(f) = 1$.

20-2 The energy theorem

The energy in a wave is proportional to the square of its amplitude. For a wave of simple shape, the energy in one period will be proportional to $\int_{t_0}^{t_0+T} A^2 dt$. We can also relate the energy to the Fourier coefficients. We write

$$\int_{t_0}^{t_0+T} f^2(t) dt = \int_{t_0}^{t_0+T} \left[a_0 + \sum_{n=1}^{\infty} a_n \cos n\omega t + \sum_{n=1}^{\infty} b_n \sin n\omega t \right]^2 dt. \quad (20.22)$$

When we expand the square of the bracketed term we will get a few terms, such as a_0^2 , etc. But there are two. We have shown above, however, that Eqs. (20.11) and (20.12) the n th integral of x^n over one period is zero.

¹¹ The series can be evaluated in the following way. First we notice that $\int_0^{\pi/2} \sin x dx = 1$, and $\int_0^{\pi/2} x \sin x dx = \text{constant}$, so expand the integral in powers of $x/\pi/2$: $x^2 = 1 - x^2/2 + x^4/2^2 - x^6/3! + \dots$ We integrate the series term by term. Then we substitute to obtain $\int_0^{\pi/2} x \sin x dx = \pi/2 - \pi^2/8 + \dots$. Setting $x = 1$, we have the stated result, since $\int_0^{\pi/2} \sin x dx = 1$.

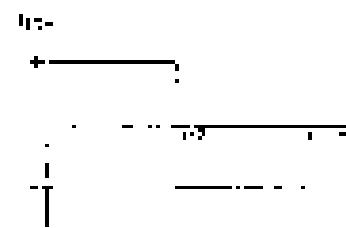

Fig. 20-3. Square-wave function
 $f(t) = 1 \text{ for } 0 < t < T/2$
 $f(t) = -1 \text{ for } T/2 < t < T$

We have left out the square term like $\omega_0^2 \sin^2 \omega_0 t$. The integral of any cosine squared or sine squared over one period is equal to $T/2$, so we get

$$\begin{aligned} \int_0^T f^2 dt &= T\omega_0^2 + \frac{T}{2}(\omega_0^2 - \omega_0^2 + \dots - \omega_0^2 - \omega_0^2 + \dots) \\ &= T\omega_0^2 - \frac{T}{2} \sum_{k=1}^{\infty} (\omega_k^2 + \omega_k^2) \end{aligned} \quad (30.23)$$

This equation is called the "energy theorem," and says that the total energy in a wave is just the sum of the energies in all of the Fourier components. For example, applying this theorem to the series (30.18), since $|f(n)|^2 = 1$ we get

$$\pi = \frac{\pi^2}{2} \cdot \left(\frac{4}{\pi}\right)^2 \left(1 + \frac{1}{3^2} + \frac{1}{5^2} + \frac{1}{7^2} + \dots\right),$$

so we learn that the sum of the squares of the reciprocals of the odd integers is $\pi^2/8$. In a similar way, by calculating the Fourier series for the function and using the energy theorem, we can prove that $1 + 1/2 + 1/3 + \dots$ is $\pi^2/6$, a result we needed in Chapter 25.

30.6 Nonlinear responses

The y , in the theory of harmonics, has an important precursor which should be recalled since because of its practical importance that of nonlinear effects. In all the systems that we have been considering so far, we have supposed that everything was linear, that the response to forces, say the displacement or the accelerations, were always proportional to the forces. Or that the currents in the circuit were proportional to the voltages, and so on. We now wish to consider cases where there is no strict proportionality. We think of the manner of some device in which the response, which we will call x_{out} at the time t , is determined by the input x_{in} at the time t . For example, x_{in} might be the force and x_{out} might be the displacement. Or x_{in} might be the current and x_{out} , the voltage. If the device is linear, we would have

$$x_{\text{out}}(t) = K x_{\text{in}}(t), \quad (30.24)$$

where K is a constant independent of x_{in} and of t . Suppose, however, that the device is really, non-linearly, linear, so that we can write

$$x_{\text{out}}(t) = K[x_{\text{in}}(t)] + \epsilon x_{\text{in}}^2(t), \quad (30.25)$$

where ϵ is small enough compared with unity. Such linear and nonlinear segments are shown in the graphs of Fig. 30-4.

Nonlinear responses have several important practical consequences. We shall discuss some of them now. First we consider what happens if we apply a pure tone at the input. We let $x_{\text{in}} = \cos \omega t$. If we plot x_{out} as a function of time we get the solid curve shown in Fig. 30-5. The dashed curve gives, however, the response of a linear system. We see that the output is not just a cosine function. It is more peaked at the top and dithered at the bottom. We say that the output is distorted. The linear, however, has such a wave is no longer a pure wave, but it will have harmonics. We can find what the harmonics are. Using $x_{\text{in}} = \cos \omega t$ with Eq. (30.25), we have

$$x_{\text{out}} = K[\cos \omega t] + \epsilon \cos^2 \omega t. \quad (30.26)$$

From the equality $\cos^2 \theta = \frac{1}{2}(1 + \cos 2\theta)$, we have

$$x_{\text{out}} = K \left(\cos \omega t + \frac{1}{2} + \frac{1}{2} \cos 2\omega t \right). \quad (30.27)$$

The output has not only a component at the fundamental frequency that was present in the input, but also has some of its second harmonic. This may seem

appeared at the output a constant term $A(0/2)$, which corresponds to the shift of the average, $\omega_1 - \omega_2$, shown in Fig. 50.5. The process of calculating a shift of the average value is called **downmixing**.

Nonlinear responses will clearly not yet produce harmonics of the frequencies ω_1 and ω_2 . Although even linearity we assumed produced only second harmonics, nonlinearity will also produce terms which have terms like ω_1^2 and ω_2^2 . For example, " ω_1^2 " generates a harmonic higher than the second.

Another effect which results from a nonlinear response is modulation. If our linear function contains both (or more) poles at ω_1 , the output will have not only their harmonics, but still other frequency components. Let $x_{11} = A \cos(\omega_1 t + \theta_1)$ and $x_{12} = A \cos(\omega_2 t + \theta_2)$ be needed to be in the harmonic addition. In addition to the first term (which has K times the input) we shall have a component to be roughly given by

$$x_{11} = K(4 \cos(\omega_1 t + \theta_1) \cos \omega_2)^2 \quad (50.28)$$

$$= K(16 \cos^2 \omega_1 t + 8 \cos^2 \omega_2 t + 24 \cos(\omega_1 t) \cos(\omega_2 t)). \quad (50.29)$$

The first two terms in the parentheses of Eq. (50.29) are just those which gave the constant term and some harmonics terms we found above. The last term is new.

We can look at this new "cross term" in different ways in two ways. First, if the two frequencies are widely different (for example, if ω_2 is much greater than ω_1) we can consider that the cross term represents a cosine modulation of varying amplitude. That is, we can think of the factors in this way:

$$AB \cos(\omega_1 t) \cos(\omega_2 t) = C(t) \cos(\omega_1 t) \quad (50.30)$$

with

$$C(t) = AB \cos(\omega_2 t). \quad (50.31)$$

We say that the amplitude of $\cos(\omega_1 t)$ is modulated with the frequency ω_2 .

Alternatively, we can write the cross term in another way:

$$AB \cos(\omega_1 t) \cos(\omega_2 t) = \frac{AB}{2} [\cos(\omega_1 + \omega_2)t - \cos(\omega_1 - \omega_2)t] \quad (50.32)$$

We would now expect the new components have been produced, since the sum frequency ($\omega_1 + \omega_2$) and the difference frequency ($\omega_1 - \omega_2$).

We have two different, but equivalent ways of looking at the same result. In the special case that $\omega_1 \gg \omega_2$, we can relate these two different views by remarking that since $(\omega_1 + \omega_2)$ and $(\omega_1 - \omega_2)$ is closer to each other we would expect to observe beats between them. But these beats have just the effect of modulating the amplitude of the average frequency ω_1 by one-half the difference frequency ω_2 . We see, then, why the two descriptions are equivalent.

In summary, we have learned that nonlinear response produces some effects: rectification, generation, and mixing, and modulation, or the generation of components at sum and difference frequencies.

We should notice that all these effects (Eq. 50.29) are proportional not only to the nonlinear coefficient K but also to the product of their amplitudes—either A^2 , B^2 , or AB . We expect these effects to be much more significant for very large than for weak ones.

The effects we have been describing have many practical applications. First, with regard to sound, it is believed that the ear is nonlinear. This is believed to account for the fact that with local sounds we hear the same tone that we may perceive and also a certain difference frequency between the two sound waves coming out of the ears.

The components which are most important regarding equipment—among them, loudspeakers and valves—have some nonlinearity. They produce distortions in the sound—they generate harmonics, etc.—which were not present in the original sound. These new components are heard by the ear and are apparently objectionable. It is for this reason that "Hi-Fi" equipment is designed to be as linear as

possible. (Why the number of the war was not "objectionable" in case such war or how we even know that the neutrality is in the hydrocarbon oil, is true in the war is not clear.)

Non-precision and quite necessary, and one in fact, intentionally made traps in certain parts of radio broadcasting and receiving equipment. In an oscillator for the "carrier" signal (with frequency of some kilocycles per second) is combined with the "modulator" signal (with a frequency of some megacycles per second) in a nonlinear circuit called a modulator, to produce the modulated oscillation that is transmitted. In this case, the components of successive cycles are fed to a nonlinear circuit which combines the sum and difference frequencies of the modulated carrier to generate a modulated wave signal.

When we discussed the transmission of light we assumed that the induced oscillations of charges were proportional to the electric field of the light. That the assumption was correct. That is indeed a very good approximation. It is only within the last few years that light sources have been devised whose positive as intensity of light strong enough so that nonlinear effects can be observed. It is now possible to generate harmonics of light frequencies. When a strong red light passes through a piece of glass, a little bit of blue light is produced—summarized.

Waves

SI-1. Bulk waves

Although we have finished our quantitative analysis of waves, this added chapter on the subject is intended to give some approximation, qualitatively, for certain phenomena that one comes up with waves, which are too complicated to analyze in detail here. Since we have been dealing with waves for several chapters, there perhaps the subject might be called "one of the most complex phenomena associated with waves."

The first topic to be discussed concerns the effects that are produced by a source of waves, which is moving faster than the wave velocity, or the phase velocity. Let us first consider waves that have a definite velocity. The sound and light. If we have a source of sound which is moving faster than the speed of sound, then something like this happens: Suppose at a given moment a sound wave is generated from the source at point x_1 in Fig. SI-1; then, in the next instant, as the source moves to x_2 , the wave from x_1 expands by a radius $c_s t$, where t is the distance that the source moves, and, of course, another wave starts from x_2 . When the second source has moved a bit farther, to x_3 , and a wave is starting there, the wave from x_1 has now expanded to x_3 , and the one from x_2 has expanded to x_3 . Of course, the length does not increase, nor in steps, and therefore we have a series of wave circles with a common tangent line which goes through the center of the source. We see that the end of a source generating spherical waves, as it would if it were extending in σ , generates a wave front which forms a cone in three dimensions, or a pair of lines in two dimensions. The angle of the cone is very easy to figure out. In a given amount of time the source moves a distance, say $a c_s t$, perpendicular to σ , the velocity of the source. In the meantime the sound will have moved out a distance $c_s t$, proportional to $c_s t$, the speed of the wave. Therefore it is clear that the angle of opening has a sine equal to the ratio of the speed of the wave divided by the speed of the source, and this cone has a solution only if c_s is less than v , or the speed of the object is faster than the speed of the wave.

$$\sin \theta = \frac{c_s}{v}. \quad (SI.1)$$

Incidentally, although we implied that it is necessary to have a source of sound, it turns out, very interestingly, that once the object is moving faster than the speed of sound, it will move slower. That is, it is not necessary that it have a certain constant kinematic character. Any object moving through a medium faster than the speed v at which the medium carries waves will generate waves on each side, automatically, just from the motion itself. This is simple in the case of sound, but it also occurs in the case of light. At first one might think nothing can move faster than the speed of light. However, light in glass has a phase velocity less than the speed of light in a vacuum, and it is possible to share a charged particle of very high energy through a block of glass such that the particle velocity is close to the speed of light in a vacuum, while the speed of light in the glass may be only 3/4 the speed of light in a vacuum. A particle moving faster than the speed of light in the medium will produce a conical wave of light with its apex at the source, like the waves wake from a boat (which is from the same effect, as a matter of fact). By measuring the cone angle, we can determine the speed of the particle. This is most technically to determine the speed of particles in one of the methods of determining their energy in high-energy research. The direction of the light is all that needs to be measured.

SI-1. Bulk waves

SI-3. Waves in solids

SI-4. Surface waves

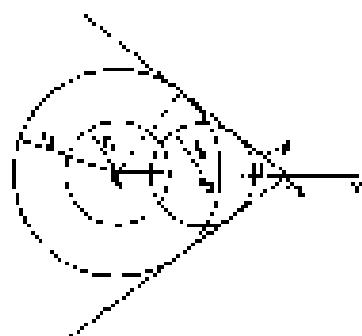

Fig. SI-1. The shock wave front lies on a cone with apex at the source and half-angle $\theta = \sin^{-1} v/c_s$.

Fig. 51-2. A shock wave emitted by an object moving faster than sound.

This light is sometimes called *Cerenkov radiation*, because it was first observed by Cerenkov. It is in effect light that is being emitted theoretically by a body and hence the name. The charged particle produces a change in refractive index, and since a suitable optical system the edge of the source can be made visible. The effect of the object moving faster than the speed of sound, however, makes production somewhat easier. The shock wave that occurs when the surface is actually cutted. It is stronger asymptotically, which is curved near the apex, and we have now discussed how the wave front, which comes up to the second ray of this chapter.

The corresponding experiment has in the last chapter been illustrated in Fig. 51-2, which is a photograph of an object moving through a gas. The object moves faster than the speed of sound. The shock wave, a wave produced because of a change in refractive index, and since a suitable optical system the edge of the source can be made visible. The effect of the object moving faster than the speed of sound, however, makes production somewhat easier. The shock wave that occurs when the surface is actually cutted. It is stronger asymptotically, which is curved near the apex, and we have now discussed how the wave front, which comes up to the second ray of this chapter.

Fig. 51-3. Wavefront propagation over time.

51-2. Shock waves

We expect that depends on the amplitude, and on the size of course the speed depends upon the amplitude in the following way. An object moving through the air has to move through all of the way, so the disturbance produced in this case is a wave front that propagates with the speed of light, which is much faster than the undisturbed region set up reached by the wave front, which is at its actual speed, say. But the air that is left behind, after the wave front passes, has been compressed irreversibly, and so since the wave front is increased. Now the speed of sound increases with the temperature, and the speed in the region behind the jump is finite, that is to say, in the air, in front. This means that every other disturbance, will be faster than the front, the front, the speed increasing with time, because the air is finite, thus makes the disturbance will receive little jumps or pressure pulses, so the pressure contour to aid visualization. We see that the first pulse pressure region in the air, to make the front, as time goes on, until eventually the compression front becomes a sharp front, if the thing is moving right, "sharpened" more and away; it is rather weak, it takes a long time, it may not be seen, that the sound is spreading out, it is not able to do this.

The sound we move is nothing else, it merely wave reflected to the atmospheric pressure, only 1 part in a million cent. But for pressure changes of the order of atmosphere, the wave velocity increases by about twenty per cent, and it makes the sharpness of a disturbance almost negligible. In nature nothing happens nothing is still, permanently and with respect to a "sharp" front has, as well, a very slight compression, it is not infinitely sharp. The distance over which the varying part of the

order of one mean free path, in which the theory of the wave equation begins to fail because we do not consider the structure of the gas.

Now, referring again to Fig. 51-2, we realize more fully why one can be understood. If we suppose that the pressures near the apex are higher than they are farther back, and so the angle α is greater. That is, v_{rel} is the result of the fact that the speed depends upon the strength of the wave. Therefore the wave does an adiabatic compression doesn't do it much faster, having speed about c , while until gets as far as the air is weakened to such an extent that spreading the air pressure bump is small compared with atmospheric pressure. The speed of the bump then approaches the speed of sound in the gas into which it is going. (In other words, it always turns out that the speed of the shock is higher than the speed of sound in the gas class, but is lower than the speed of sound in the gas behind.) That is, impinges from the front will arrive at the front but the front reduces the medium in which it is going faster than the normal speed of sound. So one cannot tell immediately that the shock is coming until it is too late. (The light from the source arrives first, but one cannot tell that the shock is coming until it arrives, because there is no sound signal coming at that time.)

This is a very interesting phenomenon, the piling up of waves and the point at which it occurs is that after a wave is passed, the speed of the resulting wave should be higher. And an example of this same phenomena is the following. Consider water flowing in a long channel with finite width and finite depth. If a piston, or a wall across the channel, is moved along the channel fast enough, water piles up like snow before a snowplow. Now suppose the situation is as shown in Fig. 51-4, with a sudden step in water along x coordinate in the channel. It can be demonstrated that long waves are cleaned out faster in deeper water than they are in shallow water. Therefore any new bump is irregular. A energy supplied by the piston runs forward and piles up at the front. Again, summary what we have is just water not a gas if you, thermally. However, as Fig. 51-4 shows there is a complex flow. Picture is a wave coming up a channel, the piston is at constant height and in the channel. At first it might look appearance like well-behaved wave, as one might expect. But then along the channel, it has become sharp and changes out. It means you get scattered. There is a tendency of moving at the surface, as the pieces of water fall down. In, it is essentially a very sharp rise with distance of the water above.

Actually water is much more complicated than wind. However, just will take a point, we will be interested in point at $x = 0$ in a shallow box, as a model. The point $x = 0$ is not really of any great importance for our purposes; it is not a generalization, it is only to illustrate that the laws of mechanics that we already know are capable of explaining the phenomena.

Imagining for a moment that the water does look something like Fig. 51-5, show the water in the higher height h_2 moving with a velocity v , and the front is moving with velocity v in uniform horizontal water which is of height h_1 . We would like to determine the speed at which the front moves. In this we draw a vertical plane initially at $x = 0$, moves a distance s to the right, while the front of the wave has moved $s + a$.

Now we apply the equations of conservation of matter and momentum. First the former: Per unit channel width, we see that the amount of air at earlier that has moved past $x = 0$ (area shrinks) is compensated by the air created again when it moves to $(x_0 + s)$. So, dividing by dt we get $s(h_2 - h_1)$. This does not yet give us enough, because while up we have h_2 and h_1 , we do not know either v or a ; we are trying to get both of them.

So the next step is to use conservation of momentum. We have now discussed the problems of water pressure, in any long hydrocyclone, but it is clear anyway that the pressure of water at a given depth is just enough to hold up the column of water above it. Therefore the volume of water is equal to the density of water times the depth below the surface, since the pressure increases linearly with depth b , the average pressure over the column is $\rho g b$, which is also the average force per unit width and per unit height pressing the base toward $x = 0$. Now multiply by another v to get the total force which is acting on the water,

Figure 51-4

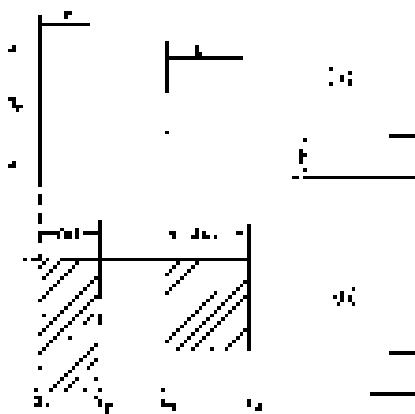

Fig. 51-5. Two cross sections of a wave in a channel, with z the depth of interface at later time t .

passing from the left. On the other hand, the \hat{v} produced by the water on the right also, exerting an opposite force on the right in \hat{v}_2 , relation, where \hat{v}_2 is, by the same kind of analysis, $\hat{v}_2 = \hat{v}_1 - \frac{1}{2} \Delta v$. Now we must balance the forces against the rate of change of the momentum. Thus we have to figure out how much momentum there is in motion (say in \hat{v}_1) \times $-$ from there (say \hat{v}_2). We see that the additional mass that has acquired the speed \hat{v}_2 is just $m \hat{v}_2 \Delta t$ — where m (per unit width), and multiplying this by \hat{v}_1 gives the additional momentum to be supplied to the impulse $F \Delta t$.

$$F \Delta t = m \hat{v}_2 \Delta t = (\hat{v}_1 - \frac{1}{2} \Delta v) m \Delta t.$$

If we eliminate Δv from this equation by substituting $\hat{v}_2 = \hat{v}_1 - \frac{1}{2} \Delta v$, we may divide, and simplify, we get finally that $m \hat{v}_1^2 / \hat{v}_2 = \Delta v / \Delta t$.

If the length difference is very small, so that \hat{v}_1 and \hat{v}_2 are nearly equal, this says that the velocity $= \sqrt{\hat{v}_1}$. As we will see later, that's only one criterion the wavelength of the wave is longer than the depth of the channel.

We would like to do the analogous thing for sound waves. Including the consideration of internal energy, and the conservation of energy, because this theory is reversible. In fact, it can carry the conservation of energy in the here problem, even though that energy is not conserved. If the length difference is small, it is found perfectly agreeable, but as soon as the length difference becomes very appreciable, there is a net loss of energy. This is illustrated as the falling water and the changing \hat{v}_1 in Fig. 8-4.

In shock waves there is a corresponding apparent loss of energy, from the point of view of adiabatic relations. The energy in the sound wave, behind the shock, goes into heating of the gas after shock passes, corresponding to turning of the wave at the bow. In focusing it out, three equations for the sound case turn out to be necessary for solution, and the temperature behind the shock is not the same as the temperature in front as we have seen.

If we try to make a bore that is upscale down ($\hat{v}_2 < \hat{v}_1$), then we have had the energy loss just second is negative. Since that is not available from anywhere, that bore cannot then maintain it; it is unusable. If we were to start a wave of that sort it would dampen out, because the speed dependence on height that resulted in sharpening in the case we discussed would now have the opposite effect.

8-3 Waves in solids

The next kind of waves to be discussed are the more complicated waves in solids. We have already discussed sound waves in gas and in liquid, and there is something in a solid wave in a solid. If a suddenly push is applied to a solid, it is compressed. Increases the compression, and a wave propagates outward if it is strong. However, there is another kind of wave that is possible in a solid, and which hence propagates in a fluid. If a solid is disturbed by pushing it sideways (either sideways displacement to pull itself back), that is by definition what distinguishes a solid from a liquid: if we distort a liquid (like milk), hold it a minute so that it comes down, and then let go, it will stay that way, but if we take a solid and push it, like shearing a piece of "Velva," and let it go, it does both and starts a shear wave, traveling to the wave very fast compression wave. In all cases, the shear wave speed is less than the speed of longitudinal waves. These shear waves are somewhat more longitudinal, so far as their polarizations are concerned to light waves. Sound has no polarization, i.e., it is pressure wave. Light has a characteristic polarization perpendicular to its direction of travel.

In a solid, the waves are of both kinds. First, there is a compressional wave analogous to longitudinal waves of one speed. If the solid is not yet broken, then a shear wave polarized in any direction will propagate at a characteristic speed. Of course, it will be one solid, i.e., the wave has a characteristic speed established by all scientists, the crystallographers, to say, and so on.

Another interesting question concerning sound waves is the following: What happens if the wavelength in a solid gets shorter, and shorter, and shorter? Thus shock wave gets? It is interesting that it cannot get any shorter than the space $\lambda = \frac{c}{f}$.

between the atoms. Because "there is supposed to be a wave in which one point goes up and another goes down," the energy "available wavelength" is clearly the atom spacing. In terms of the modes of oscillation, we say that there are longitudinal modes, and transverse modes, long waves, called shear waves, etc. As we consider various types of propagation, the spacing between the atoms, even the speed are no longer constant; there is a dispersion effect where the velocity is not independent of the wave number. But, if a wave, the higher mode of vibration always would be that in which every atom is doing the opposite of neighboring atoms.

Now from the point of view of seismic, vibration is like the two pendulums that we were talking about, for which there are two modes, one in which they both go together, and the other in which they are apart. It is possible to imagine the longitudinal wave in a very, in terms of a system of coupled harmonic oscillators, like a chain of mass-spring pendulums, with the highest mode such that they oscillate together, and lower modes with different characteristics of the timing.

The shortest wavelengths are so short that they are not usually available technically. However they are of great interest because, in the theory of thermodynamics, for solid, the heat properties of a solid, for example specific heats, can be analyzed in terms of the properties of the various sound waves. During all the waves of sound waves of ever shorter wavelength, one necessarily comes to the individual "intrinsic" frequencies that we think are the most ultimate.

A very interesting example of seismic waves in a solid, both longitudinal and transverse, is the waves that are in the solid earth. What makes the waves we do not know, but since the earth, from time to time, has some transverse waves rock slides, just to the other rock. That is like a little noise. The waves that are caused by rock slides are something very much longer in wavelength than usually considered seismic waves. Some of them are transverse, and they travel much in the earth. The earth is not homogeneous, however, and the properties of pressure, density, compressibility, and so on, change with depth, and therefore the speed varies with depth. Then the waves do not travel in straight lines—there is kind of like a refraction, and they go in curves. The longitudinal waves and the transverse waves have different speeds, so they are different at different depths in the earth. Therefore if we place a seismograph or some longitudinal waves, we see the longitudinal to the first moment of quake somewhere else, then we do not just get it immediately. We might get a jiggling, and a ground-shake, and then another jiggling, and an instant of seismic when the longitudinal. If it were close enough, we would first receive longitudinal waves from the disturbance, and then, a few moments later, transverse waves, because they travel more slowly. By measuring the time difference between the two, we can tell how far away the earthquake is, and we know enough about the speeds and properties of the interior regions involved.

An example of the seismic pattern of waves in the earth is shown in Fig. 21-6. The outbreak of waves is triggered off by different methods. If there were an earth quake at the place marked "source," the transverse waves and longitudinal waves would arrive at different times at the station by the solid lines. But, there would also be reflections at the boundary, reflecting waves back, and there would also be reflections at the boundary, reflecting waves back. In, in general, there is a source in the earth which does not carry transverse waves. If the source is supposed to consist, transverse waves still arrive, but the timing is not right. What happens is that the transverse wave comes in the same, and when it is reflected from some surface, it is reflected, between the boundaries, two new waves are generated, one transverse and one longitudinal. But inside the core of the earth, a transverse wave is not propagated (at least, there is no evidence for it), only the longitudinal wave, it comes out again in both forms and arrives in the station.

This incident behavior of these earthquake waves has not been determined. But, however, we can say that a propagating wave in the inner circle. This means that the outer shell of the earth is opaque in the sense that it is not propagating transverse waves. The only way to know what is inside the earth is by studying earthquakes and, by using a large number of observations of many seismographs at different

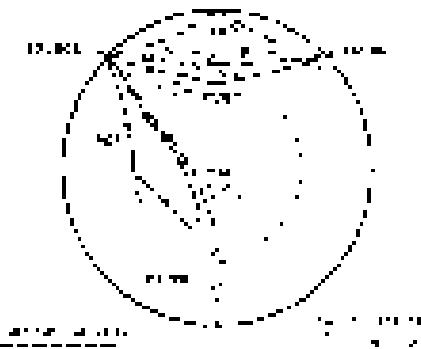

Fig. 21-6. Structure of the earth, showing paths of longitudinal and transverse seismic waves.

and one that has been worked out—the speed. We can do this all along. We know what the speeds of various kinds of waves are in any crystal. Knowing that, therefore, it is possible to figure out what the normal modes of the crystal are. Because we know the speed of propagation of sound waves—in other words, the elastic properties of both kinds of waves in every crystal. Suppose the waves were scattered like an elliptical and let us. It is just a matter of superimposing waves travelling out and in. In principle we determine the individual strings in a framework. We have figured out that if there is a line, hence, between two or more nodes, from the lowest, which is ellipsoidal, to higher modes with more structure.

Fig. 31-7. Power ratio spectrum as detected at seismographs in Chile, Peru, and Antioquia, Colombia. The coherence is a measure of the coupling between the oscillations. (From Van der Pol, Proc. Roy. Soc. (London), A, 200, 605 (1961)).

The Chilean earthquake of May 1960 made a good enough "model" for the signals were simple and not many others, and now when you have a good definition made just right to determine the frequency of the fundamental modes of the earth, to compare them with values that were calculated from the theory of sound with the known velocities, as assumed for the longitudinal waves. The result of this experiment is illustrated in Fig. 31-8, where a plot of the strength of the signal versus the frequency of its oscillation is Fourier analyzed. Note that in each particular frequency, there is much more being received than at other frequencies, the ones very definite numbers. These are the natural frequencies of the earth. Even so, there are two main frequencies at which the earth is oscillating. In other words, if we take a section of the earth, there would be many different modes, we would expect to obtain, in each section, irregular beatings which indicate a superposition of many frequencies. If we analyze this in terms of frequencies, we should be able to find the characteristic frequencies of the earth. The vertical axis in the figure is the superposed frequencies, and we find two characteristic agreement by agreement are to the fact that the theory of sound is right for the inside of the earth.

A very curious point is revealed in Fig. 31-8, which shows a very careful measurement, with below resolution of the lowest mode, on a large range of the earth. Note that it is very simple minimum, but it double set, 7.7 minutes and 37.1 minutes—slightly different. The reason for the two different frequencies was not known at the time that it was measured; either it may have been beyond the time limit. There are at least two possible explanations. One would be that there may be asymmetry in the earth's distribution, which would result in two different modes. Another possibility, which is even more interesting, is this: Imagine the waves going round the earth in two directions from the source. The speeds will not be equal because of effects of the rotation of the earth in the equations of motion, which does not mean that they are out of step during the analysis. Motion in a rotating system is modified by Coriolis forces, and they may cause the observed splitting.

Repeating the method by other cases quakes have set up already, which is obtained on the seismograph is not a curve of amplitude as a function of frequency but, disconcerting as it looks at first, is very irregular. Instead, to had the amount of all the different size waves for all different frequencies, we know that the total ω is roughly the sum by a sine wave of a given frequency and intensity, i.e., average \bar{A} , and in the average all other frequencies disappear. The results were thus, peaks of the integrals (sums) when the data were multiplied by one waves of different waves per minute and integrated.

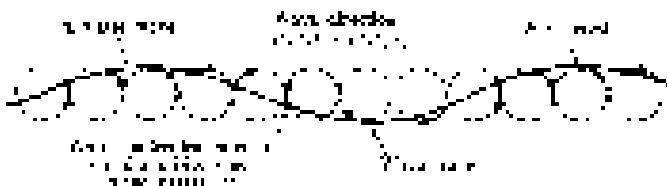

Fig. 31-8. Digital computer analysis of one of the Wadsworth records, showing spectral doublet.

51-4 Surface waves

Now, the next waves of interest, that is easily seen by everyone and which everybody sees or has ample of water in elementary courses, are **wave waves**. As we shall soon see, they are the worst possible example, because they are in no respects like sound and light. They have all the complications that waves can have. For instance w₁ large water waves in deep water. If one ocean is considered, it is very deep and a disturbance is made on the surface, waves are generated. All kinds of irregular motions occur, but the simplest type motion, with a very small disturbance, trips back like the common elastic wave waves coming in toward the shore. Now with such a wave, the water, of course, on the average, is standing still, but the wave moves. What is this motion, is it transverse or longitudinal? It may be either; it is not transverse, nor is it longitudinal. Although the water at a given place is alternately thrown up, it cannot simply harmonizing up and down, by the conservation of energy. That is, if it goes down, water is too water going to go up. Water is essentially incompressible. The speed of compression of waves, that is, sound in the water, is much, much higher, and we are not considering that now. Since water is incompressible on this scale, as a hill comes down the water must move away from the region. What actually happens is that particles of water, etc., the surface moves approximately in circles. When smooth wheels are turning, a person looking in a tire can look at a nearby object and see it going in a circle. So it is a mixture of longitudinal and transverse, breaking in the confusion. At greater depth in the water the motions are smaller circles until, reasonably far down, there is nothing left of the motion (Fig. 51-9).

Fig. 51-9. Deep-water waves, now formed from particles moving in circles. Note the systematic phase shift from wave to wave.

To find the velocity of such waves is an interesting problem: It must be some combination of the density of the water, the acceleration of gravity, which is the restoring force, that makes the waves, and possibly of the wavelength and of the depth. If we take the case where the depth goes to infinity, it will, in some sense depend on the depth. Whatever formula we are going to get for the velocity of the surface of the waves must combine the various factors to make the proper discussion, and if we try this in various ways, we find only one way to combine the density, ρ , and g in order to make a velocity, namely, $\sqrt{\rho g}$, which does not include the density at all. Actually, this formula for the phase velocity is not exactly right, but a complete analysis of the dynamics, which we will not pursue, shows that the formula we do have them, except for $\sqrt{\rho g}$:

$$v_{phase} = \sqrt{gk}/2\pi \text{ (for gravity waves).}$$

It is interesting that as long waves go faster than the short waves. This is about right, but not, however, there is some apparent contradiction, travelling by, this is not so, where the waves come to shore with slow sloshing at first and then more and more rapid sloshings, because the short waves travel longer. The waves get shorter and shorter as the time goes on, because the velocities grow in proportion to the wavelength.

One may object, "That is not right, we must look at the group velocity in order to figure it out." Of course this is true. The formula for the phase velocity does not tell us what is going to arrive first: what tells us is the group velocity. So we have to work out the group velocity, and it is left as a problem to show that, in fact, of the phase velocity, assuming that the velocity goes as the square root of the wavelength, which is all that is needed. The group velocity also goes as the square root of the wavelength. How can the group velocity go half as fast as the phase? If one looks at the bunch of waves that are made by a boat travelling

along. Moving a particular wave, he finds the wave front in the group and gravity gets weaker and distorted in the front, and magnetically the waves have a weak one in the back which is now lower than the rest of the magnet. In short, the waves are moving through. In a magnetized plasma, the group is only moving at half the speed that the waves are moving.

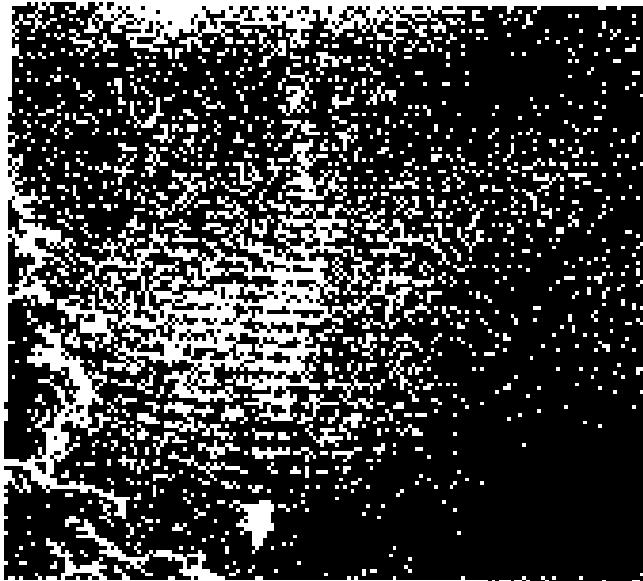

Fig. 51-10. The wake of a boat.

Because the group velocities and phase velocities are not equal, there are waves that are produced by an object moving through air no longer almost a wave, but it is really more interesting. We can see this in Fig. 51-10, which shows the waves produced by a object moving through the water. Now, too, it is quite different than what we expect from for sound, in which the velocity is independent of wave length, where we would have wanted to calculate the wave amplitude by summing them, we know waves in the water with fronts moving parallel to the motion of the boat, and then we have little waves on the sides of the boat. This is the pattern of waves coming, with amplitude, for example, by knowing easily that for the phase velocity is proportional to the square root of the wavelength. For small k , that is just the pattern of waves is stationary relative to the (constant) velocity; but, for other patterns would get lost from the boat.

The water waves that we have been considering so far are long waves in which the large of restoration is due to gravitation. But when waves get very short in the water, the main restoring force is capillary attraction, i.e., the energy of the surface, the surface tension. For capillary tension waves, it turns out that the phase velocity is

$$v_{\text{phase}} = \sqrt{\frac{2\pi}{\rho g}} \cdot \frac{1}{k} \quad (\text{capillaries})$$

where ρ is the surface tension and g the density. If k is the wave, opposite the phase velocity is higher, the shorter the wavelength, when the restoring force very small. When we have both gravity and capillary action, as we always do, we get the cancellation of the two together,

$$v_{\text{phase}} = \sqrt{\frac{2\pi}{\rho g} + \frac{1}{\rho k^2}}$$

where $k = 2\pi/l$ is the wave number. So the velocity of the waves which are really going along is ... The phase velocity as a function of the wave length is shown in Fig. 51-11; for very long waves it is fast, for very long waves it is fast and there is a minimum wavelength at which the waves stop going. The group velocity is to be calculated from the formula: it goes to λ the phase velocity too, up to the phase velocity for a given wave. To the left of the minimum the group velocity is 1, plus when the phase velocity goes to the right, the group velocity is less than or

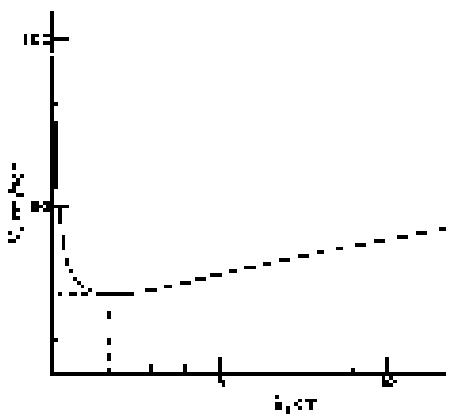

Fig. 51-11. Phase velocity vs. wave length in water.

phase velocity. There are a number of interesting phenomena associated with these facts. In the first place, since the group velocity is increasing as rapidly as the wavelength goes down, it can make a difference that will be a thousand fold in the dispersion going at the minimum, equal with the corresponding wavelength, and then it follows, going at a higher speed, will be a short wave and a very long wave. It is easy to see the long waves, but it is easy to see the difference in a water tank.

So we see that the ripples which result in shallow simple waves are quite interesting and complicated; they do not have a sharp wave front. At all, we are rather like simple waves like sound and light. The ripples are like little ripples which run out away. A sharp discontinuity in the wave does not produce a sharp wave because of the dispersion. This comes the very fine waves. Naturally, if an object moves through the water at a certain speed, a rather complicated pattern results, because of the different waves it is going at different speeds. One can demonstrate this very simply in water and see that the waves are not the true equilibrum waves. There are shallow waves, of a certain kind, which go forward by touching the bottom. One sees that when the depth h is large, the speed is lower. The wave moves in an angle; the rate of maximum slope it tends and tends to follow that line. In this way one can show various things, and we can only say waves are more complicated in water than in air.

The speed of long waves in water with no translation motion is slower when the depth is less, lesser in deep water. That is, waves come toward a beach when the depth is great, the waves go slower. But when the water is deeper, the waves go faster, so we get the effects of break waves. This runs, since the wave is not so simple, the sheets are much more scattered, and the wave overcomes itself, in the familiar way shown in Fig. 51-12. This is what happens when waves encounter the shore, and the next chapter's lecture will reveal to such circumstances. Nature has yet been able to figure out what shape the wave should take just before it breaks. It is easy enough when the waves are small, but when the sea gets large and winds, then it is a difficult problem.

Fig. 51-12. A Water Wave.

An interesting feature about equilibrum waves can be seen in the disturbances made by an object moving through the water. From the point of view of the object itself, the water is flowing past, and the waves which ultimately catch up with it are always the waves which have had the right speed to stay still with the object in the water. Similarly, consider an object in a stream, with the current flowing by, the pattern of waves is stationary, and at least the right wavelength to go at the same speed as the water goes up the. But if the group velocity is less than the phase velocity, then the C-tube has group velocity going backwards in the stream, because the group velocity is not quite enough to keep up with the stream. If the group velocity is less than the velocity of the plane, the pattern of waves will appear in front of the object. If one walks directly across just in a stream, one can see that there are little ripples in front and long "valleys" in the back.

Another interesting feature of this solution can be observed in pouring liquids from a funnel held through air or a bottle. For instance a large number of waves can be seen crossing both ways in the outgoing stream. They are wave scattering along the surface at the edges, and running out much like the waves about an object in a stream. There are effects from both sides which produce the crossed patterns.

We have investigated some of the interesting properties of waves, and the very many complications of dependence of phase velocity on wavelength, the speed of two waves on each other and so forth, that produce the really complex, and therefore interesting, phenomena of nature.

Symmetry in Physical Laws

52-1 Symmetry operations

The subject of this chapter is what we may call symmetry in physical laws. We have already discussed certain features of symmetry in physical laws in connection with wave analysis (Chapter 1), the theory of relativity (Chapters 16), and rotation (Chapter 26).

Why should we be concerned with symmetry? In the first place, symmetry is fascinating to the human mind, and we find objects or patterns that are in some way symmetrical to be appealing. It is no accident that most of our children attain levels of symmetry in the mirror we find in the world around us. Perhaps the most symmetrical things imaginable are spheres, and we are full of spheres—sun, planets, water droplets in clouds. The crystals found in rocks exhibit many different kinds of symmetry, the study of which tells us some important things about the structure of solids. Even the simplest and very early works done concerning symmetry, although the symmetry of a flower or of a bee is not as perfect as we sometimes think, is full of insights.

But our main concern here is not with the beauty of the objects of nature and their symmetries. Rather, we wish to examine some of the even more remarkable symmetries of the universe—the symmetries that exist in the basic laws themselves which govern the operation of the physical world.

First, what is symmetry? How can a physical law be "symmetrical"? The problem of defining symmetry is an interesting one and we have already noted that West gave a good definition, the substance of which is that a thing is symmetrical if there is something we can do to it so that after we have done it, it looks the same as it did before. For example, a symmetrical equation of motion will look the same if we reflect in time; it will look the same as it did before. The question we wish to consider here is what we can do to physical phenomena, or to a physical situation *at the same instant*, and yet leave them the same. A list of the known operations which various physical phenomena remain invariant is shown in Table 52-1.

52-2 Symmetry in space and time

The first thing we might try would, for example, be to translate the phenomenon in space. If we do an experiment in a certain region, and then build another apparatus at another place in space for doing the same sort every time, whatever went on in one apparatus, in a certain order in time, will occur in the same way if we have arranged the same conditions, with all care according to the restrictions that we mentioned before. But all of these features of the environment which make it act the same way have also been "fixed" here—we could always move ... define how much we should include in these circumstances, and we shall not go into those details again.

In the same way, we can do better today than yesterday or later, or we can do worse. (That is as far as we know today)—all of these things are as far as we know today.) That means that, if we're able to do an experiment and start it at a certain time, say on Tuesday at 10:00 a.m., and then build the same apparatus and start it at, say, three days later, in the same location, the two experiments will go through the same motions in nearly the same way as a function of time, no matter what the starting time, provided again, of course, that the relevant features of the environment, and so on, don't change significantly. That's symmetry because,

Interchange of identical atoms
or identical particles

Quantum mechanical phase

Mass antimatter (charge conjugation)

of course, cost of one bought. General Motors check those numbers up, the same thing would happen to us if he bought it now!

We have to watch out for geographical differences too. On the one, of course, rotations in the characteristics of the earth as far. So, for example, if we rotate the magnetic field in a certain region and move the apparatus to some other region, it may not work in precisely the same way because the magnetic field is different, but we say that is because the magnetic field is associated with the earth. We can imagine that "we turn the whole system upside down, it would make no difference in the operation of the apparatus."

Another thing that we discussed in considerable detail was rotation in space: if we turn an object round an angle it works just as well, provided we turn everything else that is relevant along with it. In fact we discussed the problem of symmetry under rotation in space in considerable detail in Chapter 11, and we invented a mathematical system called tensor analysis to handle it as neatly as possible.

On a more advanced level we had another symmetry—the symmetry under uniform velocity in a straight line. That is, in regard to the remarkable effect that if we leave a piece of apparatus working a certain way and then take the same apparatus and put it in a car, and move the whole car, plus all the relevant circumstances, at a uniform velocity in a straight line, then to keep the phenomena inside intact we must make no difference; at the basis of this is again the same. We even know how to express this more technically, and that is that the mathematical equations of the physical laws must be unchanged under a Lorentz transformation. As a matter of fact, it was a result of the relativity problem that unconnected physical entities can apply in symmetry in physical laws.

Now the above mentioned symmetries have all been *x*-symmetries, i.e., in time and space being more or less the same, but there are other symmetries of a different kind. For example, there is a symmetry which describes the fact that we can replace one atom by another of the same kind. To put it differently, there are atoms of the same kind. It is possible to hold a sample of some particular sort of ion-charges *a* *plus*, it makes no difference—the atoms are *identical*. Wherever one atom of oxygen of a certain type will go, another atom of oxygen of that type will go. One may say, "That is ridiculous, that is the definition of equal types." That may be merely the definition, but then we still do not know whether there are many "atoms of the same type"; the fact is that there are many, many atoms of the same type. Thus it does mean something to say that "no difference if we replace one atom by another of the same type." The so-called elementary particles of which the atoms are made are also identical, and also in the above sense—all electrons are *the same*; all protons are *the same*; all positive pions are *the same*; and so on.

After such a long list of things that can be done without changing the phenomenon, one might think we could do practically anything; so let us give some examples of the contrary, just to see the difference. Suppose that we ask: "What the physical laws symmetric under a change of size?" Suppose we build a certain piece of apparatus, and then build another apparatus five times bigger; is every part will it work exactly the same way? The answer is, in this case, no! The wavelength of light emitted, for example by the atoms inside, one hole of sodium atoms and the wavelength of light emitted by a gas of sodium atoms the same in volume is not five times longer, but is, in fact, exactly the same as the older. So the ratio of the wavelength to the size of the emitter will change.

An other example: we see in the newspaper, every once in a while, pictures of a given correspondence with real materials, e.g., sometimes such a set by some noted letter etc. keeps going mathematical figures. They much more elaborate and wonderful than any real correspond. If we imagine that this wooden cathedral were suddenly built on the scale of a m^3 as usual, we see where the building is—it would not last—the whole thing would collapse because of the enormous strength involved and just not strong enough. "Yes," one might say, "but we also know that water exerts an influence from the outside—this must be changed in proportion!" We are talking about the ability of the object to withstand gravitation. So what we should do is first to take the model cathedral of real materials and

the nuclear, and then we know it is stable. Then we should take the finger out of the hole and have a bigger error. But keep it at exact zero, here [sic] the gravitation is increased still more!

Today, of course, we might extend the last one, phenomena depending on the weak on the grounds that matter is always in contact, and certainly if we break an egg, the fact that we can't there are only five atoms in it. It would be really something you could never compare down arbitrarily. The size of an individual atom is not at all arbitrary—it is quite definite.

The fact that the laws of physics are not unchanged under a change of scale was discovered by Galileo. He realized that the strength of materials is constant in exactly the right proportion to their sizes, and he illustrated this property that we were just discussing, about the strength of materials, by showing, for instance, the bone of one dog, in the right proportion for holding up his weight, and the imaginary bone of a "super dog" that would be, say, ten or a hundred times bigger—that bone was a big solid thing with give it. To cut you a long story, we do not know whether he ever argued the argument similar to the one given that the laws of nature must have a definite scale, but he was so impressed with this discovery that he considered it to be so important in the character of the laws of motion, because he published from time in the same volume, called "In Two New Sciences."

Another example in which the laws are not symmetric etc., that we know quite well, is that a system in rotation at a uniform angular velocity does not give the same apparent laws as one that is not rotating. If we make an experiment and take our apparatus, a soccer ball and have the ground spinning it, carry a particle at a constant angular velocity, the apparatus will not work the same way however, as we know, things inside the apparatus will be drawn to the outside, and so on, by the centripetal or centrifugal forces, etc. In fact, we can tell that there is rotation, by using a so-called Foucault pendulum, without looking outside.

Next we mention a very interesting symmetry which is obviously false, i.e. reversibility in time. The obvious laws apparently except by symmetry in time, because, as we know, all obvious phenomena are irreversible on a large scale: "The moving finger writes, and having writ, moves on." So far as we can tell, this irreversibility is due to the very large number of particles involved, and if we could see the individual molecules, we would not be able to see which in the machinery was working forward or backwards. To make it more precise we make a *moving* picture in which we know what all the atoms are doing, in which we can see them jiggling. Now we have another appearance like it, but which can be made, at the final condition of the other one, with all the velocities perfectly reversed. If not then you through the same medium, but exactly in reverse. Building a molecular movie if we take a moving picture, at sufficient detail, of all the inner motion of a piece of material and show it on a screen and put it backwards the physician will be able to say, "That is against the laws of physics, that's doing something wrong." If we do the same in the other, of course, he can tell well by perfectly clear. If we see the egg shattering on the sidewalk and the shell cracking open, and so on, then we say "simply no." That is impossible. Because if we put the moving picture backwards the egg will collect together and the shell will go back together, and that is obviously ridiculous! But if we look at the molecular atoms themselves, the laws look completely reversible. This is, "comes, a man," under directly to have made, but apparently it is true that the fundamental physical laws, on a microscopic and fundamental level, are completely reversible—true!

52-3 Symmetries and conservation laws

The symmetries of the physical laws are very interesting at this level, but only just as in the end, do we ever need to be using and applying when we come to quantum mechanics. There is reason when we cannot make clear at the level of the present discussion, in that the most physicists still find somewhat surprising, a most profound and basic thing is that in quantum mechanics, for every symmetry of symmetry there is a corresponding conservation law; there is a definite

connection between the two of conservation and the symmetries of physical laws. We can only conclude that at present, without any attempt at explanation.

In fact, for one, plus the two laws are symmetrical but translation is static when we add the p insights of quantum mechanics, there can be no such connection or symmetry.

But the laws of symmetries under translation in time means, in quantum mechanics, that energy is conserved.

Translational invariance through a fixed angle is space corresponds to the conservation of angular momentum. These connections are very interesting and beautiful things, among the most beautiful and profound things in physics.

Incidentally, there are a number of symmetries which appear in quantum mechanics which have no classical analog, which I use in another of describing it, classical physics. One of these is as follows. If ψ is the amplitude for some process or other, we know that the absolute square of ψ is the probability that the process will occur. Now if someone else were to make his calculations, not with this ψ , but with ψ' which differs merely by a change in phase: that is to be some constant, and multiply ψ' times the old ψ , the absolute square of ψ' , which is the probability of the event, is then equal to the absolute square of ψ .

$$|\psi'|^2 = |\psi|^2; \quad |\psi'|^2 = |\psi|^2. \quad (52.1)$$

Therefore, the physical law is unchanged if the phase of the wave function is shifted by an arbitrary constant. That is another symmetry. Physical laws must be of such a nature that a shift in the quantum-mechanics phase makes no difference. As we have mentioned in quantum mechanics, there is a renormalization law for this symmetry. The conservation law which is common to all the quantum-mechanical phase seems to be the conservation of electrical charge. This is together a very interesting business.

52-4 Mirror Reflections

Now the next question which is going to concern us for most of the rest of this chapter, is the question of symmetry under reflection in space. The question is this: Are the physical laws symmetrical under reflection? We may put it this way. Suppose we hold a piece of equipment, let us say a clock, with lots of wheels and cogs and so forth, in a box. It works, and it goes ticking round and inside. We look at the clock in the mirror. Now a clock in the mirror is not the question. But let us actually build another clock which is exactly the same as the first clock looks in the mirror. Now if there is a gear with a right-hand thread in one, we also have with a left-hand thread in the corresponding place of the other, where one is marked "2" on the face we mark a "5" on the face of the other. Each cogged spring is twisted one way in one clock and the other way in the mirror-image clock: when we are all finished, we have two clocks, both physical, which have in them other the relation of a mirror and its mirror image, although they are both actual, material objects we emphasize. Now the question is: If the two clocks are started in the same condition, do they go in corresponding right motion, will the two clocks tick side by side, forever after, as exact mirror images? (This is a physical question, zero-dimensional question). Our intuition about the laws of physics would suggest that they would.

We would suggest that, first of all, in the case of these clock reflections in space, is one of the symmetries of physical laws, that if we change everything from "right" to "left" and leave it otherwise. To some, we cannot tell the difference. Let us, then, suppose it is a comment that this is true. If it is true, then it would be impossible to distinguish "right" and "left" by any physical phenomenon, just as it is, for example, impossible to define a "universal" positive velocity by a physical phenomenon. So it should be impossible, by any physical phenomenon, to define absolutely what we mean by "right" as opposed to "left," because the physical laws should be symmetrical.

Of course, the world does not have to be symmetrical. For example, using what we may call "geography," such "right" can be defined. For instance, we stand

to New Orleans and look at Chicago, and Florida is to our right (where our feet are on the ground). Surprised? Right" and "left" by geography. Of course, the same situation in our system does not have to be. We can say that we are talking about it; it is a creation of mine, the human imagination—in other words, which is, is where the person has to have a space like the earth with "left-handed air" on it and a person like ourselves standing looking at a city like Chicago from a side like New Orleans, but with everything the other way around, so Florida is on the other side. I think it seems sort of impossible, yet again, the person now has to have everything changed left for right.

Another point is that our definition of "light" should not depend on history. An easy way to distinguish right from left is to go to a bad neighborhood pick up a bunch of sand. The odds are it has a right-hand twist—not necessarily, but it is much more likely to have a right-hand twist than a left-hand one. This is a question of history or convenience, or the fact things happen to be, and is again not a question of fundamental laws. As we can well appreciate, everyone could have started out making left-handed screws!

So we must try to find some polarization in which "right" and "left" is intended fundamentally. The most possibility we have is the fact that polarized light rotates the plane of polarization as it goes through, say, sugar water. As we saw in Chapter 29, it rotates, let us say, to the right, a certain amount of them. This is sort of defining "left-hand" because we may dissolve some sugar in the water and then the polarization goes to the right. But sugar has no living things, and if we try to make it, say, artificially, then we discover that after you dissolve the plane of polarization. But if we then take that same sugar which is made artificially and which does not rotate the plane of polarization, and put it back and at it take out some of the sugar and then blow it in the heat lamp, we find that we still have sugar left (so much less sugar as we had before), and this time it does rotate the plane of polarization, but the other way. It seems very convincing, but is really explained.

Fig. 32-1. L-L Alanine (left) and D-alanine (right).

Take another example. One of the substances which is common in all living creatures and that is fine-surfaced is the lipoprotein. Proteins consist of chains of amino acids. Figure 32-1 shows a model of an amino acid like, amino acid L-alanine. This form of acid is called L-alanine, and the molecular arrangement would look like that in Fig. 32-1, if it came out of a protein of a real living thing. On the other hand, if we try to make alanine from carbon dioxide, chlorine, and some kind we can make it, it is not a complicated molecule; we discover that we are making right, mirror image of the molecule and the one shown in Fig. 32-1 (left). The first molecule, the one that comes from the living thing, is called *D-alanine*. The *D*-alanine, which is the same chemically, in that it has the same kinds of atoms and the same connections of the atoms, is a "right-hand" molecule, compared with the "left-hand" L-alanine and it is called *D-alanine*. The interesting thing is that when we make alanine at home in a laboratory, more simple process, we get an equal mixture of both kinds. However, the only thing that life uses is L-alanine. (This is not exactly true. Here and there in living creatures there is a special use for D-alanine, but it is very rare. All proteins use L-alanine exclusively.) Now if we make both kinds, and we find that this is the same animal which likes to "eat" our right hands, it cannot eat D-alanine, so it only uses the L-alanine, and is well accustomed to the "right" after the last time. In short, that makes

well for the *s*, only the "wrong" kind is well. β -D-glucose sugar tastes sweet but not the same as right-handed sugar.

So it looks as though the whole game of "left" versus "right" distinction between " left " and " right " in chemistry permits a discrimination, because the two molecules are chemically different—but no, it does not! So far as physical measurements can be made, such as cf energy, the rates of chemical reactions, and so on, the two kinds work exactly the same way if we make everything else in a mirror image too. One molecule is well suited to one sugar, and the other will confuse it at the "if" it scatters the same amount, through the same volume of fluid. Thus, so far as physics is concerned, these two amine acids are equally spectroscopic. & that is the unfortunate thing today, the fundamental of the Schrödinger equation however that the two molecules should behave in exactly corresponding ways, so that one is to the right as the other is to the left. Nevertheless, in life, it is all over now!

It is presumed that the lesson here is the following. If we suppose, for example, that life is somehow living matter in a very high tension at which all the proteins in some creatures have left-handed amino acids, and at the same time are imposed—every substance in the living creature is imposed—it is non-symmetrical. So when the living creature comes by its living chemicals to the food from the tree, he would turn his head or swallow "this" into his stomach. But the snake king does not like Cinderella and the prince, except that it is a "left hand" (that we are told up). So far as we know, in principle, we could build a frog, for example, in which every molecule is reversed, everything is to the "left-hand" in the image of a real frog, we have a left-hand frog. This left-hand frog would go on all right for a while, but he would find according to us, because it has "hands over there, his enzymes are not built to digest it. The frog has the wrong "hand" of amino acids unless we give him a left-hand frog. So as far as we know, the chemicals and life processes would continue in the correct manner if everything were reversed.

If there is actually a physical and chemical phenomenon, then we can understand that the proteins are all made in the same way, or you know the idea that all the non-living forms living creatures, by accident, got started and a few more, somewhere, once, one organic molecule was kapooshed in a certain way, and from this *accident* came the "right" happens in nature in our particular perspective; a particular "bias", however was one-sided, and ever since then the "bias" has propagated itself. Once having begun that bias, that is, in now of course, it will always continue—all the enzymes digest the right things, manufacture the right things; when the carbon dioxide and the water vapor and so on, go in the plant leaves, the enzymes that take the oxygen in them happen because the enzymes are kapooshed. Many new kind of virus or living things were to originate at a later time, we would survive only if we could "read" the kind of living matter already present. This is the most of the problem.

There is no conservation of the number of right-handed molecules. Once started, we could keep increasing the number of right-handed molecules. So the presumption is, that the replacement in the course of time shows a loss of symmetry in physical law, but it *fails*, on the contrary, the universal nature and the commonness of electric charge, will exist on our earth in the sense described above.

52.5 Polar and axial vectors

Now we go together. We observe next in discussing the case of light in other places where we have "right" and "left," the situation is a matter of fact when we carried about vector analysis with the right-hand rule; we have to use it in order to get the angular momentum, torque, magnetic field, and so on, all come out right. The case of a vector involving a magnetic field, for example, is $\mathbf{E} \times \mathbf{B}$. In a given situation, in which we knew \mathbf{E} , \mathbf{B} and \mathbf{B} , isn't that sufficient enough to define right-handedness? As a matter of fact, if we go back and look at where the vectors start from, we know that the "right-hand rule" was really a convention; it wasn't true. The original quantities, like the angular momenta and the angular velocities, and charges of this kind, were not really vectors in all. They are al-

motion associated with a surface plane, and it is just because there are three dimensions to space that we can associate the quantity with a direction perpendicular to that plane. Of the two possible directions, we choose the "right-hand" direction.

So if the laws of physics are symmetric, we should find that if some denoted were to break into 2, the physics abides the same. Right" for "left" in every book in which "right-hand rules" are given, and instead we were to use all "left-hand" rules," nothing there would make no difference whatsoever in the physics area.

Let us give an illustration. There are two kinds of vectors. There are "translatory" vectors. For example, see diagram: If in our system of there is a piece of wood moving elsewhere, then its motion component in there will be the image piece Q. The image since being one, and if we draw a vector from the "piece" to the "something else," the vector is the mirror image of the other (Fig. 52-2). The vector arrow changes its head, just as the whole wood turns inside out; such a vector we call a polar vector.

The other kind of vector which has to do with rotations, is of a different nature. For example, suppose that in three dimensions something is rotating as shown in Fig. 52-3. Then unless it is frozen in a mirror, it will be rotating as indicated, namely as the mirror image of the original motion. Now you cannot expect to represent the direction of rotation by the same rule it is a "vector" which, on reflection, does not change around as the polar vector does, but is reversed relative to the polar vector and to the geometry of the space, such a vector is called an axial vector.

Now if the law of reflection symmetry is right in physics, then it must be true that the equations must be unchanged that it is clearly the case of each polar vector and each corresponding axial vector, which would be what corresponds to reflection, nothing will happen. For instance, when we write a formula which says that the angular momentum is $\mathbf{L} = \mathbf{r} \times \mathbf{p}$, that equation is all right, because, if we change to a left-handed coordinate system, we change the sign of \mathbf{L} , and if and we do not change the cross product sign is changed, since we must change from a right-hand rule to a left-hand rule. As another example, we know that the force on a charge moving in a magnetic field is $\mathbf{F} = q\mathbf{v} \times \mathbf{B}$, but, if we change from a right- or a left-handed system, since Faraday's law is to be preserved the sign of \mathbf{F} is also changed, required by the correspondence that we reflected by a sign change in \mathbf{B} . When this is so, \mathbf{B} must be an axial vector. In other words, if we make such a reflection, \mathbf{B} must go to $-\mathbf{B}$. So if we change our coordinates from right to left, we must also change the place of magnets from north to south.

Let us assume that there is no asymmetry. Suppose that we have two magnets as in Fig. 52-4. One is a magnet with the ends pointing toward a certain way, and were placed in a given direction. The other magnet looks like the reflection of the first magnet in a mirror. The coil will wind the other way, everything that happens inside the coil is exactly reversed, and the current goes as shown. Now, from the law for the propagation of magnetic fields, which we do not know yet exactly, but which we most likely learned at high school, it turns out that the magnetic field is as shown in the figure. In one case, the pole is a south magnetic pole, while in the other magnet the current is going the other way, and the magnetic field is reversed—it is a north magnetic pole. So we see that when the problem right about instead magnet from north to south.

Never mind changing $\mathbf{magnetic}$ field; these too are mere conventions. Let us talk about electric fields. Suppose now, that we have an electron moving through one field, going into the page. Then, if we use the formula for the force $\mathbf{F} = q\mathbf{E}$ (remember, the charge is minus), we find that the electron will deviate in the indicated direction according to the physical law. But the phenomenon is that we know a coil with a current going in a specified direction, an electron moves in a certain way. This is the physics, never mind how we label every thing.

Now let us do the same experiment with a mirror: we send an electron through a coil carrying a current and now the force is reversed, if we calculate it here the same rule, and it is very good because the corresponding mirror is the mirror image!

Fig. 52-2. A step in space and its mirror image.

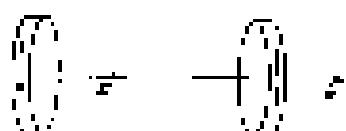

Fig. 52-3. A rotating wheel and its mirror image. Note that the angular velocity "vector" is not reversed in direction.

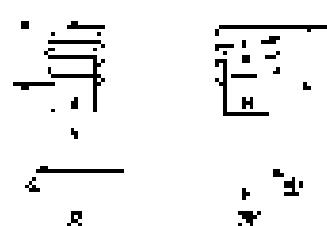

Fig. 52-4. A magnet and its mirror image.

52-6 Which hand is right?

So the fact of the matter is that in studying any phenomenon there are always two right-hand rules, or an even number of them, and the net result is that the phenomena always looks symmetrical. In your receiver, we can see left-right from left if we turn it around with north pointing south. However, it may seem that we can feel the more pull of a magnet. The north pole of a compass needle, for example, is one that prefers to be north. This is of course not a physical property that has to do with geography of the earth; that's just the talk-up about it which makes us Chicago, so it does not count. If we have seen compass needles we may have noticed that the north-seeking pole is a sort of "visible" pole. But that is just due to the man who painted the magnet. These are all local, comparative effects.

However, if a magnet were to have no property, that if we looked at it closely enough we would see same bars pointing in its north pole but not on its south pole, if that were the general rule, or if there were no unique way to distinguish the north from the south pole of a magnet, then we would tell which of the two poles was actually the , and that would be the end of the law of reflective symmetry.

To illustrate this whole problem of irreversibility, imagine that we are telling two Indians, or someone very far away, by telephone. We cannot allow us and him any visual contact to inspect; so, I suppose if we can't send light, we could send some right-hand or rather polarized right and left, "This is right and light just watch the way it is going," but we cannot give him anything, we can only tell him. He is far away, or in some strange location, and he cannot see anything we can say. For instance, we cannot say, "Look at this magnet; now see? Two thumb-screws are arranged. What we mean by right is . . ." We are only allowed to describe him.
